Proof Techniques for Recursive Programs

Jean Vuillemin

Abstract

The concept of least fixed-point of a continuous function can be considered as the unifying thread of this dissertation.

The connections between fixed-points and recursive programs are detailed in Chapter 2, providing some insights on practical implementations of recursion. There are two usual characterizations of the least fixed-point of a continuous function. To the first characterization, due to Knaster and Tarski, corresponds a class of proof techniques for programs, as described in Chapter 3. The other characterization of least fixed points, better known as Kleene's first recursion theorem, is discussed in Chapter 4. It has the advantage of being effective and it leads to a wider class of proof techniques.

Acknowledgments

First of all, I am grateful to Dana Scott, Robin Milner, and David Park who, by their respective works, made this thesis possible. I am deeply indebted to:

Donald Knuth for his reading of the manuscript; his criticisms of Chapter 2 led to rewarding improvements in the generality of the results.

Zohar Manna for his constant encouragement and help; he has been a model adviser throughout my work.

Robin Milner for all the things I learned from him, and the many interesting discussions we had.

I also want to thank my friends Jean Marie Cadou, Ashok Chandra, Cyril Grivet, Gilles Kahn, Lockwood Morris, Steve Ness, Mark Smith, and Phyllis Winkler who all helped me in their many different ways.

Introduction

The goal of this work was to study and hopefully compare in a precise way the various techniques for proving properties of programs existing in the literature. It soon turned out that nothing interesting could be said if one did not state precisely what the various methods really are within a common logical system. A perfectly adequate system for doing so was the Logic for Computable Function of Milner [18], which is based on the work of Scott [29] and [30].

In this framework, proof techniques fall rather nicely into two classes: for the first class, which includes the methods of Burstall [1], Floyd [7], Hoare [9], Manna-Pnueli [16], the semantics needed for validating the techniques only demand that programs be interpreted as monotone functions in the sense of Scott [29]; for methods in the second class, such as those of Scott [30] and Morris [23], programs must be interpreted as continuous functions.

The methods in the second class are then "more powerful" in that they can be used for justifying the other techniques; furthermore, provided that all methods are expressed within the same logical system, we can exhibit properties of programs which are provable with the proof-techniques in the second class, and not provable with the techniques in the first class, and not vice-versa.

Before studying the various proof techniques, we present a minimal background in Scott's Theory of Computation in Chapter 1. One of the points of the theory which we thought needed clarification was the relations between the abstract notion of least fixed-point and the
concrete notion of trace of a program. Chapter 2, which is the most original part of this thesis, is devoted to this question. We believe that Theorems 1, 3 and 4 are new while Theorem 2 is a generalization of a result by Cadiou [2].

In Chapter 3, we study the proof-technique in the first class. The formal system used is original, although a mere adaptation of Milner's LCF to a different semantic domain. Reduction of the proof techniques presented to the rule of fixed-point induction are due to Park [26].

In Chapter 4, we describe reductions of some methods to the rule of induction of Scott [30]; some of these reductions are also used, implicitly or explicitly in deBakker-Scott [6], Scott [30], Milner [18], and Milner-Weyrauch [21].
Chapter 1. SCOTT'S THEORY OF COMPUTATION

In this chapter, we shall present an overview of Scott's theory of computation, whose goal was to give a "mathematical" as opposed to "operational" semantics for high-level programming languages. Only the parts of the theory which are relevant to this dissertation will be described. In particular, one of Scott's most impressive achievements was to construct a model for the $\lambda$-calculus, which in turn provides a mathematical semantics for programming peculiarities such as self-modifying machine codes or procedures taking other procedures as arguments. We shall not concern ourselves with this problem, and the kind of procedure we are willing to consider has a definite type -- a function from individuals to individuals, or a functional from functions to functions, etc. Limited as it is, the theory that we shall describe is nevertheless powerful enough not only to describe the semantics of non-trivial subsets of any programming language, but also to justify all the existing proof techniques for those languages. The presentation of this chapter, whose only purpose is to make the thesis more or less self-contained, is based on Scott [29] except for some minor technical details.

We assume that the reader has some knowledge of elementary lattice and recursion theories.
1. **Data Types**

As a first step, let us consider some examples of what one would like to call data types:

(a) the boolean values **true** and **false**;
(b) the set of integers;
(c) the n-dimensional arrays of integers;
(d) the set of subsets of integers;
(e) the set of computable partial functions over some data-type;
(f) the set of non-negative real numbers.

Some of those sets contain as elements objects like total functions or irrational real numbers, which we shall call "infinite elements". They cannot be described entirely, but one can give better and better finite approximations to what they really are. For example, the intervals \([3,4]\), \([3.1,3.2]\), \([3.14,3.15]\), ... form a sequence of approximations of \(\pi\).

This suggests that data-types ought to be partially ordered sets. The notation \(x \subseteq y\) means that \(x\) approximates \(y\), and \(\subseteq\) must therefore be a reflexive, transitive and antisymmetric relation over the data-type. For example, if \(A\) and \(B\) are some subsets of the integers, \(A \subseteq B\) means that \(A\) is a subset of \(B\). Similarly, for any two intervals \([x,x']\) and \([y,y']\) of non-negative real numbers \([x,x'] \subseteq [y,y']\) will mean that \(x \leq y\) and \(y' \leq x'\), i.e., \([y,y']\) gives us a better idea of where the real number lies than \([x,x']\).

Considering now two integers \(k\) and \(l\), we do not wish to say that one is an approximation of the other. However, it may be the case that \(k\) is not explicitly known, but has to be determined as
the result of some computation. As we all know, this computation may
never terminate, in which case \( k \) is said to be undefined; we denote
this by \( k = \text{UU} \) and clearly \( \text{UU} \sqsubseteq t \) for any \( t \). We use a different
equality sign " \( = \) " in order to avoid confusion with the regular
equality " \( = \) " over the integers. Here, \( x = y \) means that \( x \sqsubseteq y \)
and \( y \sqsubseteq x \), while \( x = y \) is true whenever \( x \) and \( y \) are the same
integer. For example, \( 1 = 1 \) and \( 1 = 1 \) are both true, while \( \text{UU} = 1 \)
is false and \( \text{UU} = 1 \) is undefined. To be precise, one should write
\((\text{UU} \sqsubseteq 1) = \text{UU} \sqsubseteq \text{B} \) where the subscripts are here to remind us that \( \text{UU} \)
is an undefined integer, while \( \text{UU} \sqsubseteq \text{B} \) is an undefined boolean.

To clarify those ideas, it is helpful to describe more precisely
the partial orderings over our favorite data types.

(a) For the boolean values, the data type looks like \( \text{TT} \sim \text{UU} \sim \text{FF} \),
where \( \begin{array}{c}
\text{b} \\
\text{a}
\end{array} \) means that \( b \) covers \( a \), i.e., \( a \sqsubseteq b \) with \( a \neq b \)
and \( a \sqsubseteq c \sqsubseteq b \) for some \( c \) implies either \( a = c \) or \( c = b \).

(b) Although there are infinitely many integers, the corresponding
data type is not much richer:

\[ \begin{array}{c}
1 \\
2 \\
\vdots \\
\text{UU} \\
\text{n} \\
\vdots
\end{array} \]

Data types of this kind, where elements are either completely specified
or undefined will be called discrete.
(c) The data type of pairs of Boolean has already a richer structure:

\[
\begin{array}{c}
\langle \text{TT}, \text{TT} \rangle \\
\langle \text{TT}, \text{FF} \rangle \\
\langle \text{FF}, \text{TT} \rangle \\
\langle \text{FF}, \text{FF} \rangle \\
\langle \text{FF}, \text{UU} \rangle \\
\langle \text{UU}, \text{TT} \rangle \\
\langle \text{UU}, \text{FF} \rangle \\
\langle \text{UU}, \text{UU} \rangle \\
\text{UU}
\end{array}
\]

(d) In the data type of subsets of some set, \( A \subseteq B \) means that \( A \) is a subset of \( B \); the least element \( \text{UU} \) is the empty set.

(e) As indicated before, the elements of the data type of real numbers are closed intervals \([x, x']\) with \( 0 \leq x \leq x' \) and \([x, x'] \subseteq [y, y']\) whenever \( x \leq y \) and \( y \leq x' \). It is convenient to complete the real line with an element \( \infty \), thus allowing \([7.1, \infty]\) for example, to be a real number. The interval \([0, \infty]\) reflects a complete lack of information and should therefore be identified with the undefined real \( \text{UU} \).

(f) If \( \mathcal{B} \) is a data type partially ordered by \( \subseteq_{\mathcal{B}} \), the partial functions mapping \( \mathcal{B} \) into \( \mathcal{B} \) are ordered by:

\[
f \subseteq g \text{ iff } f(x) \subseteq_{\mathcal{B}} g(x) \text{ for all } x \text{ in } \mathcal{B}.
\]

The minimal element \( \text{UU}_{\mathcal{B}} \) is the partial function which is everywhere undefined, i.e., \( \text{UU}(x) = \text{UU} \) for all \( x \) in \( \mathcal{B} \).

