DISJOINT COMMON
PARTIAL TRANSVERSALS OF
TWO FAMILIES OF SETS
D. R. Fulkerson

This research is supported by the United States Air Force under Project RAND. Contract No. F16209-67-C-0015, monitored by the Directorate of Operational Requirements and Development Plans, Deputy Chief of Staff, Research and Development, Hq USAF. Views or conclusions contained in this study should not be interpreted as representing the official opinion or policy of the United States Air Force.

DISTRIBUTION STATEMENT
This document has been approved for public release and sale; its distribution is unlimited.
This study is presented as a competent treatment of the subject, worthy of publication. The RAND Corporation endorses the quality of the research, without necessarily endorsing the opinions and conclusions of the authors.

Published by The RAND Corporation
The theory of flows in capacity-constrained networks has been a useful tool in the study of a variety of combinatorial problems. Another application of this kind is discussed in this Memorandum, which continues RAND's basic work on topics in combinatorial mathematics. Earlier relevant RAND publications include:

The specific problem treated in this Memorandum is that of finding necessary and sufficient conditions in order that two finite families of subsets of a finite set possess $k$ mutually disjoint common partial transversals, each of prescribed size $p$. A more general problem, mentioned but not solved in the paper, is that of characterizing the blocking matrix of the incidence matrix of all common partial transversals, of size $p$, of two finite families of subsets of a finite set.
SUMMARY

The theory of flows in networks is applied to obtain necessary and sufficient conditions on two finite families of subsets of a finite set in order that there exist $k$ mutually disjoint common partial transversals, each of size $p$, of the two families.

DISJOINT COMMON PARTIAL TRANSVERSALS OF
TWO FAMILIES OF SETS

1. Introduction. Let $\mathcal{A} = (A_i : i \in I)$ and $\mathcal{B} = (B_j : j \in J)$ be two families of subsets of a finite set $E$, the cardinalities $|I|$ and $|J|$ of the index sets $I$ and $J$ being assumed finite also. A subset $P$ of $E$, with $|P| = p$, is a partial transversal (of size $p$) of the family $\mathcal{A}$ if there is a one-one mapping $\psi$ from $P$ into $I$ such that $e \in A_{\psi(e)}$ for all $e \in P$. If $P$ is a partial transversal of $\mathcal{A}$ and also of $\mathcal{B}$, then $P$ is a common partial transversal of $\mathcal{A}$ and $\mathcal{B}$. A partial transversal of $\mathcal{A}$ of size $p = |I|$ is a transversal of $\mathcal{A}$, and, if $|I| = |J|$, a common partial transversal of $\mathcal{A}$ and $\mathcal{B}$ of size $p = |I|$ is a common transversal of $\mathcal{A}$ and $\mathcal{B}$.

In this note we show how the theory of flows in networks [3] can be used to solve a packing problem for common partial transversals, of prescribed size $p$, of the families $\mathcal{A}$ and $\mathcal{B}$. Specifically, we answer the question: What are necessary and sufficient conditions in order that there exist $k$ mutually disjoint common partial transversals, each of size $p$, of the two families $\mathcal{A}$ and $\mathcal{B}$?

2. A packing theorem. For the case $k = 1$ and $p = |I| = |J|$, the following theorem is known [3,4].
Theorem 2.1. The finite families \( \mathcal{A} = (A_i : i \in I) \) and \( \mathcal{B} = (B_j : j \in J) \) of subsets of the finite set \( E \), with \( |I| = |J| \), have a common transversal if and only if

\[
|I'| + |J'| - |I| \leq \bigcup_{i \in I'} A_i \cap \bigcup_{j \in J'} B_j
\]

holds for all \( I' \subseteq I, J' \subseteq J \).

The inequalities (2.1) can be generalized in a simple way to provide an answer to the question posed above. This generalization is described below in Theorem 2.2 (ii); an equivalent set of conditions is provided by (iii) of Theorem 2.2. To state (iii), we use the notation, for \( E' \subseteq E \):

\[
\#(\mathcal{A}, E') = |\{ i \in I : e_i \in A_i \text{ for some } e \in E' \}|.
\]

In words, \( \#(\mathcal{A}, E') \) is the number of members of the family \( \mathcal{A} \) represented by elements of \( E' \).

Theorem 2.2. Let \( \mathcal{A} = (A_i : i \in I) \) and \( \mathcal{B} = (B_j : j \in J) \) be finite families of subsets of the finite set \( E \). Then the following statements are equivalent.

(i) There exist \( k \) mutually disjoint common partial transversals, each of size \( p \), of \( \mathcal{A} \) and \( \mathcal{B} \).

(ii) The inequality

\[
k|p - \left(|I - I'| + |J - J'|\right)| \leq \bigcup_{i \in I'} A_i \cap \bigcup_{j \in J'} B_j
\]

holds for all \( I' \subseteq I, J' \subseteq J \).
The inequality
\[(2.4) \quad k[p-(\#(E',E) + \#(E'''))] \leq |E-(E'\cup E'')|\]
holds for all \(E' \subset E, E'' \subset E\).

