INTRODUCTION

The problem discussed in this paper arises naturally in the study of transportation networks. Roughly stated, it is as follows. Consider a network connecting two nodes by way of a number of intermediate nodes, and suppose the arcs and nodes can handle certain designated amounts of traffic per unit time. Assuming a steady state condition, find a maximal flow of traffic from one given node (the source) to the other (the sink).

For example, let the network be that of Fig. 1.

![Fig. 1](image1)

where source and sink are denoted by + and - respectively, with flow capacities of the arcs and nodes as indicated. A maximal
flow from source to sink is shown in Fig. 2. Notice that the quantity of flow leaving the source (or entering the sink) is equal to the sum of the capacities of the two nodes and one arc which are emphasized in the figure, and that this collection of nodes and arcs forms a "cut" in the network; i.e., meets every chain from source to sink.

A nonconstructive proof based on convexity arguments has been given in an unpublished manuscript by L. R. Ford, Jr. and one of the present writers (D. R. Fulkerson) that the maximal flow value, relative to a given source and sink, attainable in any network is equal to the minimal sum of capacities on arcs and nodes constituting a cut. Our aim is to formulate the problem of finding a maximal flow as a linear programming problem (61) and to deduce the max flow min cut theorem from the dual problem (63). In §4 we observe that a combinatorial form of this theorem yields Menger's theorem [4, p.244] concerning linear graphs.

1. THE PROGRAMMING PROBLEM

There are various ways of formulating the flow problem as a linear programming problem. One way, convenient from both

\[1\] A. Hoffman has given a different formulation of the problem which also yields the max flow min cut theorem. While the techniques employed in his approach are similar to those of this paper, he uses an entirely different set of variables which are of interest in themselves.
a computational and theoretical viewpoint, is as follows. Set up the pseudo transportation array

\[
\begin{bmatrix}
-x_{00} & x_{01} & x_{02} & \cdots & x_{0n} \\
x_{10} & -x_{11} & x_{12} & \cdots & x_{1n} \\
x_{20} & x_{21} & -x_{22} & \cdots & x_{2n} \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
x_{n0} & x_{n1} & x_{n2} & \cdots & -x_{nn}
\end{bmatrix}
\]

Totals 0 0 0 0 \cdots 0

schematizing the equations

(1a) \[-x_{ii} + \sum_{j, j \neq i} x_{ij} = 0 \quad (i=0,1,\ldots,n)\]

(1b) \[-x_{jj} + \sum_{i, i \neq j} x_{ij} = 0 \quad (j=0,1,\ldots,n),\]

where \(x_{ij} \geq 0 \ (i,j=1,\ldots,n; i \neq j)\) denotes the flow from node \(i\) to node \(j\), \(x_{ii} \geq 0 \ (i=1,\ldots,n)\) represents the total flow through node \(i\), \(x_{0j} \geq 0 \ (j=1,\ldots,n)\) is the flow from the source to node \(j\), and \(x_{10} \geq 0 \ (i=1,\ldots,n)\) the flow from node \(i\) to the
sink. Thus \( x_{oo} \) is the total flow through the network and the problem is to maximize \( x_{oo} \) subject to (1a), (1b), and

\[
(2) \quad x_{ij} + x_{ji} \leq c_{ij} \quad (c_{ij} = c_{ji})
\]

\[
(3) \quad x_{ii} \leq c_{ii} \quad (1, j = 1, \ldots, n)
\]

\[
 x_{io} \leq c_{io}
\]

\[
 x_{oj} \leq c_{jo}
\]

\[
(4) \quad x_{ij} \geq 0 \quad (1, j = 0, \ldots, n),
\]

where the \( c \)'s are given nonnegative constants. We have formally included all variables \( x_{ij} \) in the problem; arcs not present in the network have \( c_{ij} = 0 \).

Because of (2), we refer to this as the undirected problem; that is, except for source and sink arcs, the direction of flow is not specified in the arcs.

Given an undirected problem, it is easy to describe an equivalent directed problem. Simply replace each undirected arc by a pair of oppositely directed arcs, each with capacity equal to that of the original arc. That the two problems are equivalent follows from the fact that given any \( x = (x_{ij}) \) satisfying (1), (3), (4), and

\[
(2') \quad x_{ij} \leq c_{ij}
\]

\[
 x_{ji} \leq c_{ji} \quad (c_{ij} = c_{ji})
\]
a flow \( x' \) of equal value is obtained by setting

\[
x_i^1 = x_{10} \quad (i = 0, \ldots, n)
\]
\[
x_i^j = x_{0j} \quad (j = 0, \ldots, n)
\]
\[
x_i^j = \max (x_i^j - x_{j1}, 0) \quad (i, j = 1, \ldots, n; 1 \neq j)
\]
\[
x_i^1 = x_{11} - \sum_{j=1}^{n} \min (x_i^j, x_{j1}) \quad (i = 1, \ldots, n).
\]

Thus (2) may be replaced by (2') without changing the value of a maximal flow.