**Infinite Elements as Limits**

Let us contemplate again the sequence

\([3, 4], [3.1, 3.2], [3.14, 3.15], \ldots\) \( \ldots\). We would like to be able to
define \( n \) as the "limit" of these intervals. Abstractly, this will require that any chain*:

\[
x_0 \subseteq x_1 \subseteq \cdots \subseteq x_i \subseteq x_{i+1} \subseteq \cdots
\]

has a limit \( y \) in the data type \( \mathcal{D} \), which is the least-upper bound of the \( x_i \)'s, that is, \( x_j \subseteq y \) for every \( j \) and, for any \( z \) in the data type, \( x_j \subseteq z \) for every \( j \) implies \( y \subseteq z \). We write \( y = \bigcup_{i \geq 0} x_i \).

According to this notation, in the data-type of real numbers

\[
[1,2] = \bigcup_{i \geq 0} \left[ \frac{i}{i+1}, \frac{(2i+1)}{i} \right]
\]

and for sets of integers,

\[
\{ k \mid k \text{ is odd} \} = \bigcup_{i \geq 0} \{ 1, 3, \ldots, 2i+1 \}.
\]

Let us define the constant function \( \text{one} \) as \( \text{one}(x) = 1 \) for any integer \( x \), while \( \text{one}(\text{UU}) = \text{UU} \); this function can also be defined as a limit of partial functions

\[
\text{one} = \bigcup_{i \geq 0} [\lambda x. \text{if } x < i \text{ then } 1 \text{ else } \text{UU}].
\]

**Computability**

Asking that the infinite object \( \bigcup_{i \geq 0} x_i \) be computable will require that the \( x_i \) themselves be computable. We therefore postulate the existence of an effectively given subset \( E \) of the data type \( \mathcal{D} \), such that any element of \( \mathcal{D} \) is the limit (not necessarily effective) of some chain of elements of \( E \). Such a set \( E \) will be called a recursive basis of \( \mathcal{D} \). For example, a data-type in which there are no infinite ascending chains (booleans, integers, arrays) is its own recursive basis.

---

* Strictly speaking, we only need denumerable chains to have a limit. However, when data-types have a denumerable basis (see below), requiring that countable chains have limits implies that any chain (and in fact directed set) also has a limit.
basis provided that it is recursive. The finite sets of integers constitute a basis for the set of subsets of the integers. Similarly, the set of functions which are undefined for all but a finite number of arguments is a basis for the data type of partial functions. Finally, a basis for the real numbers is the set of rational-end-point intervals.

We can remark that the recursive basis of a data type \( \mathfrak{B} \) must be denumerable. Consequently, all of its elements being obtained as limits of denumerable chains in the basis, \( \mathfrak{B} \) itself has at most a continuum number of elements. In particular, since there are at most denumerably many computable objects (i.e., objects defined as limits of effectively given chains), a non-denumerable data-type will possess many non-computable elements.

We can summarize the above discussion by the postulate

A data-type is a partially ordered set with a minimal element, possessing a recursive basis and in which every ascending chain has a limit.

Note: This notion of data-type is slightly different from the one advocated by Scott [29], namely that data-types ought to be complete lattices. The main technical reason for this choice was the difficulty which seems to arise for defining our notion of sequential function in Chapter 2, with complete lattices.
2. **Computable Functions over Data Types**

The next step is to consider programs as functions mapping data types into data types, and to derive some mathematical properties of such functions.

**Programs as Monotone Mappings**

Let \( f \) be a partial function computed by some program. Whenever the input \( x \) is less defined than the input \( y \), the output \( f(x) \) must be less defined than \( f(y) \), i.e., \( x \succeq y \) implies \( f(x) \succeq f(y) \). This motivates the hypothesis that functions computed by programs are monotonic mappings over the data type.

**Examples**

— The successor function \( \lambda x. x+1 \) over the integers is monotone if we choose \( \text{UU+1} = \text{UU} \).

— The conditional \( \text{if } p \text{ then } x \text{ else } y \) where

\[
\begin{align*}
\text{if } \text{UU} \text{ then } x \text{ else } y &= \text{UU} \\
\text{if } \text{TT} \text{ then } x \text{ else } y &= x \\
\text{if } \text{FF} \text{ then } x \text{ else } y &= y
\end{align*}
\]

is monotone with respect to \( p \), \( x \) and \( y \). (A function of several variables is monotone when it is monotone in each of its arguments.)

— As for sets, the functions \( A \cup B \) and \( A \cap B \) are both monotone in \( A \) and \( B \).

— The following definition of division over the reals makes it a monotone function:
\[ [x, y] / [x', y'] = \left[ \frac{x}{y'}, \frac{y}{x'} \right] \text{ where } \]
\[ \frac{x}{\infty} = 0 \text{ and } \frac{y}{\infty} = 0 \text{ for all } x \in [0, \infty) . \]

Programs as Continuous Mappings

As it stands now, the theory is already quite adequate for expressing and proving properties of programs, and Chapter 3 describes some results which can be derived from the assumption that mappings between data-types are monotone functions.

However, we are still missing an essential property of computable functions. Knowing the values of a monotone function over the basis of a data-type does not determine in general its values over the data-type. For example, the function

\[
\text{funny-union}(A, B) = \begin{cases} 
A \cup B & \text{if } A \text{ or } B \text{ is finite} \\
\mathbb{N} & \text{if } A \text{ and } B \text{ are infinite}
\end{cases}
\]

where \( A \) and \( B \) are two subsets of \( \mathbb{N} \), is monotone but clearly not computable.

Intuitively, the value \( f(x) \) of a computable function \( f \) at an infinite object \( x \) should be obtained as the limit of the values \( f(x_i) \) over the finite approximation \( x_i \) of \( x \). More precisely, let us consider an arbitrary chain

\[ e_0 \equiv e_1 \equiv \cdots \equiv e_n \equiv e_{n+1} \equiv \cdots \]

of elements in the basis of the data type. Since \( f \) is monotone, the set \( \{ i \geq 0 \mid f(e_i) \} \) is also a chain

\[ f(e_0) \equiv f(e_1) \equiv \cdots \equiv f(e_n) \equiv f(e_{n+1}) \equiv \cdots \]
and the computability of $f$ demands that

$$f(\bigcup_{n>0} e_n) = \bigcup_{n>0} f(e_n)$$  \hspace{1cm} \text{(a)}$$

A monotone function satisfying equation (a) for arbitrary chains will be called continuous. We shall therefore postulate that

**Computable functions are continuous mappings between data-types.**

Again, a function of several arguments is continuous if it is continuous in each of its arguments.

**Examples**

— The function $[\lambda p,x,y. \text{if } p \text{ then } x \text{ else } y]$ is continuous. Addition of two integers, union of two sets, division of reals are also continuous operations. The functional $[\lambda F.[\lambda x. \text{if } x = 0 \text{ then } 1 \text{ else } x.F(x-1)]]$ over the data-type of natural numbers is continuous, both in $F$ and in $x$.

— Let us define the mappings $\exists x \ p(x)$ and $\forall x \ p(x)$ which associate a boolean to each function $p$ from natural numbers to booleans as follows:

- $\exists x \ p(x)$ is equal to $\text{TT}$ if $p(n) = \text{TT}$ for some natural number $n$ and equal to $\text{UU}$ otherwise.

- $\forall x \ p(x)$ is equal to $\text{TT}$ if $p(n) = \text{TT}$ for all natural numbers $n \neq \text{UU}$ and equal to $\text{UU}$ otherwise.

We shall verify that $[\lambda p. (\exists x)p(x)]$ is continuous while $[\lambda p. (\forall x)p(x)]$ is monotone but not continuous in general. Let $p_0 \leq \ldots \leq p_1 \leq p_{i+1} \leq \ldots$
be a chain of partial predicates over the natural numbers. We easily verify that \((\bigcup_{i \geq 0} p_i(x)) = \bigcup_{i \geq 0} (p_i(x))\). Now, if \((\bigcup_{i \geq 0} p_i)(x) = \bigcup_{i \geq 0} p_i(x) = \text{TT}\) for some \(x\), there must exist an \(i_0\) such that \(i \geq i_0\) implies \(p_i(x) = \text{TT}\); otherwise, either \((\bigcup_{i \geq 0} p_i)(x) = \text{FF}\) and again there is an \(i_0\) such that \(p_{i_0}(x) = \text{FF}\) or \((\bigcup_{i \geq 0} p_i)(x) = \text{UU}\) and \(p_i(x) = \text{UU}\) for all \(i\). In all cases we have \((\exists x)(\bigcup_{i \geq 0} p_i(x) = \bigcup_{i \geq 0} (\exists x)p_i(x)\) and \(\exists\) is indeed continuous. One shows that \(\forall\) is monotone in a similar way and the chain \(p_i(x) = (x < i)\) provides a counterexample to the continuity of \(\forall\).

