THE DECOMPOSITION OF ARGENTIC AND ARGENTOUS OXIDES IN CONCENTRATED KOH ELECTROLYTE
THE DECOMPOSITION OF ARGENTIC AND ARGENTOUS OXIDES IN CONCENTRATED KOH ELECTROLYTE

Prepared by:
F. M. Bowers, R. D. Wagner, N. R. Berlat and G. L. Cohen

ABSTRACT: The rate of decomposition of AgO in 40% (ION) KOH electrolyte was studied at temperatures ranging from 4.4°C to 71°C. No decomposition was observed at 4.4°C. After 35 days at 71°C there was complete reduction to Ag₂O and metallic silver. The addition of 6.5-8.5% ZnO by weight decreases the rate of decomposition of AgO and possibly prevents the decomposition of Ag₂O. The decomposition of Ag₂O to metallic silver under the conditions studied is thermodynamically feasible.

This report covers the initial results of an investigation on the effects of temperature on the decomposition of silver oxides in concentrated potassium hydroxide electrolyte. The investigation has been performed under Task RUTO 3E000/217.

The results should be of interest to manufacturers and users of silver oxide-zinc batteries.

INTRODUCTION

The following two reactions

\[ 2\text{AgO} \rightarrow \text{Ag}_2\text{O} + \frac{1}{2}\text{O}_2 \]  
\[ \text{Ag}_2\text{O} \rightarrow 2\text{Ag} + \frac{1}{2}\text{O}_2 \]

could affect the charge retention of the cathode in the AgO/KOH/Zn system. It is important, therefore, to know the rates at which the decomposition proceeds under various conditions. Measuring the volume of gas as it is evolved during the course of the above reactions is a convenient method for determining the decomposition rate.

To eliminate the unknown effects of organic separators, electrolyte additives, electrolyte concentration, and anode and cathode manufacturing processes, which are peculiar to the various silver-zinc cell manufacturers, the initial phases of this investigation were conducted with commercial chemically prepared AgO powder (approximately 99% AgO) in 40% (1ON) KOH with and without ZnO additive. The experiments were planned so that not only the volume of gas would be measured but the silver oxide would be analyzed at the beginning and end to determine the amount of AgO converted to \( \text{Ag}_2\text{O} \) and Ag.

EXPERIMENTAL

The apparatus used was a gasometer designed by Otto and Eickel which measures the gas produced by a chemical reaction (Fig. 1). As the sample in the container (5) gasses, the pressure forces the mercury in the manometer (11) away from the platinum wire (3) opening a light bulb circuit between contacts (12) and (13). When mercury is removed from the reservoir (6) through stopcock (7), the mercury in the manometer (11) rises closing the light bulb circuit. The amount of gas evolved from the sample can be calculated from the amount of mercury removed. The accuracy of the results is dependent upon a gas tight system and accurate temperature control. The leakage of the apparatus was tested by a mass spectrometer and found to be less than 2 cc/yr.

Table I shows the conditions under which the experiments were performed. The reactants were placed in constant temperature boxes (ovens or refrigerators). Necessary precautions were taken to ensure that the mercury was removed from the
system when it was at the temperature of study. Two forms of AgO supplied by Handy and Harman were used for these experiments. One was the type which purportedly Amlie and Ruetschi studied. The second, labeled "low gassing" by the manufacturer, was reportedly the result of improved process control. Both forms were analyzed for total oxygen content by heating to 500°C to drive off the oxygen and for silver by the Volhard method. These analyses indicated that both materials were more than 99% pure AgO. However, analysis by the Topf and Diehl method as modified by Jirsa indicated a purity of only about 95%. Analysis by x-ray diffraction showed both alpha and beta forms of AgO and a trace amount of Ag2O. No free silver was detected in either material.

To determine the actual composition of the gas evolved, a sample was removed from the gasometer and analyzed by gas chromatography. Since this analysis showed a definite increase in the order of 5% in the proportion of oxygen over that ordinarily contained in air, and no increase in the proportion of nitrogen, hydrogen or carbon dioxide, it was concluded that only oxygen was evolved.

RESULTS AND DISCUSSION

Figure 2 shows a comparison of the rates of decomposition of AgO in 10N KOH at three of the four temperatures at which the studies were made. These data show that the rate of oxygen evolution increases with increasing temperature. At 4.4°C (40°F) no evolution of oxygen was observed during a 70-day period.