A cut in an undirected network has been defined as a collection of arcs and nodes meeting every chain joining source and sink; a cut in a directed network is similarly defined as a collection of directed arcs and nodes meeting every directed chain from source to sink. The value of a cut in either case is the sum of the capacities of all its member nodes and arcs. One proves easily that the minimal cut value is the same for an undirected network and its equivalent directed network. Thus, to prove the max flow min cut theorem, it suffices to consider directed networks only. Accordingly, we shall make no further use of the condition \( c_{1j} = c_{j1} \) in (2').

Let us now rewrite the inequalities (2'), (3), as

\[
x_{ij} + y_{ij} - c_{ij}, y_{ij} \geq 0 \quad (i, j = 0, 1, \ldots, n)
\]

where, to avoid special cases, we have included a sufficiently large upper bound of \( c_{00} \) on the variable \( x_{00} \); for example, choose \( n \in \sum_{i=1}^{n} c_{io} \). Then the problem is to maximize \( x_{00} \) subject to (1a), (1b), (4), and (5).
2. BASES

We turn momentarily to the question of what constitutes a basis, in order to note that the Hitchcock-Koopmans transportation theory carries over to the flow problem.

There are \((n+1)^2 + 2(n+1) - 1\) linearly independent equations in the set (1a), (1b), (5), since one of the set (1a), (1b), is redundant. Drop the first equation of (1a) as the redundant one, and denote by \(x_{ij}, y_{ij}\) the column vectors of the coefficient matrix of the remaining equations corresponding to the variables \(x_{ij}, y_{ij}\), respectively.

It is clear that at least one of \(x_{ij}, y_{ij}\) must belong to any basis \(B\). Thus the pairs \(ij\) fall into one of three classes:

\[\alpha: \text{those } ij \text{ for which } x_{ij} \in B, y_{ij} \in B;\]
\[\beta: \text{those } ij \text{ for which } x_{ij} \in B, y_{ij} \notin B;\]
\[\gamma: \text{those } ij \text{ for which } x_{ij} \notin B, y_{ij} \in B.\]

The number of pairs \(ij\) of type \(\alpha\) is always \(2n+1\). For if there are \(k\) of type \(\alpha\), hence \((n + 1) - k\) of types \(\beta\) and \(\gamma\), then

\[\text{Let } \sum_{j=1}^{n} a_{ij}x_j = b_i, x_j \geq 0 \quad (i = 1, \ldots, m) \text{ be the constraints of a linear programming problem, and suppose } A = (a_{ij}) \text{ has rank } m. \text{ A set of } m \text{ linearly independent columns of } A \text{ is a "basis", the corresponding } x_j \text{ are "basic variables". The vector } \hat{x} = (\hat{x}_1, \ldots, \hat{x}_n) \text{ obtained by assigning non-basic variables zero values and solving the resulting equations for the basic variables is called a "basic solution". If } \hat{x} \text{ has non-negative components, it is termed a "basic feasible solution". Geometrically, basic feasible solutions correspond to extreme points of the convex set defined by the constraints.}\]
\[ 2k + (n + 1)^2 - k = (n + 1)^2 + 2(n + 1) - 1, \quad k = 2n + 1. \]

Moreover, it is impossible to find among the pairs of type \( \prec \) a subset of the form

\[ i_1 j_1, \ i_1 j_2, \ i_2 j_2, \ i_2 j_3, \ldots, \ i_k j_k, \ i_k j_1 \]

where the \( i \)'s and \( j \)'s are distinct among themselves, as otherwise the column vectors \( X_{ij}, Y_{ij} \) corresponding to these pairs can easily be shown to be dependent.

These two statements together imply that \( B \) can be arranged in triangular form, just as in the Hitchcock-Koopmans case. To see this, it is convenient to associate a linear graph \( G \) with \( B \), and to look at the problem of finding the basic solution corresponding to \( B \) in terms of this graph.  

Let \( a_0, \ldots, a_n, b_c, \ldots, b_n \) be the nodes of \( G \); the arcs of \( G \) are those \( a_i b_j \) for which \( i j \) is of type \( \prec \). As we have seen, \( G \) has \( 2n + 1 \) arcs and contains no cycles. It is therefore a tree. Call a node of \( G \) which has only one arc on it an "end-node". There are at least two such.

