SMALL DEFORMATIONS OF A PLASTIC-RIGID BODY AT THE YIELD POINT

By E. T. Onat*

1. *Introduction.* Consider a body of plastic-rigid material which is loaded by monotonically increased surface tractions. Let us assume that the history of loading is completely specified. At the earlier stages of loading the body will generally remain rigid. If the loads are increased further some portions of the body may become locally plastic. However, plastic deformation of these portions may be prevented by adjacent rigid portions until the moment when the body actually begins to deform. Following Hill [1], we refer to this critical moment as the yield point of the plastic-rigid body. If the material is perfectly plastic (i.e., non-strain-hardening) and if the accompanying change in geometry is disregarded, plastic flow is found to continue under constant loads [2]. However, when the change in geometry and the effects of strain-hardening are taken into account, continuing deformation under constant external forces is possible only in exceptional cases [1]. Thus, as a rule, quasistatic flow requires either increasing or decreasing external forces. Under the assumed monotonically increasing loading, the first case represents a stable process, whereas the second case leads to sudden collapse.

* F. E. Jewett Fellow at Brown University, Providence, R. I.

# Numbers in square brackets refer to the Bibliography at the end of the paper.
The distribution of stress and the corresponding velocity field at the yield-point can be found in some cases (e.g., by the method of characteristics in plane strain problems) and in other cases approximations from above and below to the yield-point load can be obtained [1,2]. However, in many cases the present first order theory does not furnish a clear criterion for collapse. Therefore it seems worthwhile to investigate the second order effects in the deformation of a plastic-rigid body at the yield point.

In the following the investigation is limited to problems where the entire body is in the plastic state at the yield point and where the incipient stress and velocity fields are known. A perturbation scheme is developed to obtain equations governing Lagrangian stress and velocity increments of the subsequent quasi-static motion. Some examples are worked out (compression of block between rough plates and the thick walled tube under internal pressure). In the first case the results obtained with the theory are found to agree with the experimental results. In the second example the minimum rate of strain-hardening necessary to prevent collapse is found.

2. Notations and Stress-strain Relations Employed in the Analysis. Let \( x_i \) denote the rectangular Cartesian coordinates of a generic particle at the time \( t \). If the velocity of this particle is denoted by \( v_i \), the velocity strain tensor is given by

\[
\varepsilon_{ij} = \frac{1}{2} \left( \frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i} \right)
\]

where Latin indices take the values 1, 2, 3.
The stress and deviatoric stress tensors are denoted respectively by $\sigma_{ij}$ and $s_{ij}$:

$$s_{ij} = \sigma_{ij} - \left(\frac{1}{3} \sigma_{kk}\right) \delta_{ij},$$  \hspace{1cm} (2)

where summation convention is used and $\delta_{ij}$ represents the Kronecker delta.

If the second invariant of the deviatoric stress tensor is denoted by $J_2$,

$$J_2 = \frac{1}{2} s_{ij} s_{ij}.$$  \hspace{1cm} (3)

The particular stress-strain relations considered in this paper are

$$\varepsilon_{ij} = F(J_2) s_{ij} \frac{DJ_2}{Dt} \text{ when } J_2 \geq k^2 \text{ and } \frac{DJ_2}{Dt} \geq 0$$

$$\varepsilon_{ij} = 0 \quad \text{ when } J_2 < k^2 \text{ or } \frac{DJ_2}{Dt} < 0$$  \hspace{1cm} (4)

where $\frac{DJ_2}{Dt}$ is the material derivative of $J_2$.

The limiting case where

$$F(J_2) \rightarrow \infty \quad \frac{DJ_2}{Dt} \rightarrow 0$$

defines an ideally plastic material:

$$J_2 = k^2,$$

$$\varepsilon_{ij} = \lambda s_{ij} \quad \text{ when } \lambda \geq 0$$

$$\varepsilon_{ij} = 0 \quad \text{ when } \lambda < 0.$$  \hspace{1cm} (5)
The stress and deviatoric stress tensors are denoted respectively by \( \sigma_{ij} \) and \( s_{ij} \):

\[
\sigma_{ij} = \epsilon_{ij} - \frac{1}{3} \epsilon_{kk} \delta_{ij},
\]

where summation convention is used and \( \delta_{ij} \) represents the Kronecker delta.

