STRENGTHENING OF ROCK AGAINST SHOCK EFFECTS
DASA SUB-TASK NO. 13.192
TESTS FOR STRENGTH CHARACTERISTICS OF ROCK
PILEDRIVER PROJECT

MRD LABORATORY NO. 64/90
SEPTEMBER 1964
CORPS OF ENGINEERS
U.S. ARMY
MISSOURI RIVER DIVISION LABORATORY
OMAHA, NEBRASKA
THE CONTENTS OF THIS REPORT ARE NOT TO BE USED FOR ADVERTISING, PUBLICATION, OR PROMOTIONAL PURPOSES
The studies reported herein were authorized by the Chief of Engineers (ENGRC-EM) and were initially funded in FY 1964 by sub-allotment from the U. S. Army Corps of Engineers Waterways Experiment Station through the U. S. Army Corps of Engineers Ohio River Division Laboratories for research in techniques of rock strengthening.

Additional funds were received in FY 1964 from the Defense Atomic Support Agency, DASA MPR 571-64, by sub-allotment from the U. S. Army strengthening for the PILEDRIVER project under DASA NWER Sub-Task No. 13,192 "Strengthening of Rock Against Shock Effects."

The initial emphasis of the studies conducted and reported herein are for the purpose of establishing the strength characteristics of intact and jointed rock necessary for the design, installation, and evaluation of rock strengthening systems to be incorporated in the PILEDRIVER project.

The laboratory tests were performed at the U. S. Army Corps of Engineers Missouri River Division Laboratory by members of the Physical Tests and Investigations Section under the supervision of Messrs. E. J. Deklotz and Wm. J. Heck, who also jointly prepared this report. Mr. L. A. Brown was Director of the Missouri River Division Laboratory during the conduct of the program.

Additional studies to develop strength characteristics of the fractured (jointed) rock bonded with chemical adhesives and to develop a preliminary rock bolting theory have been conducted by the U. S. Army Corps of Engineers Ohio River Division Laboratories and U. S. Army Corps of Engineers Omaha District respectively as a part of the DASA NWER Sub-Task No. 13,192 and will be presented in separate reports by those agencies.

The strength characteristics of the quartz monzonite has been determined by direct tensile, unconfined compression, and triaxial compression tests. The data indicate that the rock behaves elastically and retains its brittleness throughout the range of confining pressures used. In general, the rock is uniform in composition and structure, having an average bulk, dry density of 2.66 and an average porosity of 0.27 percent. Feldspar and quartz are the principal mineral constituents with a small amount of biotite making up most of the remainder of the rock.

The Mohr strength envelop for the intact rock and rock with healed joints that acted as intact rock, determined by using the average tensile strength of 1,450 psi, an average unconfined compressive strength of 30,530 psi, and average maximum principal stresses of 32,690, 36,340 and 46,050 psi at 150, 450, and 1,350 psi confining pressures respectively, is a slightly curved line from which a coefficient of internal friction angle of 56 degrees and a cohesive strength of 3,600 psi is obtained.

The angle of friction was found to be 31 degrees for the natural open joints and 28 degrees for sawed joints as determined from a plot of the points of shear and normal stresses on these pre-established planes. These values indicate that small irregularities on the joint surface have little effect on the coefficient of friction. All of the open and sawed joint surfaces showed the development of slickensides and granulation of mineral grains.

Statistical evaluation of the limited number of test results indicates that in general the rock has rather uniform strength characteristics and that the test data are reasonably consistent. The test results all fall within 95 percent Confidence Limits, assuming \( t \) distribution and using Student's \( t \) values. Coefficient of variation ranged from 3.3 percent for unconfined compression tests to 28.2 percent for the tensile strength tests. Values of 10.8 to 16.8 percent were obtained for the intact rock triaxial compression tests.
TESTS FOR STRENGTH CHARACTERISTICS OF ROCK

PILEDRIVER PROJECT

INTRODUCTION

1. This report presents results of tests for shear, compressive, and tensile strength characteristics of rock of the type which will be encountered and subject to rock strengthening techniques and evaluation as part of Piledriver Project. Triaxial compression tests were made of intact rock and of rock having natural healed or open joints, and joints smoothly sawed in the laboratory. Unconfined compression and direct tension tests were made of intact rock and of rock containing natural healed joints. Certain testing and instrumentation techniques were developed and are described in detail where it is considered the information may be of value in future work of a similar nature.