Let us now discuss some properties of continuous functions. First of all, it is possible to define a topology over data-types such that a function is continuous in the above sense if and only if it is continuous in the topological sense (see Scott [31]). Without describing the topology, we can nevertheless say that a subset \(X\) of the data-type \(B\) is directed if for all \(x, y \in X\), there exists a \(z \in X\) such that \(x \leq z\) and \(y \leq z\). Together with the existence of a denumerable basis for \(B\), the fact that continuous functions preserve limits of denumerable chains implies that continuous functions also preserve least-upper-bounds of directed sets. Continuous functions do not however preserve least-upper-bounds or greatest-lower-bounds (when they exist) of arbitrary sets.
3. **Fixed Points**

Let $f$ be a function over a data-type $\mathcal{D}$. We say that $x \in \mathcal{D}$ is a fixed-point of $f$ if $x = f(x)$; we say that $y$ is the least-fixed-point of $f$ if $y = f(y)$ and $y \preceq x$ for any other fixed-point $x$.

Note that, whenever it exists, the least-fixed-point of $f$ must be unique; we shall denote it either by $\mu x. f(x)$ or by $x_f$.

**Theorem (Kleene).** Any continuous function over a data-type $\mathcal{D}$ has a least-fixed-point $x_f$ and

$$x_f = \bigcup_{n \geq 0} f^n(\bot)$$

**Proof.** Here $f^n(\bot)$ means $f(f(...(f(\bot)))...)$ (n times) and, by monotonicity of $f$, the set $\{f^n(\bot)\}$ for $n \geq 0$ is indeed a chain. We first prove that $\bigcup_{n \geq 0} f^n(\bot)$ is a fixed point of $f$. This is easy since

$$f(\bigcup_{n \geq 0} f^n(\bot)) = \bigcup_{n \geq 0} f^{n+1}(\bot) = \bigcup_{n \geq 0} f^n(\bot)$$

by continuity of $f$.

We now prove that $\bigcup_{n \geq 0} f^n(\bot)$ must be minimal. Let $y$ be an arbitrary fixed-point of $f$, i.e., $y = f(y)$. It is easy to prove by induction that $f^n(\bot) \subseteq y$ for any $n$. The conclusion $\bigcup_{n \geq 0} f^n(\bot) \subseteq y$ follows immediately.

**Examples**

- In any data type, $\bot = [\mu y. y]$ and $x = [\mu y. x]$.

If $\tau = \lambda f. [\lambda x. \text{if } x = 0 \text{ then } 1 \text{ else } x.f(x-1)]$ and $\sigma = \lambda f. [\lambda x. \text{if } x > 100 \text{ then } x-10 \text{ else } f(f(x+11))]$ over the natural numbers,
then \( \tau^{n+1}(UU) = [\lambda x. \text{if } x \leq n \text{ then } x! \text{ else } UU] \)
and \( \sigma^{n+1}(UU) = [\lambda x. \text{if } x > 100 \text{ then } x-10 \)
\[ \quad \text{else if } x-100 \geq n \text{ then } 91 \text{ else } UU \] ;
therefore, \( f_\tau = [\lambda x. x!] \) and \( f_\sigma = [\lambda x. \text{if } x > 100 \text{ then } x-10 \text{ else } 91] \).

From these examples, the reader may already suspect that there must be a relation between recursively defined functions and least fixed points. The next chapter will be entirely devoted to this question.
Chapter 2.  FIXED-POINTS AND RECURSION

The object of this chapter is to detail the connections between fixed-points of continuous functionals and recursively defined functions in a very simple programming language. We first illustrate that the semantics of recursively defined functions will depend on the implementation. A careless implementation of recursion will introduce unnecessary computations, which may even prevent the program from terminating. A general criterion for the correctness of an implementation will be proved. We then describe an implementation of recursion which is both correct and optimal in a general class of sequential languages and therefore constitutes an attractive alternative to both "call by value" and "call by name".

1. Computations of Recursively Defined Functions

Before defining a computation rule, we must describe two programming languages, lang S and lang P. Although those two languages were chosen for their extreme simplicity, their use of recursion is as general as any, and the results of this chapter provide some insight into semantics and implementation of more complex programming languages.

Lang S permits only sequential computations, and corresponds precisely to a certain "typed" subset of Algol or LISP.

Lang P requires some parallel operations, and thus departs from more classical programming languages, although we could undoubtedly write an interpreter for lang P in any of those classical languages.
1.1 Description of \( \text{lang} \ S \) and \( \text{lang} \ P \)

Syntax

Both languages have the same syntax:

\[
\begin{align*}
\text{⟨program⟩} & := \text{P}(X_1, \ldots, X_n) \Leftarrow \langle \text{term} \rangle \\
\text{⟨term⟩} & := A_1 | A_2 | \ldots \\
& \mid X_1 | \ldots | X_n \\
& \mid G_1(\langle \text{term } 1 \rangle, \ldots, \langle \text{term } p_1 \rangle) \\
& \mid \ldots \\
& \mid G_k(\langle \text{term } 1 \rangle, \ldots, \langle \text{term } p_k \rangle) \\
& \mid F(\langle \text{term } 1 \rangle, \ldots, \langle \text{term } n \rangle) 
\end{align*}
\]

We limited ourselves to a single recursive equation, the extension of the results in this chapter to systems of mutually recursive equations being straightforward.

Here, \( A_1, A_2, \ldots, G_1, \ldots, G_k \) denote fixed constants and functions respectively. It is convenient to use a more standard syntax, e.g.,

\[
F(X) \Leftarrow \text{IF } X = 0 \text{ THEN } 1 \text{ ELSE } X \cdot F(X-1)
\]

instead of

\[
F(X) \Leftarrow G_1(P_1(X, A_0), A_1, G_2(X, F(G_3(X))))
\]

The meaning of a program will be a continuous mapping in

\[
[B_1^x \cdots x B_n^\beta - \beta]
\]

where each \( B_1 \) and \( \beta \) are some data-types; for simplicity, the \( B_1 \)'s will be identical to \( \beta \) unless explicitly specified.

Semantics of terms in \( \text{lang} \ P \)

The meaning of a \( \langle \text{term} \rangle \) is a (continuous) functional

\[
\lambda f \cdot \lambda x_1, \ldots, x_n \, \beta(\langle \text{term} \rangle)
\]

where the semantic function \( \beta \) is defined inductively as follows:

(i) \( \beta(A_1) = a_1 \) where \( a_1 \) \( \in \beta \)
(ii) \( J(X) = x_1 \)

(iii) \( J(g_k((\text{term } 1), \ldots, (\text{term } p_k))) = i_\beta(k, J((\text{term } 1)), \ldots, J((\text{term } p_k))) \)

where \( g_k \) is some continuous function in \([\beta^p_k - \beta]\).

(iv) \( J(F((\text{term } 1), \ldots, (\text{term } n))) = f(J((\text{term } 1)), \ldots, J((\text{term } n))) \).

Here we have to prove that this is continuous, i.e., that continuous functions are closed under composition, \(\lambda\)-abstraction and fixed-point operation. The reader can find these proofs either in Scott [50] or in Milner [19].

**Semantics of Terms in lang S**

The semantics of lang S is defined in precisely the same way as that of lang P, the difference lying in restrictions on the interpretation of base functions. In lang S, we require functions to be sequential, i.e., roughly that their arguments can be computed in sequence. We shall give later a precise definition of this notion. For expository purposes, however, we shall limit ourselves for the moment to studying a particular sequential language.

The data-types on which our particular lang S is computing are discrete, i.e., they look like:

\[
\beta: a_1 \ a_2 \ \ldots \ \ a_n \ \ \ldots \ \text{or} \ \ \beta: tt \ ff \\
\]

In what follows, we use \( w \) instead of \( uu_\beta \) and \( \Omega \) in place of \( uu_\beta \rightarrow \beta \) in order to help the eye avoid type confusions. Among the base functions, we point out a particular one, denoted IF-THEN-ELSE whose interpretation is the usual conditional, i.e., \( \text{if } uu \text{ then } x \text{ else } y = w \), \( \text{if } tt \text{ then } x \text{ else } y = x \), \( \text{and if } ff \text{ then } x \text{ else } y = y \).
All other base functions are required to be strict, i.e.,
\( g_i(\ldots, w, \ldots) = w \): they are undefined as soon as at least one of their arguments becomes undefined. They are meant to correspond to the "hardware" functions: \text{add}, \text{addone}, \text{test-for-equality}, \ldots .

It will be shown that all functions definable in \text{lang} S are sequential. The symmetric OR defined by the table:

<table>
<thead>
<tr>
<th>x</th>
<th>uu</th>
<th>tt</th>
<th>ff</th>
</tr>
</thead>
<tbody>
<tr>
<td>uu</td>
<td>uu</td>
<td>tt</td>
<td>uu</td>
</tr>
<tr>
<td>tt</td>
<td>tt</td>
<td>tt</td>
<td>tt</td>
</tr>
<tr>
<td>ff</td>
<td>uu</td>
<td>tt</td>
<td>ff</td>
</tr>
</tbody>
</table>

or the symmetric multiply \* where \(0* x = x * 0 = 0\) are not sequential, and are therefore not definable in \text{lang} S, nor in Algol for that matter.