If the second invariant of the deviatoric stress tensor is denoted by \( J_2 \),

\[
J_2 = \frac{1}{2} s_{ij} s_{ij}.
\]

The particular stress-strain relations considered in this paper are

\[
\epsilon_{ij} = F(J_2) s_{ij} \frac{DJ_2}{Dt} \quad \text{when} \quad J_2 \geq k^2 \quad \text{and} \quad \frac{DJ_2}{Dt} \geq 0
\]

\[
\epsilon_{ij} = 0 \quad \text{when} \quad J_2 < k^2 \quad \text{or} \quad \frac{DJ_2}{Dt} < 0
\]

where \( DJ_2/Dt \) is the material derivative of \( J_2 \).

The limiting case where

\[
F(J_2) \to \infty \quad \frac{DJ_2}{Dt} \to 0
\]

defines an ideally plastic material:

\[
J_2 = k^2,
\]

\[
\epsilon_{ij} = 0 \quad \text{when} \quad \lambda < 0
\]

\[
\epsilon_{ij} = \lambda s_{ij} \quad \text{when} \quad \lambda \geq 0
\]
3. **Formulation of the Problem.** Consider a plastic-rigid body at the yield point. Suppose that the boundary conditions are such that every element of the material is in the plastic state. Moreover assume that a velocity field \( v^0 \) is associated with the stress-state \( \sigma_{ij}^0 \) where \( v_i^0 \) and \( \sigma_{ij}^0 \) are the Cartesian components of the velocity and stress tensors. \( v_i^0 \) and \( \sigma_{ij}^0 \) satisfy the boundary conditions imposed on the displacements and the stresses in addition to the following equations:

\[
\sigma_{ij,j}^0 = 0, \quad \text{(Equilibrium)} \tag{6}
\]

\[
\frac{1}{2} s_{ij} s_{ij}^0 = 2k^2, \quad \text{(Yield condition)} \tag{7}
\]

\[
\frac{1}{2} (v_i^0 + v_j^0) = \varepsilon_{ij}^0 = \lambda s_{ij}^0 \quad \text{(Stress strain relation)} \tag{8}
\]

where \( \lambda > 0 \).

We note that this solution is valid for an ideally plastic material and also for a newly annealed rigid-strain-hardening material which has the same yield stress, \( k \), in pure shear.

Now assume that the surface tractions are varied in such a manner that the further distortion following the reaching of the yield point takes place in a quasi-static manner.

We now consider the early stages of the distortion such that the state of velocity-strain and stress differs only slightly from the state which is given by Eqs. (6), (7), and (8).

Let \( x_i \) be the Cartesian coordinates of the material point \( \mathbf{a}_p \) at time \( t \):

\[
x_i = x_i[\mathbf{a}_p, \delta(t)] \tag{9}
\]

where \( \delta(t) \) is a monotonously increasing function of time and
\( \delta(0) = 0, \quad x_i[a_p, 0] = a_i \).

If the velocity and acceleration at time zero are continuous functions of the space variables, the validity of the following expansion may be assumed:

\[
x_i = a_i + v_i^0(a_p) \delta + \gamma_i(a_p) \frac{\delta^2}{2} + \ldots \tag{10}
\]

where to obtain a quasi-static flow, \( \frac{\delta \delta}{dt}; \frac{\delta^2 \delta}{dt^2} \) are supposed to be as small as desired. Since the stress-strain relations envisaged in this theory are homogeneous in time, the actual form of these functions is of no importance in the problem considered.

The velocity of the material point \( a_p \) at time \( \delta \) referred to the fixed rectangular Cartesian coordinates is then given by

\[
v_i = (v_i^0 + \gamma_i \delta + \ldots) \frac{d\delta}{dt}. \tag{11}
\]

The velocity strain tensor defined in the Eulerian manner is

\[
\epsilon_{ij} = \frac{1}{2} \left( \frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i} \right) = \frac{1}{2} \left( \frac{\partial v_i}{\partial a_p} \frac{\partial a_p}{\partial x_j} + \frac{\partial v_j}{\partial a_p} \frac{\partial a_p}{\partial x_i} \right) + \ldots \tag{12}
\]

From (10), \( \frac{\partial a_p}{\partial x_j} \) can be evaluated (see Appendix) in terms of \( v_i^0 \):

\[
\frac{\partial a_p}{\partial x_i} = \delta_{pj} - a_{p,i,j} + \ldots \tag{13}
\]

where a comma denotes partial differentiation with respect to \( a_j \).