We defer the proof of Theorem 2.2 to Section 4, following the discussion in Section 3 of a certain decomposition theorem for network flows that will be needed in the proof. Here we note only that it is enough to state (2.4) for all disjoint subsets \(E', E''\) of \(E\), since this yields an equivalent set of conditions.

3. Flows and matching flows. Let \(f\) be an integral flow from a set \(S\) of sources to a set \(T\) of sinks in a (directed) network having node set \(N\). Thus \(S\) and \(T\) are disjoint subsets of \(N\), and
\[
(3.1) \quad f(x,N) - f(N,x) = \begin{cases} a(x), x \in S, \\ -b(x), x \in T, \\ 0, x \in N- (S \cup T), \end{cases}
\]
\[
(3.2) \quad f(x,y) \geq 0, (x,y) : N \times N.
\]
Here \(a(x), x \in S,\) and \(b(x), x \in T,\) are nonnegative integers, and \(v = a(S) = b(T)\) is the size (or amount) of the flow \(f\).

(We are using the notation of \([3]\), e.g. \(f(x, N) = \sum_{y \in N} f(x, y)\), and \(a(S) = \sum_{x \in S} a(x).\))

If \(a(x) = 0\) or 1 for all \(x \in S,\) and \(b(x) = 0\) or 1 for all \(x \in T,\) we say that \(f\) is a matching flow from \(S\) to \(T.\)
An integral flow from $S$ to $T$ of amount $v$ can be decomposed into a sum of an integral cyclic flow, or circulation, (all right-hand sides zero in (3.1)), and $v$ unit chain-flows, where each chain begins at a node of $S$ and ends in a node of $T$ [3]. In particular, if $f$ is a matching flow, the chain-flows in such a decomposition induce a matching between those nodes $x \in S$ such that $a(x) = 1$ and those nodes $x \in T$ such that $b(x) = 1$, by pairing first and last members of each chain. (Several different matchings can result in this way, since the decomposition of $f$ need not be unique.) This justifies calling $f$ a matching flow.

For the proof of Theorem 2.2, we shall be interested in decomposing an arbitrary integral flow from $S$ to $T$ into a sum of matching flows, each of the same size.

**Theorem 3.1.** Let $f$ be an integral flow from $S$ to $T$ of size $v = a(S) = b(T)$, and let

$$m = \max (\max_{x \in S} a(x), \max_{x \in T} b(x)).$$

Then $f$ decomposes into a sum of $k$ matching flows, each of size $p$, if and only if $v = kp$ and $m \leq k$.

**Proof.** Necessity is clear. To prove sufficiency, we can proceed as follows. Decompose $f$ into the sum of a cyclic flow and $v$ unit chain-flows from $S$ to $T$. Use the chains in this decomposition to construct a bipartite graph $G$ having node parts $S$ and $T$ by inserting an edge in $G$ joining first
and last nodes in each chain. In general, G will have multiple edges joining the same vertices, but in any event, G has \( v = kp \) edges and the maximum valence in G is \( m \). By a theorem of Dulmage and Mendelsohn [1], G has a matching consisting of \( \lceil \frac{V}{m} \rceil \) edges that hits all nodes of valence \( m \), i.e. each node of valence \( m \) is incident with some edge of the matching. (This theorem can also be derived using flows in networks [2].) One can use this fact and induction on \( k \) to show that G decomposes into a sum of \( k \) matchings, each containing \( p \) edges, as follows. The case \( k = 1 \) is trivial. Assume the assertion for \( k - 1 \) and consider \( k \).

If \( m < k \), then G has a matching \( M \) containing \( p = \frac{V}{k} \leq \lceil \frac{V}{m} \rceil \) edges. Moreover, the graph \( G-M \) has \( kp - p = p(k-1) \) edges and maximum valence at most \( k-1 \). If \( m = k \), then G has a matching \( M \) containing \( \lceil \frac{V}{m} \rceil = p \) edges that hits all nodes of valence \( k \), and thus again \( G-M \) has \( p(k-1) \) edges and maximum valence \( k-1 \). Hence, by the induction assumption, G decomposes into a sum of \( k \) matchings, each having \( p \) edges. It follows that \( f \) decomposes into a sum of \( k \) matching flows, each of size \( p \).

4. Proof of Theorem 2.2. Using the families \( \mathcal{G} \) and \( \mathcal{Q} \), construct the flow network with source \( s \) and sink \( t \) shown below:

</tr>
</tbody>
</table>

![Diagram of directed graph with nodes $s$, $t$, $S$, $R$, $R'$, $T$, and edges labeled with capacities $k$, $\infty$, and $1$.]
It follows from Theorem 3.1 that the families $\mathcal{S}$ and $\mathcal{T}$ have $k$ mutually disjoint common partial transversals of size $p$ if and only if there is an integral flow $f$ from $s$ to $t$ in this network of size $v = kp$ that satisfies the capacity constraints $f \leq c$ on all edges. By the max-flow min-cut theorem and the integrity theorem for network flows, such a flow exists if and only if all cuts separating $s$ and $t$ have capacities at least $kp$, i.e. if and only if

$$(4.1) \quad kp \leq c(X, N-X)$$

for all $X \subseteq N$ such that $s \in X$, $t \in N-X$. Let

$$
\begin{align*}
S \cap X &= U \\
S \cap (N-X) &= \bar{U} \\
R \cap X &= V \\
R \cap (N-X) &= \bar{V} \\
R' \cap X &= V' \\
R' \cap (N-X) &= \bar{V'} \\
T \cap X &= W \\
T \cap (N-X) &= \bar{W}
\end{align*}
$$