We associate with node \( a_i(b_j) \) of \( G \) the equation \(-x_{ii} + \sum_{\substack{j, j+1 \in \mathbb{Z} \setminus \{i, i+1\} \in \mathbb{Z}}} x_{ij} = 0 \). Now locate an end-node, 

---

There are several alternative ways one can view the equation solving process in terms of a linear graph. Since the equations came from such a graph, one way would be to use the original network. This appears to be most efficient for hand-computation. Another way, in terms of the array \( (i) \), can be developed as in [2]. A third way, the one we adopt, is suggested in [1b]. In all of these, the notion of "basis" in the programming sense is closely related to the notion of "tree" in the graph sense.
say \( a_k \), and let its arc be \( a_k b_k \). Since for pairs \( ij \) of type \( \beta \), 
\[ y_{ij} = 0, \quad x_{ij} = c_{ij}, \] 
and similarly \( x_{ij} = 0, \quad y_{ij} = c_{ij} \) for pairs 
of type \( \gamma \), all the variables of the equation 
\[ -x_{kk} + \sum_{j, j \neq k} x_{kj} = 0 \]
are determined but one, \( x_{kk} \), and thus its value may be found 
immediately. Then use (5) to get 
\[ y_{kk} = c_{kk} - x_{kk}. \] 
Delete 
\( a_k \) and \( a_k b_k \) from \( G \), leaving a tree, and repeat the procedure. 
After \( 2n + 1 \) steps, the values of all variables are determined.

Notice that only addition and subtraction are required. 
Thus, if the \( c_{ij} \) are integral, so are the values of all variables 
in a basic solution, hence in a basic feasible solution. We 
will make use of this fact in the concluding section.

3. SIMPLEX CRITERION AND THE DUAL PROBLEM

Let \( u_i, v_j, w_{ij} \) be the multipliers (dual variables) 
corresponding to the equations (1a), (1b), (5), respectively, 
in applying the simplex algorithm. Then the conditions for an 
optimal basis \( B^* \) are:

\begin{align*}
(6a) \quad -u_i - v_i + w_{ij} & \geq \delta_{i0} \\
(6b) \quad u_i + v_j + w_{ij} & \geq 0 \\
(6c) \quad w_{ij} & \geq 0
\end{align*}

\((\delta_{00} = 1, \quad \delta_{i0} = 0 \text{ for } i > 0)\)
with equality holding in (6a), (6b), if the corresponding
\(X_{ij} \in B^o\), in (6c) if \(Y_{ij} \in B^o\). Ignoring the redundant equation
amounts to taking \(u_0 = 0\). Then, since \(Y_{oo} \in B^o\),
\(w_{oo} = 0, v_0 = -1\). For all other pairs \(ij\) of type \(\prec\), \(w_{ij} = 0,\)
and the equations \(u_1 + v_j = 0\) hold. It follows that all \(u_1 = 0\)
or \(1\), all \(v_j = 0\) or \(-1\). (A convenient way to see this is to
associate the variable \(u_1(v_j)\) with node \(a_i(b_j)\) of the graph
\(G^o\) corresponding to \(B^o\) and the equations \(u_1 + v_j = 0\) with the appropriate
arcs of \(G^o\)). Substituting these values into (6a), (6b), to
determine the \(w_{ij}\) corresponding to \(Y_{ij} \in B^o\) and noting (6c)
shows that all \(w_{ij} = 0\) or \(1\).

The dual programming problem is to minimize \(\sum c_{ij}w_{ij}\)
subject to (6a) – (6c), and the multipliers corresponding to an
optimal primal solution solve the dual problem. Thus

\[
\max x_{oo} = \min \{\sum c_{ij}w_{ij} = \sum_{G} c_{ij}\}
\]

where \(G\) is that set of pairs \(ij\) corresponding to \(w_{ij} = 1\); in
terms of the network, \(G\) is some subset of those (directed)
arcs and nodes which are at capacity in the flow \(x\). We claim
that \(G\) is a cut. For suppose all \(c_{ij}, ij \notin G\), are increased
by \(\epsilon > 0\). This does not change the solution to the dual, hence

\footnote{Our choice of \(c_{oo}\) implies that \(Y_{oo} \in B\) for any \(B\) yielding
a basic feasible solution; also clearly \(X_{oo} \in B^o\) except possibly in the trivial case where the maximal flow over the
network is zero. The assertion is valid in general, however, as otherwise all multipliers have zero values, violating (6a)
with \(i = 0\).}
cannot increase the flow in the network. But if there were some directed chain from source to sink not meeting $\mathcal{C}$, the maximal flow value would be increased by at least $\epsilon$. Thus $\mathcal{C}$ is a cut, and since it is clear that no flow can exceed the value of any cut, the proof of the max flow min cut theorem is complete.

4. Menger's Theorem

Given an arbitrary linear graph $G$, let $I_1, I_2$ be two disjoint sets of nodes of $G$. Menger's theorem states that the maximal number of pairwise node-disjoint chains joining $I_1$ to $I_2$ is equal to the minimal number of nodes necessary to separate $I_1$ from $I_2$. To deduce this theorem from the max flow min cut theorem, join all the nodes of $I_1$ to a new node, the source, and all the nodes of $I_2$ to another new node, the sink; then assign unit capacity to each of the old nodes, infinite capacity to each arc. Menger's theorem now follows by selecting a maximal flow $x$ with integral components.