ROCK IDENTIFICATION

2. Sections of the 2 3/8 inch diameter rock core, from Exploratory Drill Hole U1501-U1 at the project site were submitted for test. Top elevation of hole is 4254.7 feet. The hole is an inclined boring at a downward angle of 210 from horizontal. Throughout this report all depths are inclined depths of core along the boring. Only that portion of rock core which lies in the quartz monzonite was submitted for test. The quartz monzonite is generally a light gray, dense, porphyritic rock with a fine to medium-grained groundmass. Orthoclase and plagioclase feldspars with quartz are the most abundant minerals; however, a small but varying amount of biotite mica occurs as scattered flakes or clusters. Occasionally large, pink crystals of feldspar up to 2 1/2-inches in length are present. Very little alteration and weathering was noted in the core specimens tested. Most of the healed joints observed in the rock are well cemented with quartz and feldspar along with a small amount of calcite. Pyrite was also a common mineral in some of the healed joints. A few of the cores were partially healed with a water soluble mineral which dissolved when the cores were soaked prior to test; consequently these cores separated at the joint and had to be tested as open joint rock specimens. The natural open joints were generally free of mineral deposits or rock dust and their surfaces, although rough, were essentially planar.

TEST PROGRAM

3. Core specimens were selected for test as follows:

Pieces of core cut from the ends of the several strength test specimens identified above were tested for bulk saturated surface-dry specific gravity, bulk dry density, and porosity.

4. The stress-strain data presented graphically in this report can be made available in tabulated form upon request.
PROCEDURE AND RESULTS

Specific Gravity, Density, and Porosity

Procedure

5. In the preparation of the strength test specimens, the longest end piece cut from each strength test core was squared on both ends and used in the determination of bulk saturated surface-dry specific gravity, measured bulk dry density, and porosity. Lengths of these end pieces varied from 1.16 to 4.35 inches. According to the procedure provided in the authorizing test requests, each specimen was measured for length at quarter points and for diameter at third points about the circumference and the volume computed from these measurements. The specimens were permitted to absorb water at room temperature by immersion within a pressure vessel for 1/2-hour at 1200 psi pressure and, upon completion of the saturation period, were individually weighed in water, surface dried, and again weighed in air. The oven dry weight was determined after drying for 72 hours at 230 F. The several parameters were computed as follows:

a. Specific gravity, bulk saturated surface-dry

\[ g = \frac{B}{B-D} \]

where -

\( g \) = Specific gravity, bulk saturated surface-dry
\( B \) = Weight in grams of saturated surface-dry specimen in air
\( D \) = Weight in grams of saturated specimen in water (saturated by immersion in water for 1/2-hour under 1200 psi pressure)

b. Measured bulk dry density

\[ d = \frac{A}{V_1} \]

where -

\( d \) = Measured bulk dry density
\( A \) = Weight in grams of oven dried specimen in air
\( V_1 \) = Volume in cubic centimeters of specimen calculated from measurements.
c. Porosity

\[ p = \frac{V_2}{V_3} \times 100 \]

where:

- \( V_2 \) = Void volume, B-A
- \( V_3 \) = Solid volume, \( V_1 - V_2 \)

Results

6. Results of these tests are presented in Table 1, and indicate that the quartz monzonite is very uniform in composition and structure.

Triaxial Compression Tests

Procedure

7. Tests in triaxial compression were made to determine the shear strength of the several conditions of rock. All cores were cut to an L/D ratio of 2, ends ground and lapped, and immersed for 72 hours in water at room temperature before testing. Particular care was taken in cutting and finishing the ends of the cores to assure that they were approximately normal to the axis and that essentially parallel, flat, smooth end surfaces were obtained. Final finishing was accomplished by hand lapping on a glass plate with No. 600 carborundum compound. The sawed joints were produced with a diamond saw at the preselected angles and rough ground with No. 240 carborundum to remove the saw grooves.