Then

$$(4.2) \quad c(X, N-X) = c(s, U) + c(U, V) + c(V, \bar{V'}) + c(V', \bar{W}) + c(W, t).$$

The inequality (4.1) holds automatically unless the sets of edges $(U, \bar{V})$ and $(V', \bar{W})$ are empty. Let

$$
\begin{align*}
B(\bar{V}) &= \{x_i \in S \mid (x_i, y_e) \text{ is an edge for some } y_e \in \bar{V}\} \\
A(V') &= \{z_j \in T \mid (y'_e, z_j) \text{ is an edge for some } y'_e \in \bar{V}'\}
\end{align*}
$$

Then $(U, \bar{V})$ is empty if and only if $B(\bar{V}) \subseteq \bar{U}$, and $(V', \bar{W})$ is empty if and only if $A(V') \subseteq \bar{W}$. Thus (4.2) is,
if anything, decreased by taking $\bar{U} = B(\bar{V})$, $W = A(V')$.

Consequently (4.1) holds if and only if

$$\text{(4.3) } kp \leq k|B(\bar{V})| + k|A(V')| + c(V, V')$$

holds for all $V \subseteq R$, $V' \subseteq R'$. Translating (4.3) into the notation of Section 2 yields (2.4) as a necessary and sufficient condition for the existence of $k$ mutually disjoint common partial transversals, each of size $p$, of $\tau$ and $\sigma$.

Condition (2.3) can be derived from (4.1) in a similar way.

A corollary of Theorem 2.2 is the following formula for the maximum number $k(p)$ of mutually disjoint common partial transversals, of size $p$, of two families $\tau$ and $\sigma$:

$$\text{(4.4) } k(p) = \min_{E' \subseteq E, E'' \subseteq E} \left[ \frac{|E-(E' \cup E'')|}{p-\#(\tau, E') - \#(\sigma, E'')} \right]$$

where the minimum in (4.4) is taken over all disjoint subsets $E'$, $E''$ of $E$ such that the denominator is positive.

Theorem 2.2 can be viewed as a generalization of the main result in [5], which gives necessary and sufficient conditions in order that a $p$ by $n$ $(0,1)$-matrix $A = (a_{ij})$, with $p \leq n$, can be written as a sum

$$\text{(4.5) } A = P_1 + \cdots + P_k + R,$$

where each $P_i$ has exactly one 1 in each row and at most
one 1 in each column. To see this, let \( I = \{1, \ldots, p\}, J = \{1, \ldots, n\} \), and define \( E = \{(i, j) \in I \times J | a_{ij} = 1\} \),
\( A_i = E \cap \{i\} \times J \), \( i \in I \), \( B_j = E \cap \{1 \times \{j\}\} \), \( j \in J \). Then a permutation matrix \( P \) in the decomposition (4.5) corresponds to a common partial transversal of size \( p \) of the families \( \mathcal{A} = (A_i : i \in I) \) and \( \mathcal{B} = (B_j : j \in J) \), and Theorem 2.2 reduces to the result of [5] mentioned above.

Theorem 2.2 also gives some information on the following maximum packing problem. Let \( A \) be the \((0,1)\)-incidence matrix of all common partial transversals of size \( p \) of two families \( \mathcal{A} \) and \( \mathcal{B} \) of subsets of \( E \), where the rows of \( A \) correspond to the common partial transversals and the columns of \( A \) correspond to members of \( E \). Associate a weight \( w(e) \geq 0 \) with each \( e \in E \), and ask for a solution vector \( y \) to the linear program

\[
\begin{align*}
yA & \leq w \\
y & \geq 0 \\
\max l \cdot y,
\end{align*}
\]

where \( 1 = (1, \ldots, 1) \). If \( w(e) = 1 \) all \( e \in E \), and if we restrict \( y \) to be a \((0,1)\)-vector in (4.6), then the formula (4.4) is applicable. That is, \( k(p) \) in (4.4) is then equal to \( \max l \cdot y \) in (4.6). The case \( w(e) = 0 \) or 1 can be treated in this fashion also. Knowing how to solve the linear program (4.6) is tantamount to knowing the blocking matrix \( B \) for the incidence matrix \( A \) [6]. But the general maximum packing problem (4.6) does not seem to be amenable to the network flow approach used in this note.
REFERENCES

An application of the theory of flows in networks to obtain necessary and sufficient conditions in order that two finite families of subsets of a finite set possess $k$ mutually disjoint common partial transversals, each of prescribed size $p$.