From the last three equations, we obtain

\[
\epsilon_{ij} = \left[ \epsilon_{ij} + \delta \epsilon_{ij} \right] \frac{d\delta}{dt} \tag{14}
\]

where \( \epsilon_{ij} = \frac{1}{2}(v_{i,j} + v_{j,i}) \) and
\[ \varepsilon'_{ij} = \frac{1}{2}(\gamma_{j,j} + \gamma_{j,j}) - \frac{1}{2}(v^{o}_{p,p}v^{o}_{p,j} + v^{o}_{j,p}v^{o}_{p,j}). \] (15)

Let \( \sigma_{ij}(a_p, \delta) \) be the components of the stress tensor at the point \( x_i = x_i(a_p, \delta) \), referred to the fixed rectangular Cartesian coordinates. For small deviations from the yield point state we again assume that

\[ \sigma_{ij} = \sigma^{o}_{ij}(a_p) + \delta\sigma_{ij}^{o}(a_p) + \ldots. \] (16)

We now examine conditions and equations which must be satisfied during the quasi-static distortion of the body after the yield point.

a. Equations of Equilibrium: Since a quasi-static notion of the body is considered, the Equations of Equilibrium must be satisfied during the subsequent flow:

\[ \frac{\partial \sigma_{ij}}{\partial x_j} = \frac{\partial \sigma^{o}_{ij}}{\partial a_p} \frac{\partial a_p}{\partial x_j} = 0, \] (17)

where body forces are neglected.

Using (13) and (16) this becomes

\[ \frac{\partial \sigma^{o}_{ij}}{\partial a_j} + \delta \left[ \frac{\partial \sigma^{o}_{ij}}{\partial a_j} - v^{o}_{p,j} \frac{\partial \sigma^{o}_{ij}}{\partial a_p} \right] = 0 \] (18)

where only the terms up to the order \( \delta \) are retained. The first term of this equation vanishes according to \( (6) \), hence the Equilibrium Equations satisfied by the Lagrangian stress increments are

\[ \frac{\partial \sigma^{o}_{ij}}{\partial a_j} - v^{o}_{p,j} \frac{\partial \sigma^{o}_{ij}}{\partial a_p} = 0. \] (19)
b. Stress-Strain Relations. An investigation of the stress-strain relations at time zero and time $t$ provides six additional equations for Lagrangian Stress- and Strain increments.

At time $t = 0$, 

$$\varepsilon_{ij}^0 = F(J_2) s_{ij}^0 \frac{dJ_2(a_p, \delta)}{d\delta}$$

(20)

where

$$2J_2(a_p, \delta) = s_{ij}^0 s_{ij}^0 + 2s_{ij}^0 s_{ij}^1 + \ldots$$

and $s_{ij}^1$ denote increments of the deviatoric stress tensor. Therefore if the terms up to the order of unity are retained,

$$\frac{dJ_2}{d\delta} = s_{pq}^0 s_{pq}$$

and (20) gives

$$s_{pq}^0 s_{pq} = \frac{\varepsilon_{ij}^0}{s_{ij}^0 F(J_2)}$$

(21)

where the right hand side is not summed and any combination of $(i, j)$ may be chosen provided that $s_{ij}^0 \neq 0$.

If the material is ideally plastic (21) becomes

$$s_{pq}^0 s_{pq} = 0.$$  

(22)

At time $t$, in addition to the equation of incompressibility, the stress-strain relations provide four independent equations of the following type:

$$\frac{\varepsilon_{ij}}{s_{ij}} = \frac{\varepsilon_{pq}}{s_{pq}}$$

(23)

where again the summation convention does not apply. Using (8), (15) and the definition of $s_{ij}^1$, and retaining terms up to the order of $\delta$ one obtains the following equations.
\[ \varepsilon_{ij} s_{pq}^0 + \varepsilon_{ij} s_{pq}' - \varepsilon_{pq} s_{ij}' - \varepsilon_{pq} s_{ij}^0 = 0, \quad (24) \]

where \((i,j,p,q)\) are to be chosen in order to give four independent equations.