8. The triaxial compression testing was conducted with the apparatus shown in Plate 1 in which confining pressures up to 10,000 psi can be maintained while axial loads up to 400,000 pounds are applied with a universal hydraulic testing machine. Axial strain was measured by a 1/10,000-inch dial gage. Corrections were made for the deformation of the hardened steel parts (Rockwell C 58 or harder), in order to determine the true strain of the rock specimen during test. All of the core specimens were surface dried after the 72-hour immersion period. A thin (15 mil) sheet of vinyl plastic was placed around the core and the top and bottom steel platens to prevent punctures at the interface. The assembly was then covered with a thick rubber membrane made from a section of motor bike inner tube and sealed with rubber O-rings to prevent oil from entering the specimen.
9. After the triaxial apparatus was completely assembled, anti-foaming hydraulic oil was pumped into the chamber until it drained from the overflow tube and air bubbles ceased to rise. The confining pressure was raised to the desired value and maintained constant throughout the test by manual operation of the screw piston device attached to the base of the apparatus. Axial loads were applied to produce, as nearly as possible, a rate of strain of 1/1000 inch per minute in the specimen until failure occurred. Pre-established joint or failure planes were subjected to multi-stage triaxial tests in which, after failure, the confining pressure was raised to the next higher preselected value and the test continued. In some cases this procedure was repeated a number of times.

Results

10. Stress-strain curves and companion Mohr diagrams for the several test conditions are shown in Figures 1 through 78 with a brief description of each core specimen and a diagram of the manner of failure. Photographs of cores showing typical failure planes after test are presented in Plates 2 and 3.

11. The modulus of elasticity, $E$, is determined as the slope of the straight line portion of the stress-strain curve and the value is shown with each curve. The average values of $E$ of intact rock cores and of cores with healed joints which failed as intact rock are:

<table>
<thead>
<tr>
<th>Confining pressure, psi</th>
<th>150</th>
<th>450</th>
<th>1350</th>
</tr>
</thead>
<tbody>
<tr>
<td>Modulus of elasticity, $10^6$ psi</td>
<td>11.75</td>
<td>11.74</td>
<td>11.38</td>
</tr>
</tbody>
</table>

12. The $E$ values for the unconfined compression and tensile test specimens determined by strain gage measurements are $10.46 \times 10^6$ and $8.48 \times 10^6$ psi, respectively.

13. A statistical summary of the triaxial compression test results for the average maximum principal stresses of five specimens, three of intact rock and two of well-healed jointed rock, at each of the selected confining pressures is as follows:

Unconfined Compression Tests

Procedure

14. Specimens for unconfined compressive strength tests were cut, prepared, and immersed in water prior to test in the same manner as the triaxial compression test specimens described in paragraph 7 above. Axial and diametric strains were measured by use of Type A-1 SR-4 strain gages cemented to the specimens with Eastman 910 cement. Three axial gages were equally spaced around the specimen at the center of its height, and three diametric gages were similarly located around the diameter. Specimens were loaded through a high strength steel spherical head and solid pedestal of Rockwell Hardness C 58, at a rate of 50 psi/sec. The bearing face of the spherical head and solid pedestal is 2.42 inches in diameter and is ground flat to 0.0005-in. No capping material was used on the test specimens. Plate 4 is a photograph of one of the test specimens in the testing machine immediately prior to loading.

Results

15. Results of these tests are graphically presented in Figures 79 through 83. Poisson's Ratio was computed using values taken from the curves for diametric and axial strain. Ignoring infinitesimals of the second order it can be shown that the volumetric strain is equal to the axial strain plus 2 times the diametric strain. The stress-volumetric strain curve appears to be of interest as it seems to provide a means for determining the "yield point" of the rock which can be defined as that point on the curve at which the slope of the tangent changes sign. The curve seems to indicate further a consolidation of particles as the load increases up to this point; beyond this point the rock structure begins to disrupt and tear apart. For the 5 specimens tested using strain gage instrumentation, it will be observed that this point ranges between approximately 20,000 and 25,000 psi. Two additional specimens, Core Nos. 32 and 84, were tested for compressive strength with no strain gage instrumentation. These cores showed ultimate strengths of 29,480 and 32,200 psi, respectively. The results of all seven tests are summarized as follows:

- Maximum Compressive Strength, Core No. 84, psi, 32,200
- Minimum Compressive Strength, Core No. 32, psi, 28,770
- Average Compressive Strength, psi, 30,530
- Standard Deviation, psi, 1,162
- Coefficient of Variation, percent, 3.3
- 95 percent Confidence Limits, Student's t distribution, psi, 27,690 to 33,370
Direct Tension Tests