Semantics of Programs in both \text{lang} S and \text{lang} F

The functional \( \tau = \lambda f. \lambda x_1, \ldots, x_n (\langle \text{term} \rangle) \) as defined in \text{lang} S or \text{lang} F can be shown to be continuous. It must therefore have a least fixed-point \( f_\tau \) and it would be nice to define the meaning \( M \) of the corresponding program as \( M(\langle \text{program} \rangle) = f_\tau . \)

This is unfortunately not true for all implementations of recursion, and our goal will be to characterize the implementations for which the computed function is equal to this least fixed-point.

1.2 Conventions and Notations

The reader has already noticed that syntactic entities are denoted by upper case letters, while the associated semantic objects are represented by the corresponding lower-case letters. We shall keep this convention throughout this chapter. For example, if \( T \) is the term
IF $X = 0$ THEN $1$ ELSE $X \cdot F(X-1)$, then its meaning $t$ is

$\lambda f. \lambda x \; \text{if} \; x = 0 \; \text{then} \; 1 \; \text{else} \; x \cdot f(x-1)$, where $=$ in this last expression

means the equality function over the natural numbers, $0$ the number $0$, etc.

From now on, we use upper case letters other than $A, D, X, F$ and $G$ to denote (syntactic) terms. If $T$ and $S$ are terms, we denote by $T[S/X_i]$ the result of replacing all occurrences of the letter $X_i$ by the term $S$ in $T$. By $T[P/F]$, we mean the term obtained by replacing in $T$ all subterms of the form $F(T_1, \ldots, T_n)$ by $P[T_1/X_1, \ldots, T_n/X_n]$. For example,

$$
\text{if} \quad T = G_1(F(X_1, F(X_1, X_2)), X_1) \quad \text{and} \quad P = G(F(X_2, X_1))
$$

$$
\text{then} \quad T[P/F] = G_1(G(G(F(G(X_2, X_1)), X_1)), X_1)
$$

Whenever we only wish to substitute $P$ for some occurrences of $F$ in $T$, we rename, say $F_1$, the occurrences that we shall substitute and $F_2$ the others. The result of the substitutions is then $T[P/F_1, F/F_2]$. The same kind of notation also applies to semantic terms.

We use $F(\bar{x})$ and $f(x)$ as abbreviations for $F(X_1, \ldots, X_n)$ and $f(x_1, \ldots, x_n)$ respectively.

Also, it will be convenient to consider only programs $F(\bar{x}) \leq P$ where $P$ is of the form $G(P_1, \ldots, P_p)$ with the additional restriction that each of the letters $F, X_1, \ldots, X_n$ occurs at least once in $P$. That is, $P$ is required not to ignore any of its program variables, to depend upon $F$ (i.e., to be recursive) and not to be of the uninteresting form $F(X) \leq F(T_1, \ldots, T_n)$. The main results of this chapter generalize without this restriction, but the proofs are made longer by an addition of special cases.
1.3 Computation Rule

A computation rule C is an algorithm for selecting some occurrences of the letter F in each term. For any such rule and input D, we construct the computation sequence T_0, T_1, ..., T_n, ... of the term T by the program F(\bar{x}) <= P as follows: T_0 = T[\bar{D}/\bar{x}] and T_{i+1} is the result of substituting P for the F's chosen by C in T_i. For example, if P = IF X < 2 THEN X ELSE F(X-1) + F(X-2), the computation sequence of F(X) according to "call-by-value" for input X = 2 is:

T_0 = F(2)
T_1 = IF 2 < 2 THEN 2 ELSE F(1) + F(0)
T_2 = IF 2 < 2 THEN 2 ELSE (IF 1 < 2 THEN 1 ELSE F(0) + F(-1)) + F(0)
T_3 = IF 2 < 2 THEN 2 ELSE (IF 1 < 2 THEN 1 ELSE F(0) + F(-1)) + IF 0 < 2 THEN 0 ELSE F(-1) + F(-2).

T_4 = T_5 = ... = T_3.

(Here, F(1) is in fact an abbreviation for F(2-1), etc.)

In T_n, we underline the F's selected by the computation rule for substitution. It is interesting to see precisely how the underlined F is selected in this last example. For this purpose, we must introduce the notion of simplification. The simplification mechanism is discussed at length in Cadiou [2], and we refer the interested reader to this work. In our particular example, it is possible to define a simplification mechanism \lambda T simpl(T) such that
\[
\begin{align*}
simpl(T_0) &= F(2) \\
simpl(T_1) &= F(1) + F(0) \\
simpl(T_2) &= 1 + F(0) \\
simpl(T_3) &= simpl(T_4) = \ldots = 1
\end{align*}
\]
(Note that now, \(F(1)\) is no longer an abbreviation since \(simpl(2-1) = 1\).)

The rule "call-by-value" then selects the leftmost-innermost occurrence of \(F\) in simplified terms. Similarly, "call-by-name" selects the "leftmost-outermost" one.

In its most general form, simplification can be an extremely powerful computation tool. For example, if our program is
\[
F(X) \Leftarrow \text{IF } X = 0 \text{ THEN } 0 \text{ ELSE } F(X-1)
\]
it is perfectly all right to use \(F(X) \rightarrow 0\) as a simplification rule over the natural numbers, and there is no room left for substitutions! Our purpose however is to study computations which are performed by substitutions and \textbf{not} by simplifications.

We must therefore restrict the power of simplifications which we allow, and, for this purpose, we merely borrow Cadiou's notion of \textbf{standard simplifications} (see Cadiou [2] for a precise definition). Roughly, standard simplifications force us to know everything about base functions, and nothing a priori about the recursively defined function \(F\), since simplifications of the type \(F(5) \rightarrow A_i\) are not permitted. In effect, we have to compute without any "built in" value of the recursively defined function, stored for example in memory from a previous computation.

We will not study standard simplifications in \texttt{lang} \(P\), since this would require describing completely the data-type on which computations...
are performed but we will describe them in \textit{lang S}.

For all constants $A_{i1}, \ldots, A_{ip}$ and base function $G_p$ there exists a standard simplification of the type

$$G_p(A_{i1}, \ldots, A_{ip}) \rightarrow A_j$$

In effect, this says that the values of the base-functions over the domain are known, and these functions are total. Accordingly, the conditional admits the simplifications

$$\text{IF TRUE THEN } B \text{ ELSE } C \rightarrow B$$

and

$$\text{IF FALSE THEN } B \text{ ELSE } C \rightarrow C$$

These are the only standard simplifications in \textit{lang S} and we say that a term is simplified when all of its subterms have been simplified.

### 1.4 Computation Lattice of a Program

Instead of considering computation sequences for each input and computation rule, we can apprehend the set of all possible computations in one infinite diagram.

For example, the computation diagram of the term $F(F(X))$ by the program $F(X) \leftarrow G(X,F(F(X)))$ looks like
A computation rule is then an algorithm for selecting a path in such a graph for each input. This computation diagram has a very rich structure which we shall now study.

**Computation of a term according to P**

We say that \( B \rightarrow C \) or simply \( B \rightarrow C \) whenever \( C \) can be obtained by substituting \( P \) for some occurrences of \( F \) in \( B \).

The notation \( B \overset{P}{\rightarrow} C \) or \( B \overset{P}{\rightarrow} C \) means that there exists a finite sequence of terms \( D_0, D_1, \ldots, D_m \) such that \( D_0 = B \), \( D_m = C \) and \( D_i \rightarrow P D_{i+1} \) for \( 0 \leq i < m \).

**Definition**

The computation diagram of \( T \) by \( P \) is the set of terms \( U \) such that \( T \overset{P}{\rightarrow} U \), partially ordered by \( \leq \) where \( B \leq C \) whenever \( B \overset{P}{\rightarrow} C \).

It is clear that \( \leq \) is reflexive and transitive. In order to prove that it is also antisymmetric, we notice that, if \( B \overset{P}{\rightarrow} C \), the size \( ||C|| \) (where size is, say the number of symbols) of the term \( C \) is strictly larger than the size of \( B \) if at least one substitution has been performed (this is due to our restriction on \( P \)). It follows that \( B \overset{P}{\rightarrow} C \) and \( C \overset{P}{\rightarrow} B \) implies \( B = C \).

Clearly, the computation diagram of \( T \) by \( P \) has the Church-Rosser property of the \( \lambda \)-calculus. (This follows from the work of Rosen [28] for example.) However, it also has a property which is not true of the \( \lambda \)-calculus, namely:
Theorem 1

The computation diagram of \( T \) by \( P \) is a lattice under the ordering \( \leq \), and we shall name it the computation lattice of \( T \) by \( P \).