On the other hand the equation of incompressibility, which is obtained from the contraction of the tensorial equation \((^4)\), gives

\[ \varepsilon_{ii} = 0, \]

and using \((14)\) and \((15)\), and observing that \(\varepsilon_{ii}^0 = 0\), we get

\[ \gamma_{i,i} - \gamma_{i,i}^0 = 0. \quad (25) \]

We note that Eqs. \((19)\), \((21)\) (or \((22)\), \((24)\) and \((25)\) provide nine linear equations for the nine unknowns \(\sigma_{ij}^0\) and \(\gamma_i\). In the case of plane strain, Eqs. \((19)\) and \((21)\) or \((22)\) provide three independent equations for three unknown stress-increments. Therefore if the boundary conditions are of the stress type the problem is statically determined.

c. Boundary Conditions. We first examine conditions which must be satisfied at a boundary surface, \(S_F\), of the body at which surface forces are prescribed. Denote by \(Q_1\) the components of the surface tractions in the fixed rectangular Cartesian coordinate system:

\[ Q_1(a_p, \delta) = Q_1^0(a_p) + \delta Q_1^1(a_p) + \ldots. \quad (26) \]

Suppose that \(S_F\) is defined by the following equation

\[ F(a_1, a_2, a_3) = 0 \quad (27) \]

where as before
\[ x_i = x_i(a_p, \delta) \]

or
\[ a_p = a_p(x_i, \delta) \]

and it is assumed that points originally on the boundary surface remain on a surface during the deformation. At time \( \delta \), the unit normal \( n_p \) of the surface \( S_F \) has direction cosines proportional to \( \delta F/\delta x_p \). Using the series expansions and (15) one obtains:

\[ n_p = n_p^0 + \delta n_p' + \ldots = k \frac{\delta F}{\delta x_p} = k \frac{\delta F}{\delta a_p} (\delta r_p - \delta v_r^0) \]

or
\[ n_p^0 + \delta n_p' = k(\frac{\delta F}{\delta a_p} - \delta F, v_r^0, r, p) \] (28)

The magnitude of \( k \) must be such that
\[ n_p n_p = 1 \] (unit normal). (29)

From (13) and (14)

\[ k = \pm \frac{1}{\sqrt{F_r F_p}} \left\{ 1 + \delta \frac{\delta F}{F_p, r F_r, p} \right\} \] (30)

where the sign will be properly chosen to obtain the outward normal of the surface.

On the other hand, the surface tractions are related to the stresses by

\[ Q_i = n_p \sigma_{pi} \]

or

\[ Q_i^0 + \delta Q_i' + \ldots = (\sigma_{pi}^0 + \delta \sigma_{pi}') + \ldots)(n_p^0 + \delta n_p' + \ldots), \]

\[ Q_i' = \sigma_{pi} n_p^0 + \delta \sigma_{pi} n_p'. \]

From (28) and (30);
and therefore the increments of the surface tractions are related to the increments of the stresses by the following formula:

\[ \sigma_1' = \sigma_{pl}' \frac{F_p}{\sqrt{F},jF',j} + \frac{\sigma^0_{pl}}{\sqrt{F},jF',j} [F_p \frac{F_q, r^0_{r,v}, q - F_r v^0_{r,v}}{F_r k^0, k} - F_r v^0_{r,v}, u]. \]

(31)

As to the displacement boundary conditions, we infer that on \( S_v \), \( \gamma_1 \) is given as functions of the original coordinates.

The theory has now been taken to a point from which applications may be made to specific problems.

Example 1. **Compression of Block Between Rough Plates:**

Consider a block of strain-hardening (or ideally plastic)-rigid material compressed between rough plates (Fig. 1).

When the block is very wide compared with its height, the slip line field corresponding to the incipient motion is independent of \( x \), and the incipient stress and velocity fields are given by Prandtl [3] and Nadai [4]:

\[
\begin{align*}
\sigma^0_x \frac{k}{k} &= -c - \frac{m_x}{h} + 2\sqrt{1 - \frac{m^2 v^2}{h^2}} \\
\sigma^0_y \frac{k}{k} &= -e - \frac{m_x}{h} \\
\tau^0_{xy} \frac{k}{k} &= \frac{m_y}{h}
\end{align*}
\]

(32)
\[ \frac{U}{h} = c + x - \frac{2}{m} \sqrt{1 - m^2 \frac{v^2}{h^2}} \]
\[ \frac{V}{h} = -\frac{y}{h} , \]

where \( k \) is the yield stress in pure shear, \( m \) is a measure of roughness \([0 < m < 1; m = 1 \text{ for perfectly rough plates}]\) and
\[ c = \frac{\sin^{-1} m}{m} + \frac{1}{m} \sqrt{1 - m^2} , \]

These equations state that when the normal pressure, \( p \), applied by the plates reaches the value given by
\[ \frac{p}{k} = c + \frac{mx}{h} + 2 \sqrt{1 - m^2} \]
the plastic rigid block begins to deform according to the velocity field (33). As stated before we are interested in the subsequent neighboring deformation of the body and in the rate of increase of the external forces to achieve this deformation.