Procedure

16. All direct tension test specimens were immersed in water for 72 hours at room temperature prior to test. Generally the test specimens were cut to an L/D ratio of 2 and cemented into metal end caps using an epoxy resin material identified as Plastic Steel, Devcon A - Putty Type, produced by the Devcon Corporation, Danvers, Mass. After allowing to harden for 24 hours, the assembly, with SR-4 strain gages attached in the same configuration as for the unconfined compression test specimens, is suspended by means of heavy duty roller chain in the testing machine and load applied to failure. Plate 5 is a photograph of a specimen immediately prior to test. The upper and lower roller chain are at right angles to each other in order to reduce eccentricity and bending in the specimen.

Results

17. Stress-strain curves are shown in Figures 84 through 90. Initially the tests were conducted using full cross-section specimens; however, with the development of failures in the cap (Core No. 54, Figure 90) which were considered to be a manifestation of end restraint, it was decided to test reduced section specimens. The reduced sections were cut by means of a carbide tipped tool in a machine lathe operating at slow speed with a minimum amount of water. Improvement was shown in type of break by this method but, under this condition, one end break (Core No. 126, Figure 86) did occur. One specimen, Core No. 51, was tested for tensile strength with no strain gage instrumentation and showed an ultimate tensile strength of 2,353 psi. The results of all eight tests are summarized as follows:

Maximum Tensile Strength, Core No. 51, psi, 2,353
Minimum Tensile Strength, Core No. 145, psi, 1,026
Average Tensile Strength, psi, 1,452
Standard Deviation, psi, 410
Coefficient of Variation, percent, 28.2
95 percent Confidence Limits, Student's t distribution, psi, 482 to 2,422

18. In view of the values obtained for compressive strength, the difficulties encountered in developing a truly direct tensile load on the specimens, and the strength envelopes to be discussed later, it is considered that the strength shown by Core No. 51 may most nearly represent the true tensile strength of the rock. The strength of the remaining 7 cores all appear rather low.
Cyclic Loading in Unconfined Compression

Procedure

19. One specimen, Core No. 47, was cyclic loaded to failure in unconfined compression. The specimen was prepared for test in the same manner as described for the conventional unconfined compression test specimens. The first three loadings were to nominally 20,000 psi. Subsequent duplicate loadings were increased in approximately 2,000 psi increments beyond the original 20,000 psi loadings and failure occurred at the beginning of load release during the eleventh cycle. Strain readings were taken upon load release as well as during load application.

Results

20. Stress-strain data are tabulated in Tables 2 and 3. Figures 91 and 92 are stress-strain curves for a representative selection of the several loadings. It is not entirely clear why the axial strain values show a strain reversal (tension) upon load release unless perhaps this is a manifestation of strain gage slippage. If this is true, a change to epoxy resin type cement might correct this condition. Further investigation in this area seems to be indicated.

GENERAL DISCUSSION OF TEST RESULTS

21. When the shear strengths on a pre-established plane such as an open or sawed joint are plotted as in Figure 93, a strength envelop of best fit of the points is obtained from which the coefficient of friction angle is determined. It is interesting to note that the angle of friction of sawed and natural joints are very similar (28 to 31 degrees), being only 3 degrees apart. The points plotted represent points of failure at all stages of confining pressure. Generally, there appears to be little difference between the angles of friction obtained from plots of the first stage and subsequent stages. Furthermore the coefficient of friction is fairly constant for the range of joint angles tested. This would indicate that the coefficient of friction is reasonably constant for this rock and unless the joint plane surfaces are extremely nonplanar small surface irregularities have very little effect in increasing the angle of friction. Small slickensides and granulation of mineral grains were developed on the joint plane surfaces.

22. The Mohr envelop for the intact rock was determined from the average strengths of a group of 5 cores for each confining pressure and includes the averages of those tested in tension and unconfined compression. Since the rock cores with well-healed joints behaved as intact rock when tested in triaxial compression,
their results have been included with this group. Joints healed with quartz and feldspar appeared to be as strong as the intact rock, while those filled primarily with pyrite are somewhat weaker. For the three confining pressures used the strength envelop shows a coefficient of internal friction angle of about 56 degrees and a cohesive strength of about 3,600 psi. The envelop tends to be practically a straight line but becomes slightly curved when fitted to the unconfined compression and tensile strength values. A straight line projection in this area of the curve indicates a tensile strength of around 2,500 psi. This more nearly checks the value of 2,353 psi shown by Core No. 51.