Proof. */ In order to study the structure of the computation diagram of a term \( T_0 \) by a program \( P \), we need to relate the structure of \( C \) to that of \( B \) when \( B \rightarrow^* C \).

Lemma 1

(i) \( A_i \rightarrow^* C \) if and only if \( C = A_i \) and \( X_j \rightarrow^* C \) if and only if \( C = X_j \).

(ii) \( G_i(B_1, \ldots, B_{p_i}) \rightarrow^* C \) if and only if \( C = G_i(C_1, \ldots, C_{p_i}) \) and \( B_i \rightarrow^* C_i \) for \( 1 \leq i \leq p_i \).

(iii) \( F(B_1, \ldots, B_n) \rightarrow^* C \) if and only if \( C = F(C_1, \ldots, C_n) \) with \( B_i \rightarrow^* C_i \) for \( 1 \leq i \leq n \) or \( P[B_1/X_1, \ldots, B_n/X_n] \rightarrow^* C \).

Proof. Claims (i) and (ii) are easy and we only prove (iii).

If \( B = F(B_1, \ldots, B_n) \rightarrow^* C \) and \( C \) is not of the form \( F(C_1, \ldots, C_n) \), there must be a point in the computation \( B \rightarrow^* C \) where the outermost \( F \) of \( B \) is substituted, i.e., \( F(B_1, \ldots, B_n) \rightarrow^* F(B_1', \ldots, B_n') \rightarrow^* P[B_1'/X_1, \ldots, B_n'/X_n] \rightarrow^* C \) with \( B_i \rightarrow^* B_i' \) (and therefore \( B_i \rightarrow B_i'' \)) for any \( 1 \leq i \leq n \).

It follows from our definitions that \( B_i \rightarrow B_i'' \) for \( 1 \leq i \leq n \) implies \( P[B_1/X_1, \ldots, B_n/X_n] \rightarrow^* P[B_1'/X_1, \ldots, B_n'/X_n] \) and consequently \( P[B_1/X_1, \ldots, B_n/X_n] \rightarrow^* C \), as claimed in (iii). In order to get the

*/ I am grateful to Jean-Marie Cadiou for his help with this proof.
other part of the implication (iii), we simply notice that
\[ F(B_1, \ldots, B_n) = F[B_1/X_1, \ldots, B_n/X_n] \] by substituting \( P \) for the outer
\( F \) in \( F(B_1, \ldots, B_n) \).

**If** \( B \leq C \), **we can define a distance** \( \text{dist}(B, C) \) **between** \( B \) **and** \( C \)
**as follows:**

(i) if \( B = A_1 \) or \( B = X_j \) then \( C = B \) and \( \text{dist}(B, C) = 0 \);

(ii) if \( B = G_i(B_1, \ldots, B_{p_1}) \) then \( C = G_i(C_1, \ldots, C_{p_1}) \) with \( B_i \leq C_i \)
for \( 1 \leq i \leq p_1 \) and \( \text{dist}(B, C) = \max_{1 \leq j \leq p_1} \{ \text{dist}(B_j, C_j) \} \);

(iii) if \( B = F(B_1, \ldots, B_n) \) then (by Lemma 1), either \( C = F(C_1, \ldots, C_n) \)
and \( \text{dist}(B, C) = \max_{1 \leq i \leq n} \{ \text{dist}(B_i, C_i) \} \) or
\[ F[B_1/X_1, \ldots, B_n/X_n] \leq C \] and \( \text{dist}(B, C) = 1 + \text{dist}(F[B_1/X_1, \ldots, B_n/X_n], C) \).

It is easily seen that the distance between any two terms \( B \leq C \) is
finite.

**Lemma 2**

If \( B = F(B_1, \ldots, B_n) \), \( C = F(C_1, \ldots, C_n) \), \( B' = F[B_1/X_1, \ldots, B_n/X_n] \) and \( C' = F[C_1/X_1, \ldots, C_n/X_n] \) then \( B \leq C \) implies \( B' \leq C' \) and
\( \text{dist}(B', C') \leq \text{dist}(B, C) \).

**Proof.** By a straightforward induction on \( ||F|| \), one proves that
\[ \text{dist}(F[B_1/X_1, \ldots, B_n/X_n], F[C_1/X_1, \ldots, C_n/X_n]) \leq \max_{1 \leq i \leq n} \{ \text{dist}(B_i, C_i) \}, \]
hence \( \text{dist}(B', C') \leq \text{dist}(B, C) \).
We now start the proof of Theorem 1:

For any two terms \( B, C \) in the computation diagram of \( T \) by \( F \), we must show the existence of \( \min(B, C) \) and \( \max(B, C) \) such that

\[
\begin{align*}
\min(B, C) & \rightarrow B \leftarrow \neg \rightarrow C \\
\neg & \rightarrow \max(B, C) \leftarrow \neg
\end{align*}
\]

and for any \( Q \) and \( H \)

\[
\begin{align*}
Q \leq & \min(B, C) \\
\text{implies} \quad & \\
\max(B, C) \leq H
\end{align*}
\]

Existence of \( \max(B, C) \)

We shall describe an algorithm for computing \( \max(B, C) \) and then prove the correctness of this algorithm: let \( \sigma(B, C) \) be defined recursively as

(i) \( \sigma(B, B) = B \),

(ii) \( \sigma(G_i(B_1, \ldots, B_{p_i}), G_i(C_1, \ldots, C_{p_i})) = G_i(\sigma(B_1, C_1), \ldots, \sigma(B_{p_i}, C_{p_i})) \),

(iii) \( \sigma(F(B_1, \ldots, B_n), F(C_1, \ldots, C_n)) = F(\sigma(B_1, C_1), \ldots, \sigma(B_n, C_n)) \),

(iv) \( \sigma(F(B_1, \ldots, B_n), G(C_1, \ldots, C_p)) = \sigma(F(B_1/\lambda_1, \ldots, B_n/\lambda_n), G(C_1, \ldots, C_p)) \) =

\( \sigma(G(C_1, \ldots, C_p), F(B_1, \ldots, B_n)) \),

(v) in all the other cases, \( \sigma(B, C) \) yields an error symbol, (say a German gothic letter) which is not part of our set of letters.
We shall prove that \( \sigma(B,C) = \max(B,C) \) in two parts:

**Part 1.** For any terms \( T, B, C \)

\[
\begin{align*}
T^* & \rightarrow B^* \\
 & \quad \text{implies} \\
T^* & \rightarrow C^*
\end{align*}
\]

\[ B^* \rightarrow \sigma(B,C) \]

The proof is by induction on couples \( \langle \text{dist}(T,B) + \text{dist}(T,C), \|T\| \rangle \) ordered lexicographically by \( < \). Assuming the result to be true for all triples \( T', B', C' \) with \( \langle \text{dist}(T',B') + \text{dist}(T',C'), \|T'\| \rangle < \langle \text{dist}(T,B) + \text{dist}(T,C), \|T\| \rangle \), we prove it for \( T, B, C \) by a case analysis on the structure of \( T \).

**Case 1.** \( T = A_i \) or \( T = X_j \).

By Lemma 1, \( T \rightarrow^* B \) and \( T \rightarrow^* C \) implies \( T = B \) and \( T = C \); hence \( B = C = \sigma(B,C) \) and indeed \( B \rightarrow^* \sigma(B,C) \) and \( C \rightarrow^* \sigma(B,C) \).

**Case 2.** \( T = G_i(T_1, \ldots, T_{P_i}) \).

By Lemma 1, \( B = G_i(B_1, \ldots, B_{P_i}) \) and \( C = G_i(C_1, \ldots, C_{P_i}) \), with \( T_1 \rightarrow^* B_i \) and \( T_1 \rightarrow^* C_1 \) for \( 1 \leq i \leq P_i \). Since \( \text{dist}(T_1,B_1) + \text{dist}(T_1,C_1) \leq \text{dist}(T,B) + \text{dist}(T,C) \) and \( \|T_1\| < \|T\| \) for any \( 1 \leq i \leq P_i \), the induction hypothesis tells us that \( B_i \rightarrow^* \sigma(B_i,C_i) \) and \( C_i \rightarrow^* \sigma(B_i,C_i) \) for each \( 1 \leq i \leq P_i \). Regrouping everything, the conclusion \( B \rightarrow^* \sigma(B,C) \) and \( C \rightarrow^* \sigma(B,C) \) then follows from the definition

\[
\sigma(G_i(B_1, \ldots, B_{P_i}), G_i(C_1, \ldots, C_{P_i})) = G_i(\sigma(B_1, C_1), \ldots, \sigma(B_{P_i}, C_{P_i}))
\]

**Case 2.** \( T = F(T_1, \ldots, T_n) \).

By symmetry, we only need consider the subcases:
Case 3.1. \( B = F(B_1, \ldots, B_n) \) and \( C = F(C_1, \ldots, C_n) \).

The proof is similar to that of Case 2.

