ABSTRACT

Longitudinal and lateral characteristics were obtained on seven models of lenticular shape at Mach 5 and a Reynolds number of 1.5 million (based on model diameter). The effect of various control surfaces on the characteristics of the lenticular shaped body is shown. Data for a body of greater thickness-to-chord ratio and for a body with blunt edges are also presented.

INTRODUCTION

At the request of the Air Proving Ground Center (APGC), Eglin Air Force Base, tests were conducted on seven lenticular models at Mach 5 and Reynolds number of $1.5 \times 10^6$ (based on model diameter) in tunnel E-1 of the von Karman Gas Dynamics Facility, AEDC, July 13-23, 1959. These tests were the third in a series made in support of an APGC investigation of lenticular models. The previous tests, also conducted in Tunnel E-1, are reported in Refs. 1 and 2.

The primary objective of this test series was to obtain experimental data on the stability characteristics of the basic lenticular body equipped with various control surfaces.

APPARATUS

WIND TUNNEL

Tunnel E-1 is an intermittent, supersonic wind tunnel with a 12-in. square test section (Fig. 1). The top and bottom walls are flexible plates which are manually positioned with screw jacks to produce Mach numbers ranging from 1.5 to 5. Stagnation pressures from sub-atmospheric to four atmospheres are automatically regulated by throttling the flow from a high-pressure, dry-air, storage tank. Heating coils about the storage tank provide stagnation temperatures between 70 and 129° F, depending upon test conditions. A large vacuum sphere coupled to the wind tunnel diffuser permits operation at low density levels. The angle-of-attack sector, which pitches the model in the horizontal plane, covers a range from about -5 to +15 deg. The absolute humidity of the tunnel air is normally below 0.00015 lb of water per lb of air. During these tests stagnation temperatures varied from 70 to 90° F.

MODELS

The seven models and sting support were designed by APGC to accommodate an existing VKF internal balance. Model construction was of aluminum with polished surfaces. Photographs of several models are presented in Fig. 2, and a typical model-balance installation is illustrated in Fig. 3.

Manuscript released by author December 1959.
Model details are presented in Fig. 4. Model 1 had eight stabilizing surfaces (herein referred to as 'flaps') derived by hinging sections of the exterior surfaces as shown in Fig. 4a. These sections were pinned to the model base and were removable so that flap deflection arrangements of 0, 5, and 10 deg could be obtained without removing the model from the sting support. This model was also tested with these sections set out one quarter inch from the model surface (flaps-open configuration). Model 2 had twin tail booms (Fig. 4b) and was tested with and without 20-deg wedges which were glued, in various combinations, to the boom surfaces. The elevon-like surfaces of Model 3 (Fig. 4c) had fixed deflection angles of 0 and -10 deg. Model 4 (Fig. 4d) had a drooped nose and was also tested with a small, 22-deg wedge (Tab) located on the model centerline just aft of the nose breakline. Model 5 (Fig. 4e) is simply the basic lenticular shape with the addition of vertical fins. All the models except models 6 and 7 had the same basic body shape. Models 6 and 7 (Fig. 4f) had a greater body thickness ratio, and in addition, Model 7 had a blunt edge radius.

The balance locknut cavity of each model (see Fig. 3) was filled with cotton wool and sealed over by a fairing of dental plaster.

INSTRUMENTATION

The force and moment measurements were made with VKP internal balance E1-B61-8. The gage outputs from the balance were measured with 400-cps force readout units. These units are a null-balance servo system having both a dial indicator and an electrical digitizer serving as the gage input to an ERA 1102 computer.

Absolute base pressure was measured with a 1-psi differential transducer which had a vacuum for a reference pressure. The transducer output was measured with a d-c millivolt digitized recorder, which also served as the input to the computer.

Other data items, such as angle of attack and stagnation temperature and pressure, were measured, digitized, and automatically recorded.

TEST PROCEDURE

Data were obtained at Mach 5, at a constant Reynolds number, based on model diameter of 8-in., of approximately 1.5 million, and at angles of attack and yaw from -5 to +15 deg. For the yaw data, the model and balance were rolled 90-deg from the pitch plane.
Pitching and yawing moments were measured about the moment reference point (see model sketches, Fig. 4), and rolling moments were taken about the model centerline. The angles of attack and yaw were corrected for deflections of the sting support caused by air loads on the model. Data were obtained for the model configurations as summarized in Table 1.

### Precision of Data

The uncertainties in the basic measurements, listed below, were determined from the balance calibration data, the tunnel airflow calibration data, and the known precision of pressure measuring instrumentation.

<td>±0.6 x 10^{-3}</td>
<td>±0.23 x 10^{-3}</td>
<td>±0.1 x 10^{-3}</td>
</tr>
</tbody>
</table>

The variation in test section Mach number along the tunnel centerline is within ±0.01, and the estimated accuracy of the sector positioning of the angle of attack is ±0.1 deg.

### Results

The basic force and moment coefficients for models without control surface deflection are presented in Fig. 5. Included in this figure for comparison purposes are data obtained on the basic lenticular body (Model 5 with fins removed). As these data show, the inherent instability of the lenticular body was increased by increasing the thickness ratio (Models 6 and 7). The drag increase in both cases was considerable. A significant decrease in instability with a very small drag increase was obtained, however, by adding thickness at the trailing edge of the lenticular body (Model 1). The tail-booms of Model 2 gave similar results.

Although all the model configurations tested were longitudinally unstable about the mid-chordline, a significant amount of pitch control was obtained by the flaps of Model 1 and the wedges of Model 2 (Fig. 6). The decrease in effectiveness of these controls on the leeward surface with angle of attack is shown by the data presented for
10-deg flap deflections on Model 1 and the "top only" wedge locations of Model 2. These data (Fig. 6) also show that the elevons of Model 3 did not affect the stability level of the basic lenticular body and produced negligible pitch control. The drooped nose of Model 4 produced a trim lift coefficient of 0.03 (trim angle about 4 deg); the effect of the small tab on these results was negligible.

All the model configurations were laterally stable as shown in the typical data given in Fig. 7a. These data show the directional control obtained, by asymmetrically increasing drag, on Models 1, 2, and 3. Deflecting the elevons on Model 3 reduced directional stability and produced only small control moments. The maximum roll control was obtained by the wedges of Model 2 (Fig. 7b), however, all the roll control methods were effective.

Typical schlieren photographs of each model are given in Fig. 8. The photographs of Model 1 show an increase in flow separation at the trailing edge obtained with flap deflection. A photograph of Model 5 (less fin) at about 10-deg angle of attack is included to show the extent of the separation on the upper surface at this condition.

CONCLUSIONS

All configurations were longitudinally unstable and directionally stable.

Several methods for obtaining longitudinal and lateral control were effective.