At 71°C (160°F) the total volume of O2 evolved after 35 days is 7 ml (STP) greater than the amount of O2 (45 ml STP) which should have been evolved if only reaction (1) had taken place and gone to completion. At this point the gas evolution had apparently ceased, and the sample in the gasometer consisted of a white spongy material on top of a black powder. The two layers were physically separated and analyzed by x-ray diffraction. The analysis (Fig. 3) of the black layer showed that this material was principally Ag2O with small amounts of AgO and Ag2CO3. Analysis (Fig. 4) of the white spongy layer showed that this material was principally AgO with small amounts of Ag2O and Ag2CO3. No AgO was found in either layer. Thus, at 71°C, in the presence of 10N KOH electrolyte, silver oxide is reduced to metallic silver.

Figure 5 shows the degree of reproducibility when data were taken by two of the authors of this paper independently. There is a 10% deviation after eight weeks. This may be due to
variation in temperature control at the time of obtaining data.

Zinc oxide dissolved in KOH reduces the rate of decomposition. Figure 2 shows the comparison of the decomposition of AgO in 10N KOH with and without ZnO at three of the temperatures studied. The results obtained with ZnO present are in agreement with Amlie and Ruetschi. After 50 days the total volume of oxygen evolved was 48 ml. Gassing had apparently ceased. Experimental error as shown by Fig. 5 is about 10%. Assuming the experimental variation, the 48 ml value indicates that in presence of zinc oxide the decomposition proceeds only according to reaction (1). X-ray diffraction studies showed that the residue did not contain any metallic silver.

At 32.2°C (90°F) and 47.5°C (118°F) the presence of ZnO also reduces the rate of oxygen evolution. These results are consistent with those reported by Wylie. He also reports that Handy and Harman chemically prepared AgO had higher gassing rates than other AgO materials studied. He states that the gassing of various AgO materials is dependent upon the surface area of the samples used. Since no determination of surface area was made here, a comparison is not possible.

The reduction of silver oxide to silver in the presence of strong KOH electrolytes has not been reported until recently. Farmery and Smith attribute the phenomenon to the presence of some reducing impurity in KOH. However, the reduction of Ag₂O to Ag is thermodynamically feasible if Ag₂O dissolves as a negative ion of the form Ag(OH)_2⁺. Dirks suggests Ag(OH)_2 as the ionic species.

Assuming the solution reaction

\[ \text{Ag}_2\text{O} + \text{H}_2\text{O} + 20\text{H}^- = 2\text{Ag(OH)}_2^- \]  (3)

then the reaction for reduction to metallic silver can be written as

\[ 2\text{Ag(OH)}_2^- \rightarrow 2\text{Ag}^0 + 20\text{H}^- + \text{H}_2\text{O} + \frac{1}{2}\text{O}_2. \]  (4)

For a study of thermodynamic feasibility, this reaction can be broken up into the following three reactions:

\[ 2\text{Ag(OH)}_2^- \rightarrow \text{Ag}_2\text{O} + 20\text{H}^- + \text{H}_2\text{O} \]  (5)

\[ \text{Ag}_2\text{O} + \text{H}_2\text{O} + 2e^- \rightarrow 2\text{Ag}^0 + 20\text{H}^- \]  (6)

\[ 20\text{H}^- \rightarrow \text{H}_2\text{O} + \frac{1}{2}\text{O}_2 + 2e^- \]  (7)
The value of the Gibbs standard free energy at 25°C (298°K) (\(\Delta G^{\circ}_{298}\)) for reaction (4) can be calculated by using the values of \(\Delta G^{\circ}_{298}\) for reactions (5), (6), and (7).

The solubility of Ag\(_2\)O in 10N KOH at 25°C has been reported to be \(4.16 \times 10^{-4}\) moles per liter. The equilibrium constant for reaction (3) can be written as

\[
k = \frac{[Ag(CH)\_2]^2}{(OH\^-)^2}\tag{8}
\]

and \(\Delta G^{\circ}\) can be calculated from the formula

\[
\Delta G^{\circ} = -RT \ln k.\tag{9}
\]

The concentration of K\(_2\)OH in the systems studied was about 11.89 molal. However, the precise activity of OH\(^-\) ion (\(a_{OH^-}\)) is unknown. Calculations from the data of Akerlof and Bender\(^8\) indicate that the activity coefficient (\(\gamma\)) is 9.66, and the activity, therefore, is 114.8. The value of free energy calculated for reaction (3) is \(\Delta G^{\circ} = 14.6705\) kcal/mole. This value is the negative of that for reaction (5).

From values of \(E^\circ\) for reactions (6) and (7),\(^9\) by means of Eq. (10)

\[
-\Delta G^{\circ} = nFE^\circ,
\]

where \(f\) is the Faraday constant, values of \(\Delta G^{\circ}\) for the reactions were calculated. These values, along with \(\Delta G^{\circ}\) for reaction (5), are tabulated below.