Case 3.2. \( B = F(B_1, \ldots, B_n) \) and \( C = G(C_1, \ldots, C_p) \).

Let \( T' = P(T_1/X_1, \ldots, T_n/X_n) \) and \( B' = P(B_1/X_1, \ldots, B_n/X_n) \).

By Lemma 1, we know that \( T' \rightarrow C \) and \( T_i \rightarrow B_i \) for \( 1 \leq i \leq n \), hence \( T' \rightarrow B' \). By Lemma 2, we know that \( \text{dist}(T', B') \leq \text{dist}(T, B) \). Since \( \text{dist}(T', C) < \text{dist}(T, C) \), we can apply the induction hypothesis to the terms \( T', B', C \), i.e., \( B' \rightarrow \sigma(B', C) \) and \( C \rightarrow \sigma(B', C) \). Since \( B \rightarrow B' \) and \( \sigma(B, C) = \sigma(B', C) \) by definition of \( \sigma \), we have established that \( B \rightarrow \sigma(B, C) \) and \( C \rightarrow \sigma(B, C) \).

Case 3.3. \( B = G(B_1, \ldots, B_p) \) and \( C = G(C_1, \ldots, C_p) \).

Let \( T' = P(T_1/X_1, \ldots, T_n/X_n) \). By Lemma 1, we know that \( T' \rightarrow B \) and \( T' \rightarrow C \). Since \( \text{dist}(T', C) < \text{dist}(T, B) \) and \( \text{dist}(T', C) < \text{dist}(T, C) \), we can use the induction hypothesis in order to get \( B \rightarrow \sigma(B, C) \) and \( C \rightarrow \sigma(B, C) \).

Part 2. For any terms \( B, C, Q \)

\[
\begin{align*}
B & \rightarrow^* Q \\
C & \rightarrow^* Q
\end{align*}
\]

Implies \( \sigma(B,C) \leq Q \).

The proof is by induction on \( \langle \text{dist}(B, Q) + \text{dist}(C, Q), ||Q|| \rangle \).

Case 1. \( Q = A_i \) or \( Q = X_j \).

Then \( Q = B = C = \sigma(B, C) \) and \( \sigma(B, C) \rightarrow Q \).
Case 2. \( Q = F(Q_1, \ldots, Q_n) \) or \( Q = G_i(Q_1, \ldots, Q_{p_i}) \) where \( G_i \) is not \( G \).

The proof goes mutatis-mutandis as that of Part 1, Case 2.

Case 3. \( Q = G(Q_1, \ldots, Q_p) \)

We only need consider the cases:

Case 3.1. \( B = G(B_1, \ldots, B_p) \) and \( C = G(C_1, \ldots, C_p) \).

Back to Case 2.

Case 3.2. \( B = F(B_1, \ldots, B_n) \) and \( C = G(C_1, \ldots, C_p) \).

Let \( B' = F[B_1/X_1, \ldots, B_n/X_n] \). Since \( \text{dist}(B', C) < \text{dist}(B, Q) \), we know by the induction hypothesis that \( \sigma(B', Q) = \sigma(B, C) \cdot Q \).

Case 3.3. \( B = F(B_1, \ldots, B_n) \) and \( C = F(C_1, \ldots, C_p) \).

Let \( B' = F[B_1/X_1, \ldots, B_n/X_n] \) and \( C' = F[C_1/X_1, \ldots, C_n/X_n] \).

The induction hypothesis tells us that \( \sigma(B', C') \cdot Q \). One then proves by induction on \( |P| \) that \( \sigma(B', C') = \sigma(P[B_1/X_1, \ldots, B_n/X_n], B_1/C_1, \ldots, C_n/X_n) = P[\sigma(B_1/C_1)/X_1, \ldots, \sigma(B_n/C_n)/X_n] \).

We conclude the proof by noticing that \( \sigma(B, C) = \sigma(B', C') \) since \( \sigma(B, C) = F(\sigma(B_1, C_1), \ldots, \sigma(B_n, C_n)) \cdot P[\sigma(B_1, C_1)/X_1, \ldots, \sigma(B_n, C_n)/X_n] = \sigma(B', C') \).

Existence of \( \min(B, C) \)

For any terms \( B, C \) in the computation diagram of \( T \) by \( P \) the set \( \{ L \mid L \leq B, L \leq C \} \) of lower bounds of \( B \) and \( C \) is not empty because \( T \leq B \) and \( T \leq C \) and it is finite. We know from elementary lattice theory that, if any two elements in a partially ordered set have a least-upper-bound, any non-empty finite subset also has a least-upper-
bound. We then define \( \min(B, C) \) as \( \max\{L \mid L \leq B, L \leq C\} \) and verify easily that \( \min \) has all the desired properties.

Relation Between the Computation Lattice and the Data-type of Continuous Functions over \( \mathcal{D} \)

In order to characterize computed partial functions in terms of the semantic interpretation of a given computation lattice, we notice that

**Lemma C**

For any terms \( B, C \) in the computation lattice of \( T \) by \( P \),

\( B \leq C \) implies \( b(\alpha) \leq c(\alpha) \).

**Proof.** The proof is straightforward by induction on \( ||B|| \):

- If \( B = A_i \) or \( B = X_j \) then \( B = C \) and \( b(\alpha) \equiv c(\alpha) \).
- If \( B = G_i(B_1, \ldots, B_{p_i}) \), then \( C = G_j(C_1, \ldots, C_{p_j}) \) and we know by induction that \( b_j(\alpha) \leq c_j(\alpha) \) for \( 1 \leq j \leq p_i \). Since \( [\lambda x_1, \ldots, x_{p_i}, G_i(x_1, \ldots, x_{p_i})] \) is monotone with respect to any of its arguments, \( b(\alpha) = g_i(b_1(\alpha), \ldots, b_{p_i}(\alpha)) \leq g_i(c_1(\alpha), \ldots, c_{p_i}(\alpha)) = c(\alpha) \).
- Finally, if \( B = F(B_1, \ldots, B_n) \) then \( b(\alpha) \equiv \alpha \leq c(\alpha) \).

In particular, to any computation sequence \( T_0 \rightarrow T_1 \rightarrow \ldots \rightarrow T_n \rightarrow T_{n+1} \rightarrow \ldots \) according to some rule \( C \) and input \( \bar{d} \), we associate the chain

\( t_0(\alpha)(\bar{d}) \leq t_1(\alpha)(\bar{d}) \leq \ldots \leq t_n(\alpha)(\bar{d}) \leq t_{n+1}(\alpha)(\bar{d}) \leq \ldots \)

The corresponding computed partial function \( c_p \) is therefore characterized as:

\[ c_p = \lambda \bar{d} \cup \bigcup_{n \geq 0} t_n(\alpha)(\bar{d}) . \]
From these definitions follows an easy generalization of a theorem of Cadiou [2]:

**Theorem 2 (Cadiou)**

Any fixed-point of the equation \( f = p(f) \) is an extension of any function computed by the program \( F \leq P \).

**Proof.** For any natural number \( m \), let \( F^n \) be defined as \( F^0 = P(X) \) and \( F^{n+1} = P[F^n/F] \). It is easily seen that \( p^i(\Omega) = p(p(...p(\Omega)...)) \) (\( i \) times). Since Cadiou [2] proved that for any computation sequence \( T_0, T_1, ..., T_n \) where \( T_0 = P(X) \) we have \( T_i \leq P^i \) for all natural numbers \( i \), it follows from Lemma C that \( t_i(\Omega) \leq p^i(\Omega) \) for all \( i \).

The function \( p \) being continuous, \( f_p = \cup_{i \geq 0} p^i(\Omega) \), hence \( t_i(\Omega) \leq f_p \) for any \( i \). It follows that \( C_p = \cup_{i \geq 0} t_i(\Omega) \leq f_p \) and, since \( f_p \leq f \) for any fixed-point \( f \) of \( p \), the conclusion \( C_p \leq f \) holds. \( \square \)
2. Correct Implementation of Recursion

In this section, we try to characterize the computation rules \( \mathbb{C} \) such that \( \mathbb{C}_p = \mathbb{F}_p \) for any program \( F \subseteq P \), called fixed-point computation rules.

Here are some computation rules we shall consider, both in lang \( S \) and lang \( F \):

1. **Call by value**: substitute for the leftmost-innermost occurrence of \( F \) after simplifications.
2. **Call by name**: substitute for the leftmost-outermost occurrence of \( F \) after simplifications.
3. **Parallel innermost**: substitute for the occurrences of \( F \) having all of their arguments free of \( F \)'s.
4. **Parallel outermost**: substitute for all the \( F \)'s which do not occur in any argument of another \( F \).
5. **Free argument**: substitute for all the occurrences of \( F \) having at least one of their arguments free of \( F \)'s after simplifications.
6. **Full substitution**: substitute for all the occurrences of \( F \).

2.1 Incorrect Computation Rules

**Proposition 1.**

In lang \( P \), the rules (1), (2), (3) and (5) are incorrect.