23. Generally the observed shear angles approach those determined from the formula $45^\circ + \frac{\beta}{2}$ (73 degrees) with only a few degrees difference. In most cases, the measured shear plane angles of the unconfined compression tests show the greatest variation, about 7 degrees less than the computed values. It was only with the confining pressure of 1,350 psi that the core specimens tended to shear along a single plane without vertical tension fractures. For the most part, the test results appear to fit Mohr's criterion quite well.

**Core Specimen Description:**

Quartz Monzonite, light gray, porphyritic with a medium-grained groundmass. A few feldspar phenocrysts of 3/4-in. length occur in the end sections of the core specimen.

In triaxial compression, the core broke partially in shear, but mostly with vertical tension fractures. The dashed portion of the stress-strain curve is shown to indicate that the strength of the rock exceeded the yield strength of the steel used in the triaxial apparatus.

Core Specimen Description:
Quartz Monzonite, light gray, porphyritic with fine to medium-grained groundmass. Two large (1½ to 2½-in.) crystals of pink feldspar occur in the central section of the core specimen.

In triaxial compression, the core broke predominantly in shear at about 70 degrees from the horizontal. The large feldspar crystals probably affected the breaking characteristics of the core.

Core Specimen Description:
Quartz Monzonite, light gray, fine to medium-grained, with a few large (1/2 to 1-in.) crystals of pink feldspar. There is a distinct textural change which occurs irregularly along the long axis of the core in which part of the rock is medium-grained with much scattered flakes of biotite, whereas the other portion is finer grained with less biotite. The large feldspar phenocrysts occur in the fine-grained portion. This probably represents a contact zone of the quartz monzonite with the granodiorite.

In triaxial compression, the core broke partially in shear, but mostly with vertical tension fractures.

Approximate Rate of Strain, 0.001 in./min.

Core Specimen Description:
Quartz Monzonite, light gray, porphyritic with fine-grained groundmass. No large feldspar crystals were present in the core. A natural open joint with a rough but planar surface dips at about 54 degrees.

In triaxial compression, multi-stage, the core slid on the joint plane. Slight granulation of mineral grains and faint slickensides were developed along parts of the joint plane surfaces.

Core Specimen Description:

Quartz Monzonite, light gray, porphyritic with medium-grained groundmass. Two large feldspar crystals of 1 in. length occur in the central section of the core specimen. A natural open joint with a rough, wavy surface dips at about 59 degrees.

In triaxial compression, multi-stage, the core slid on the joint plane with slight granulation of mineral grains. Slickensides were not well developed because of surface irregularities.

Core Specimen Description:
Quartz Monzonite, light gray, porphyritic with medium-grained groundmass. No large crystals of feldspar were evident. The core specimen contained an open joint lined with quartz, feldspar, and calcite with a small amount of chlorite. This joint dipped at about 50 degrees from the horizontal.

In triaxial compression, multi-stage, the core slid along the joint plane with much granulation of the joint lining material. Slickensides developed on the joint plane surfaces.

Core Specimen Description:
Quartz Monzonite, light gray, porphyritic with fine-to-medium-grained groundmass. One large feldspar crystal of 1\(\frac{1}{4}\)-in. length occurs within an end section of the core specimen.

In triaxial compression, multi-stage, the core split on the sawed joint which dipped at 45 degrees. Slight granulation of mineral grains and faint slickensides were observed along the joint plane surfaces.

Core Specimen Description:

Quartz Monzonite, light gray, porphyritic with fine-grained groundmass. One large pink feldspar crystal of 1/2-in. length occurs in an end section of the core specimen.

In triaxial compression, multi-stage, the core slid on the sawed joint which dipped at 55 degrees. Slight granulation of mineral grains and faint slickensides were noted along the joint plane surfaces.

Approximate Rate of Strain, 0.001 in./min.

Core Specimen Description:
Quartz Monzonite, light gray, porphyritic with medium-grained groundmass. Several large feldspar crystals of 3/4-in. length occur near one end of the core specimen.

In triaxial compression, multi-stage, the core slid on the sawed joint which dipped at 62 degrees. Slight granulation of mineral grains and faint slickensides were observed along the joint plane surfaces.