<table>
<thead>
<tr>
<th>Reaction</th>

<tr>
<td>(4)</td>
<td>-11.955</td>
<td></td>
</tr>
</tbody>
</table>

Now

\[
\Delta G = \Delta G^{\circ} + RT \ln k,\tag{11}
\]

where \(k\) for reaction (4) is

\[
k = \frac{a_{OH^-}^2P_{O_2}^{1/2}[(Ag(OH)_2]^{2}}{[Ag(CH)\_2]^2}\tag{12}
\]

Using previously stated values for \(a_{OH^-}\) and concentration.
of Ag(OH)$_2^-$, one can calculate that $\Delta G$ will be negative for any value of $P_{O_2}$ less than about 10$^8$ atm. Therefore, if reaction (3) is a correct representation of the solubilization of Ag$_2$O in KOH, the reduction to metallic Ag° is spontaneous, assuming Ag(OH)$_2$ is the starting material.

It can be further shown that if the dissolved species is not Ag(OH)$_2^-$ but Ag(OH)$_{n+1}^-$, then the reduction will still be spontaneous. In general, one can write reaction (11) for solution of Ag$_2$O. When this reaction,

$$\text{Ag}_2\text{O} + 2n \text{OH}^- + \text{H}_2\text{O} \rightarrow 2\text{Ag(OH)}_{n+1}^-,$$  \hspace{1cm} (13)

is reversed and added to reactions (6) and (7), the overall reduction reaction is

$$2\text{Ag(OH)}_{n+1}^- \rightarrow 2\text{Ag}° + 2n \text{OH}^- + \text{H}_2\text{O} + \frac{1}{2}\text{O}_2.$$  \hspace{1cm} (14)

The equilibrium equation for reaction (13) is

$$k = [\text{Ag(OH)}_{n+1}^-]^2/(\alpha_{\text{OH}^-})^{2n}.$$  \hspace{1cm} (15)

Since $\alpha_{\text{OH}^-} = 114.8$ in 40% KOH solutions, as $n$ increases, $k$ will decrease, $\ln k$ will become more negative, and $\Delta G°$ for reaction (13) as calculated from Eq. (9) will increase in a positive sense. Therefore, $\Delta G°$ for reverse (13) will increase in a negative sense, making $\Delta G°$ for reaction (14) always negative and indicating that the reduction of Ag° to Ag° in basic solution is spontaneous.

Since Ag$_2$O is photosensitive, the possibility that light caused the decomposition was considered. However, since the sample was in a dark oven most of the time, this possibility was discounted.

It is probable that the reduction to metallic silver occurs in two overall steps, which can be represented by reactions (1) and (2). Thus Ag$_2$O is reduced to metallic silver. To verify this a sample of pure Ag$_2$O was placed in 40% KOH solution at 71°C. Within five days a substantial quantity of a metallic substance was observed on top of the dark Ag$_2$O layer.

To verify that ZnO prevents or retards the reduction of Ag$_2$O to metallic silver, a sample of Ag$_2$O was placed in KOH and ZnO solution. Whereas the presence of silver was first observed within five days without ZnO in solution, no silver was observed after 20 days in the solution containing ZnO.
In Fig. 6 the rate of thermal decomposition for "low gassing" AgO is compared with that for ordinary AgO. Although the total gas evolved per gm AgO was only 32 ml, a partially metallic residue was observed. X-ray diffraction showed that this material contained metallic silver.

Figure 7 shows the rate of gassing of a section of a Yardney Silvercel cathode in KOH solution compared with the rated gassing of AgO. There is less oxygen evolved from the cell electrode, which is expected since the AgO powder has a larger surface area than the pressed electrode.

Figure 8 illustrates the increase in volume of evolved oxygen with temperature after four periods of time.

ANALYSIS PROCEDURES

To correlate the gas evolution data with the composition of the silver residues, a search for an accurate quantitative analysis was initiated. Various chemical methods as well as x-ray diffraction were investigated. X-ray diffraction is a useful tool for rough quantitative work but does not have the required accuracy for this project. There are two main problems involved in a chemical determination. The first problem is finding an analytical method suitable for the determination of the % AgO, % Ag2O and % Ag in the same sample. The second problem is finding a suitable wash solution which will remove the KOH and ZnO without changing the composition of the residue. Alternatively, one might attempt an analysis in the presence of KOH and ZnO.

It was found that the major portion of the KOH could be removed from the residue by filtration through a sintered glass crucible. However, the small amount remaining after such a process is enough to cause significant error in the analytical results. Water is not suitable for use as a wash solution because the residues were found to be somewhat soluble. Water which had been left in contact with AgO and Ag2O for a two-month period and then filtered was tried as a wash solution. Analysis of this solution before and after use indicated that the concentration of silver ion increased due to the washing process. Various alcohols were tried. However, it was found that in the presence of KOH a reduction of one or both of the silver oxides to silver occurred on the addition of alcohol.