**Proof.** Consider the program \( F(X,Y) \triangleq \text{IF } X = 0 \text{ THEN } 0 \text{ ELSE } F(X+1,F(X,Y)) \times F(X-1,F(X,Y)) \) where \( \times \) is the parallel multiplication function \( 0 \times x = x \times 0 = 0 \). The least fixed-point over the integers
(considered as a discrete data-type) of the corresponding functional is the zero function $\lambda x, y \text{ if } x = w \text{ then } w \text{ else } 0$. The computation of $F(1,0)$ using (1), (2) or (3) is infinite. As for rule (5), we can take the program $F(X) \leq X \cdot F(F(X))$ in the data-type of sequences of letters as a counter-example.

Proposition 2 (Morris [23])

In lang $S$ the rules (1) and (3) are incorrect.

Proof. Consider $F(X,Y) \leq \text{IF } X = 0 \text{ THEN } 0 \text{ ELSE } F(X-1,F(X,Y))$. The corresponding least fixed-point over the non-negative integers is again the constant function 0 while the computation of $F(1,0)$ using rules (1) or (3) is infinite.

2.2 Safe Computation Rules

We now define the class of safe computation rules, and show that they correspond to "correct" implementations of recursion.

Let $C$ be a computation rule and $B$ an arbitrary term in the computation lattice of $T$ by $P$. In order to describe the effect of $C$ on $B$, we rename $F_1$ the occurrences of $F$ selected for substitution by $C$ in $B$ for some input $d$, and $F_2$ the others.

Definition

We say that $C$ is a safe computation rule if, for any term $B[F/F_1,F/F_2]$ in the computation lattice of $T$ by $P$ and for any input $d$, $b[\alpha/f_1,\alpha/f_2](d) = b[\alpha/f_1,\alpha/f_2](d)$. 
Intuitively, the computation is safe if the values of the F's which are not substituted (renamed $F_2$) are insufficient: as long as more information is not obtained about the other arguments (the $F_1$'s), the information about B cannot be improved.

In order to clarify this definition, let us prove the safeness of some of our computation rules.

Proposition 3

In $\text{lang } S$, the rules (2), i.e., call-by-name and (5), i.e., free argument are safe.

Proof. By induction on $|C|$ where $C = \text{simpl}(B)$: we first notice that, because of the semantic definition of $\text{lang } S$, if $F$ occurs in $C$ then $c(\Omega)(d) = w$ (remember that $C$ has been simplified and, when a simplified term has the form $\text{IF } C_1 \text{ THEN } C_2 \text{ ELSE } C_3$, we must have $F$ occurring in $C_1$).

Case $C = A_i$ then any rule is safe.

Case $C = C_i(C_{1i}, \ldots, C_{pi})$. The letter $F$ occurs necessarily in $C$, otherwise we could simplify further. Since both rules select at least one $F$ on such terms, we know by our previous remark that $c(\gamma/f_1, f_2/f_2)(\bar{d}) = w = c(\gamma/f_1, \Omega/f_2)(\bar{d})$.

Case $C = F(C_1, \ldots, C_n)$. The safeness of rule (2) is straightforward since the outermost $F$ is substituted. For the same reason, rule (5) is safe if at least one of the $C_i$ is constant. If none of the $C_i$'s is constant, then $c_i(\gamma/f_1, f_2/f_2)(\bar{d}) = w$ for $1 \leq i \leq n$ and we must prove that $f_p(w, \ldots, w) = w$. This is ensured by imposing in $\text{lang } S$...
that all program variables \(X_1, \ldots, X_n\) occur in \(\text{simp}(P)\) hence
\[f(P)(w, \ldots, w) = p(f_P)(w, \ldots, w) = w.\]

\[\square\]

**Proposition 4**

The rules (4), i.e., parallel outermost and (6), i.e., full substitution are safe in both \(\text{lang} \ S\) and \(\text{lang} \ P\).

**Proof.** By induction on \(|B|\).

- **Case** \(B = A_1\). Any rule is safe.

- **Case** \(B = C_1(B_1, \ldots, B_p)\). By induction,
  \[b_1[n/f_1, f_p/f_2](\bar{d}) = b_1[n/f_1, \Omega/f_2](\bar{d})\]
  for \(1 \leq i \leq p\) in both cases, hence safeness is also satisfied on \(b\).

- **Case** \(B = F(B_1, \ldots, B_n)\). Both rules select the outermost \(F\) hence
  \[b[n/f_1, f_p/f_2](\bar{d}) = w = b[n/f_1, \Omega/f_2](\bar{d}).\]

Note that the computation rules that we already recognized as incorrect are all unsafe. In order to prove that safe rules are correct, we need the following technical lemma:

**Lemma 5**

If \(C\) is safe, then \(B \subseteq C\) and \(\min(B, Q) = \min(C, Q)\) imply
\[q(n)(\bar{d}) \leq b(n)(\bar{d})\] for any terms \(B, C\) and \(Q\) in the computation lattice of \(T\) by \(P\), and input \(\bar{d}\).
Proof. Let us first determine some properties of the \( \min \) of two terms:

**Lemma 3**

(i) \( \min(G_1(B_1, \ldots, B_p), G_1(C_1, \ldots, C_p)) = G_1(\min(B_1, C_1), \ldots, \min(B_p, C_p)) \)

(ii) \( \min(P[B_1/X_1, \ldots, B_n/X_n], G(C_1, \ldots, C_p)) = P[M_1/X_1, \ldots, M_n/X_n] \)

where \( M_1, \ldots, M_n \) are such that

\[ F(M_1, \ldots, M_n) = \min(F(B_1, \ldots, B_n), G(C_1, \ldots, C_p)) \]

Proof. Property (i) is easy and property (ii) follows from the fact that

\[ P[M_1/X_1, \ldots, M_n/X_n] \ast M' \ast P[B_1/X_1, \ldots, B_n/X_n] \]

with \( M_i \ast B_i \)

for \( 1 \leq i \leq n \) implies that \( M' = P[M_1/X_1, \ldots, M'_n/X_n] \) where

\[ M_i \ast M_i' \ast B_i \]

for \( 1 \leq i \leq n \). \( \square \)

We now prove Lemma S: Let us rename \( F_1 \) the occurrences of \( F \) selected by \( C \) in \( B \) and \( F_2 \) the others. Let \( M = \min(B, Q) = \min(C, Q) \).

We first prove by induction on \( (\text{dist}(M, B) + \text{dist}(M, C), ||M||) \) that

\[ Q \leq B[F_1/F, F_1/F_2] \]

for some natural number \( m \). (Here \( F^m \) means \( F[F^{m-1}/F] \) for \( m > 0 \) and \( F^0 = F(X_1, \ldots, X_n) \).)

Case \( M = A_i \) or \( M = X_i \)

In this case, \( M = B = C = Q \) and we can choose \( m = 0 \).

Case \( M = G_1(M_1, \ldots, M_p) \)

By Lemma 1, \( B = G_1(B_1, \ldots, B_p) \), \( C = G_1(C_1, \ldots, C_p) \) and

\[ Q = G(Q_1, \ldots, Q_p) \]. By Lemma 3, \( M_i = \min(B_i, Q_i) = \min(C_i, Q_i) \) for
\[ 1 \leq i \leq p. \] It follows by induction that \( Q_i \leq B_i(F/F_1, F^{m_i}/F_2). \)

We can then choose \( m = \sup_{1 \leq i \leq p} \{ m_i \} \) in order to get

\[ Q \leq B(F/F_1, F^m/F_2). \]

**Case** \( M = \{M_1, \ldots, M_n\} \)

By definition of \( \min \), we need only consider the cases:

**Case** \( B = G(B_1, \ldots, B_p) \) and \( Q = F(Q_1, \ldots, Q_n) \)

Let \( M' = F(M_1/X_1, \ldots, M_n/X_n) \) and
\[ Q' = F(Q_1/X_1, \ldots, Q_n/X_n). \]
By Lemma 3,
\[ M' = \min(B, Q') = \min(C, Q'). \]
By Lemma 2,
\[ \text{dist}(M', B) + \text{dist}(M', Q') < \text{dist}(M, B) + \text{dist}(M, Q) \]
so we know by induction that \( Q' \leq B(F/F_1, F^m/F_2) \) and, a fortiori

\[ Q \leq B(F/F_1, F^m/F_2) \]

for some \( m \).

**Case** \( B = F(B_1, \ldots, B_n) \) and \( Q = G(Q_1, \ldots, Q_p) \)

Since \( \min(B, Q) = \min(C, Q) \), the term \( C \) is also of the form \( C = F(C_1, \ldots, C_n) \). Let
\[ M' = F(M_1/X_1, \ldots, M_n/X_n), \]
\[ B' = F(B_1/X_1, \ldots, B_n/X_n) \]
and \( C' = F(C_1/X_1, \ldots, C_n/X_n) \). By Lemma 3, we know that \( M' = \min(B', Q) = \min(C', Q) \).
By Lemma 2, \( \text{dist}(M', B') + \text{dist}(M', Q) < \text{dist}(M, B) + \text{dist}(M, Q) \), and the induction hypothesis tells us that \( Q \leq B'[P/F_1, P^m/F_2] \).