If \((x, y)\) are regarded as Lagrangian coordinates and if the current coordinates are denoted by \((\overline{x}, \overline{y})\),
\[ \overline{x} = x + b \frac{U}{U} + ... \]
\[ \overline{y} = y + b \frac{V}{U} + ... \]

where \( b \) denotes the compression.

Equations (19) and (21) provide three independent relations to determine the Lagrangian stress increments \( \sigma'_x, \sigma'_y, \tau'_{xy} \).

From (19), (32) and (33)
If it is assumed that \((\sigma_x' - \sigma_y')\) and \(\tau_{xy}'\) are functions of \(y\) only, the above equations, with the boundary conditions \(\sigma_x = 0\) when \(y = 0\), and \(\tau_{xy} = mk\) when \(y = h\), give

\[
\begin{align*}
\tau_{xy}' &= 0 \\
\sigma_y' &= \frac{k}{h} f - 2k \frac{m}{h^2} x + b \\
\sigma_x' &= \sigma_y' - \frac{f_y}{m^2 k^2 F} \frac{h}{y}
\end{align*}
\]

where \(b\) is an undetermined constant. To determine \(b\) let us consider the surface \(AB\) which after a small deformation becomes a plane, \(A'B'\), parallel to the \(y\)-axis, Fig. 1.

Transformation from \(AB\) to \(A'B'\) is given by

\[
\begin{align*}
\frac{\bar{x}}{h} + \frac{\delta}{h} \left( C + \frac{\bar{x}}{h} - \frac{f}{m} \right) &= \frac{\bar{x}}{h} = \text{constant} \\
\frac{\bar{y}}{h} (1 - \frac{\delta}{h}) &= \frac{\bar{y}}{h}.
\end{align*}
\]

Since the left hand edge of the block is free from stress, the overall equilibrium condition demands that

\[
\int_0^{h(1-\delta/h)} \sigma_x d\bar{y} = - mkx.
\]
Using (32), (37), (38) the last equation gives
\[ mkC + bh = \frac{-h}{m^2k^2F} \int_0^h \frac{f'y}{y} \, dy = 0, \]

hence
\[ mkC + bh = -\frac{2}{mk^2F} \arcsin m. \quad (40) \]

The normal stress in y-direction is then obtained from (37) and (40):
\[ \sigma_y = \sigma_y^0 + \sigma_y' = (f-c)k - mk \frac{h}{h} \left[ 1 + \frac{b}{h} \right] - \frac{2b}{h} \frac{\arcsin m}{mk^2F}. \quad (41) \]

The average normal pressure required to continue the deformation is therefore
\[ p = -\left(2 \sqrt{1 - m^2} - c\right)k + \frac{mkL}{2h} \left[ 1 + \frac{b}{h} \right] + \frac{2b}{h} \frac{\arcsin m}{mk^2F}. \quad (42) \]

In order to compare this result with experiment [5], let us consider the case \( m = 1 \):
\[ \frac{p}{k} = \frac{\pi}{2} + \frac{L}{2H} + \frac{b}{h} \left[ \frac{\pi}{k^3F} + \frac{L}{2H} \right]. \quad (43) \]

The dimensionless quantity \( Fk^3 \) can be obtained from the stress-strain curve in compression:
\[ Fk^3 = \frac{\sqrt{3}}{4} \frac{\sigma}{(d\sigma/d\epsilon)} \]

where \( \sigma \) is the yield stress in compression and \( d\sigma/d\epsilon \) is the slope of the stress-strain curve.

The stress-strain curve of the material used in the experiments is shown in the Fig. 2. The material begins to deform plastically at 50 Bars and at this point
\[ \frac{\pi}{Fk^3} = \frac{4\pi}{\sqrt{3}} \frac{d\sigma/d\epsilon}{\sigma} \sim 1125. \]
Hence according to (43), [the slope of the load-deformation curve] at the beginning of the deformation is strongly dependent on the rate of strain-hardening since

\[ \frac{\pi}{Fk^3} \gg \frac{L}{2H}. \]

The results obtained from the experiments agree with this observation (Fig. 3). Moreover the straight line (I) defined by the equation (43) follows closely the experimental results.

In order to have an idea on the shape of load deformation curve, one can approximate the stress-strain relation with an ideally plastic material \((F \to \infty)\) as shown in Fig. 2. The straight lines (II) defined by (43) are approximate load-deformation curves corresponding to this idealized material (Fig. 3).