None of the ordinary analytical procedures are suitable for the determination of the residue composition. By the Volhard method only the total per cent Ag in the sample can be determined. Whether the silver is present in the divalent,
monovalent or ground state cannot be determined by the use of this method. The Topf and Diehl method is suitable for determining the per cent AgO present in a sample but the presence of Ag₂O interferes with the determination.

A method of analysis whereby one could determine the exact composition of a sample containing AgO, Ag₂O and free Ag has been proposed by NAD Crane, Quality Evaluation Laboratory. Through differential thermal analysis they determined that dry AgO decomposes on heating by a two-step process consisting of reactions (1) and (2). Their results indicated that each of the steps occurs at a distinct temperature: step (1) at 210°C and step (2) at 350°C or above. The 140°C separation between the steps of thermal degradation led them to propose the so-called "crucible method of analysis." This method essentially involves the following:

A sample, approximately 0.5 gm, is heated in an oven at 210°C for a three-hour period or until no further weight loss occurs. The weight loss is then determined and from this and the initial weight of the sample the per cent AgO present in the sample is calculated. The same sample is then heated at 450°C for a period of one hour and the second weight loss is determined. By subtracting weight loss #1 from weight loss #2 the weight loss due to Ag₂O originally present in the sample is determined and from this the per cent Ag₂O.

RESULTS AND DISCUSSION OF ANALYSIS PROCEDURES

To test the accuracy of the Crane method, samples of the same Handy and Harman AgO used in the gasometer determinations were analyzed. The results obtained, some of which are shown in Table II, consistently indicated an AgO-Ag₂O composition of greater than 100%. Since x-ray diffraction indicated only a trace of Ag₂O, it is probable that the large amounts indicated by the crucible method are in error.

The conditions used for the three pairs of samples in Table II were identical with respect to the AgO sample, equipment and temperature; however, the time of heating for step (1) was varied. The first pair was heated for three hours and the second and third pairs for four hours. The wide variation in results in samples heated for different times demonstrates that this method lacks precision and accuracy. The possibility that the heating period for step (1) of the decomposition was not long enough was investigated. However, when the material was maintained at 210°C for a period longer than four hours, partial decomposition to free silver occurred. A thermogravimetric analysis of the original Handy and Harman material was made.
using the Crane method. The results of this analysis are shown in Fig. 9 and show that the steps of the decomposition overlap one another. These results demonstrate that this method is not suitable for the determination of AgO, Ag$_2$O and Ag in the same sample.

CONCLUSIONS

a. The rate of decomposition of AgO in strong KOH electrolyte increases with increasing temperature.

b. In strong KOH electrolyte AgO will completely decompose to Ag$_2$O at 71°C after 35 days, and some Ag$_2$O will be reduced to metallic silver.

c. The addition of ZnO to strong KOH electrolyte reduces the rate of decomposition of AgO to Ag$_2$O and prevents the reduction of Ag$_2$O to metallic silver.

d. Free energy calculations indicate that the reduction of Ag$_2$O to metallic silver in 10N KOH is thermodynamically spontaneous, assuming a soluble species Ag(OH)$_{1-n}$.

e. A satisfactory method for the chemical analysis of mixtures of Ag, Ag$_2$O and AgO in the presence of strong KOH electrolyte has not been developed up to this time.

PLANS FOR FUTURE WORK

Further gas evolution studies on the rates of decomposition of silver oxide powders and cathodes in strong KOH electrolyte with and without ZnO present will be carried out. A suitable analytical chemical method for determining the composition of mixtures of Ag, Ag$_2$O and AgO in the presence of strong KOH electrolyte will be developed. By means of such analysis, coupled with gassing studies, the day-to-day rate of decomposition of AgO in strong KOH electrolyte will be studied.

Further investigations will study the effects of the presence of organic separator material on the rate of decomposition of silver oxide cathode material. A zinc anode will then be added to the system and further decomposition studies carried out both on the cathode and anode. After all the components have been assembled, studies relating charged stand characteristics of silver oxide-zinc secondary batteries to chemical changes in the anode, cathode, separator and electrolyte will be carried out.

The rate of decomposition of AgO in 40% (100) KOH electrolyte was studied at temperatures ranging from 4.4°C to 71°C. No decomposition was observed at 4.4°C. After 35 days at 71°C there was complete reduction to Ag₂O and metallic silver. The addition of 6.5 - 8.5% ZnO by weight decreases the rate of decomposition of AgO and possibly prevents the decomposition of Ag₂O. The decomposition of Ag₂O to metallic silver under the conditions studied is thermodynamically feasible.

Abstract card is unclassified.