**Example 2: Cylinder Under Internal Pressure:**

A tube made of plastic-rigid material is subjected to internal pressure. The tube is supposed to be long enough so that the axial deformations of the tube can be neglected. If the yield stress of the material is denoted by \(k\), incipient stress and velocity fields are given by (Fig. 4)

\[
\begin{align*}
\sigma_r &= 2k \log \frac{b}{d} \\
\sigma_\theta &= 2k (1 + \log \frac{b}{d}) \\
\tau_{r\theta} &= 0 \\
\end{align*}
\]

\[ (44) \]

and

\[ \nu(r) = \phi \frac{b}{r}. \]

The material points situated on the circle of the radius \(r\) would move after time \(\delta\) to another circle with the radius \(\bar{r}\).
The physical components of the stress in these elements would be given by

\[
\sigma_r = \sigma_r^0 + \delta \sigma_r + \ldots \\
\sigma_\theta = \sigma_\theta^0 + \delta \sigma_\theta + \ldots \\
\tau_{r\theta} = \tau_{r\theta}^0 = 0.
\]

The Equilibrium Equation satisfied by the Lagrangian Stress-increments is found either from the tensorial Equation* (21); or from a straightforward derivation:

\[
\frac{\partial \sigma_r'}{\partial r} + \frac{\sigma_r' - \sigma_\theta'}{r} + 4k \frac{a}{r^3} = 0.
\]

On the other hand, Equation (16) gives

\[
\sigma_\theta' - \sigma_r' = \frac{a}{r^2k^2F}.
\]

Eliminating \( \sigma_\theta' \) from these Equations

\[
\frac{\partial \sigma_r'}{\partial r} - \frac{a}{k^2Fr^3} + \frac{4ka}{r^3} = 0
\]

\[
\frac{\partial \sigma_r'}{\partial r} + \frac{ak}{r^3} \left[ 4 - \frac{1}{k^2F} \right] = 0
\]

\[
\sigma_r' = \frac{ak}{2r^2} \left[ 4 - \frac{1}{k^2F} \right] + c = 0.
\]

Using the boundary condition

\[
\frac{\sigma_r'}{r} = 0 \quad \text{at} \quad r = b
\]

* This equation must first be rewritten for curvilinear coordinates.
we get
\[ \sigma' = \frac{ak}{2} \left[ \frac{4}{r^2} - \frac{kF}{r^2} \right] - \frac{1}{k^3F} \left[ \frac{1}{r^2} - \frac{1}{b^2} \right] \]
and
\[ \sigma_r(r, \delta) = 2k \log \frac{r}{b} + \frac{ak}{2} \left[ \frac{4}{r^2} - \frac{kF}{r^2} \right] - \frac{1}{k^3F} \left[ \frac{1}{r^2} - \frac{1}{b^2} \right] \delta. \tag{47} \]

It is easily seen from this equation that if
\[ F > \frac{1}{4k^3} \tag{48} \]
\[ |\sigma_r(a, \delta)| \leq |\sigma_r(a, 0)|, \]

hence a quasi-static motion can only be maintained with decreasing pressure. [In the case where \( F \to \infty \) (ideally plastic material), (47) checks with a previous analysis [6]). However if
\[ F < \frac{1}{4k^3} \]
deformation can be continued with increasing pressures. In terms of a simple stress-strain relation in compression the inequality (48) can be written
\[ \frac{d(\sigma/\sigma_o)}{d\varepsilon} < \sqrt{3} \quad \text{collapse} \]
\[ \frac{d(\sigma/\sigma_o)}{d\varepsilon} > \sqrt{3} \quad \text{no collapse}. \]

In Fig. (3), the limiting curve separating the two regions is shown.
Appendix: It is well known from Tensor Analysis [7] that

$$\frac{\partial a^p}{\partial x^i} = g^{pm} \frac{\partial x^i}{\partial a^m} \quad (49)$$

where $g^{pm}$ are the contravariant components of the metric tensor of the curvilinear system defined by $a^P$ in the deformed position. However $g^{pm}$ are given [8] to the desired order of approximation by

$$g^{pm} = \delta^p_{pm} - \delta(v^o_{p,m} + v^o_{m,p})$$

and since

$$\frac{\partial x^i}{\partial a^m} = \delta_{im} + v^o_{i,m} \delta + \cdots,$$

$(49)$ gives

$$\frac{\partial a^p}{\partial x^i} = \delta^p_{pi} - \delta v^p_{p,i} + \cdots.$$