Since the outermost \( F \) has not been selected by \( C \) in \( B \) then \( B' \leq B[P/F_2] \). Our last case is then treated since \( Q \leq B[P/F_1, P^{m+1}/F_2] \).

It is now easy to finish the proof of Lemma 5.

For any \( m \), \( p^m(\Omega) \subseteq f_p \) implies \( b[\Omega/f_1, p^m(\Omega)/f_2] \subseteq b[\Omega/f_1, f_p/f_2] \). By choosing \( m \) large enough, we know that \( q(\Omega) \subseteq b[\Omega/f_1, p^m(\Omega)/f_2] \), and therefore \( q(\Omega) \subseteq b[\Omega/f_1, f_p/f_2] \). Since \( C \) is safe, \( b[\Omega/f_1, f_p/f_2](\bar{d}) = b(\Omega)(\bar{d}) \) and the conclusion \( q(\Omega)(\bar{d}) \subseteq b(\Omega)(\bar{d}) \) follows.

### Theorem 3

Any safe rule is a fixed-point rule.

**Proof.** In the computation lattice of \( T_0 = F(\bar{d}) \) by \( P \), let \( T_0, T_1, \ldots, T_n, \ldots \) and \( S_0, S_1, \ldots, S_n, \ldots \) (where \( S_0 = T_0 \)) be the computation sequences corresponding to respectively some safe rule \( C \) and the full substitution rule. Since \( s_n(\Omega) = p^n(\Omega) \) then

\[
\bigcup_{n \geq 0} s_n(\Omega) = \bigcup_{n \geq 0} p^n(\Omega) = f_p.
\]

We know by Theorem 2 that \( C_p(\bar{d}) \subseteq f_p(\bar{d}) \), and it is therefore sufficient to show that \( \bigcup_{n > 0} s_n(\Omega)(\bar{d}) \subseteq \bigcup_{n > 0} t_n(\Omega)(\bar{d}) \), in order to prove \( C_p = f_p \).

Let \( S_n \) be an arbitrary term in \( S_0, S_1, \ldots \). Since there are only finitely many minorants of \( S_n \) in the computation lattice, there exists some \( m \) such that \( \min(T_m, S_n) = \min(T_{m+1}, S_n) \). The rule \( C \) being safe, it follows from Lemma 5 that \( s_n(\Omega)(\bar{d}) \subseteq t_m(\Omega)(\bar{d}) \), hence
\[ \bigcup_{n \geq 0} s_n(\Omega)(\vec{a}) \subseteq \bigcup_{m \geq 0} t_m(\Omega)(\vec{a}) .\]

As a corollary, rules (2) and (5) are fixed-point in \textit{lang S} and rules (4) and (6) are fixed-point rules in both \textit{lang S} and \textit{lang P}.
3. An Optimal Implementation of Recursion in lang S

Among the correct implementations of recursion, we now try to
determine which ones are efficient. This proves unsuccessful in
lang P, but we shall describe an implementation of recursion for
lang S which turns out to be optimal.

We already know that, in lang S, "call-by-name" is a fixed-point
rule, while "call-by-value" is not. However, "call-by-name" is not an
efficient way of computing. For example, in the program

\[ F(X) \leq \text{IF } X > 0 \text{ THEN } X-1 \text{ ELSE } F(F(X+2)) \]

the "call-by-name" computation of \( F(0) \) would be

\[ F(0) \rightarrow F(F(2)) \rightarrow \text{IF } F(2) > 0 \text{ THEN } F(2)-1 \text{ ELSE } F(F(F(2)+1)) \rightarrow F(2)-1 \rightarrow 0. \]

What happens here is that the term \( F(2) \) has been duplicated and
subsequently computed twice. We shall describe a computation mechanism,
called the delay-rule, which avoids those duplications, and prove its
optimality.

3.1 Never Do Today What You Can Put Off Until Tomorrow

A natural way to keep track of duplications of terms is to assign
labels to all occurrences of \( F \) in a computation sequence, so that
copies of the same \( F \) will receive the same label. This can be
achieved by first labelling differently all \( F \)'s in \( P \); then,
if \( F \) is labelled \( \alpha \) in \( T \), and is to be substituted, we label each
occurrence of \( F \) after substitution by \( \alpha \) followed by whatever
labelling this particular occurrence had in \( P \). For example, using
the same computation as before, and the labelling

\[ \text{IF } X > 0 \text{ THEN } X-1 \text{ ELSE } F_1(F_2(X+2)) \]

for \( P \), the previous computation
can be described as:
\[ F(0) - F_2(F_2(2)) - IF F_2(2) > 0 THEN F_2(2)-1 ELSE F_{11}F_{12}(F_2(2)+2) \]

\[ \rightarrow IF 1 > 0 THEN F_2(2)-1 ELSE F_{11}F_{12}(F_2(2)+2) \]

simplifies to \( F_2(2)-1 = 0 \).

The whole idea of the delay-rule is to modify "call-by-name" so that, whenever some occurrence of \( F \) is substituted, all the occurrences having the same label will also be substituted. Hence, the "delay-rule" selects for substitution the \( l \) "most-outermost \( F \) in a simplified term, as well as all the other \( F \)'s having the same label.

Consequently, the delay rule computation of \( F(0) \) in the program above is

\[ F_1(0) - F_1(F_2(2)) - IF F_2(2) > 0 THEN F_2(2)-1 ELSE F_{11}F_{12}(F_2(2)+2) \]

\[ \rightarrow IF 1 > 0 THEN 1-1 ELSE F_{11}F_{12}(1+2) \]

simplifies to \( 0 \). At this point, it is clear that the "delay rule" is safe (proof similar to that of Proposition 1); what is not clear is that the "delay rule" should be more efficient than "call-by-name" and in fact, in our last example, it was less efficient since it took four substitutions versus three for "call-by-name" in order to obtain its result. When "call-by-name" computed \( F_{11}(2) \) twice, the delay rule has been computing it three times! It is a simple exercise in data structuring however to avoid all those recomputations: instead of actually copying various occurrences of some \( F_\alpha \) in a term, we simply set some pointers to a unique copy of the term \( F_\alpha \). Whenever any occurrence of \( F_\alpha \) is chosen for substitution, the substitution is actually performed in the unique copy of \( F_\alpha \) so that all occurrences of \( F_\alpha \) are substituted at the price of one substitution.
Going a little bit away from our particular programming language we can sketch an implementation of this idea for, say Algol. The arguments of any procedure should be stored as pointers to formal expressions, together with a tag indicating that those arguments have not yet been computed. Whenever the value of an argument is explicitly needed, (for the evaluation of a conditional or on the right-hand side of an assignment), the tag is tested. If the value of the parameter is already there, we use it; otherwise the corresponding formal expression must be computed, its value kept for further references, and the tag is to be changed. In a machine like the Burroughs B5000 (see, for example, Lonergan-King [12]), the so-called "operand call syllable" would do very nicely: depending on a tag stored with the operand, a load operation on the B5000 gets its argument either directly or through a subroutine call. The delay rule would modify this procedure so that, after the subroutine call, the result would be stored in place of the tagged subroutine descriptor. Of course, one would then have to abandon "side-effects" altogether!

Before proving the optimality of the delay rule let us compare the efficiency of various computation rules on the programs

\[
\begin{align*}
\text{Zer}(X) &\leq \text{IF } X > 0 \text{ THEN } X-1 \text{ ELSE } \text{Zer}(\text{Zer}(X+2)) \\
\text{Ack}(X,Y) &\leq \text{IF } X = 0 \text{ THEN } Y+1 \\
&\quad \text{ELSE IF } Y = 0 \text{ THEN Ack}(X-1,1) \\
&\quad \quad \text{ELSE Ack}(X-1,\text{Ack}(X,Y-1)) \\
\text{Ble}(X,Y) &\leq \text{IF } X = 0 \text{ THEN } 1 \text{ ELSE } \text{Ble}(X-1,\text{Ble}(X-Y,Y)) \\
\text{Fib}(X) &\leq \text{IF } X < 2 \text{ THEN } X \text{ ELSE } \text{Fib}(X-1) + \text{Fib}(X-2)
\end{align*}
\]

over the integers.
The entries in this array indicate the number of substitutions required for computing the values at the top of the corresponding column, according to the rules at the left of the rows.

If he has been through those examples, the reader may feel quite disappointed because he can beat the delay-rule in almost all cases. For example, the hand-computation of Fib(5) only requires five substitutions if we are careful never to recompute an argument twice. It would be interesting to study a mechanism in which this type of computation would be possible; namely one could imagine a set of simplification rules which could be augmented dynamically, and allow some computations to be performed by simplifications of the style F(D) → A. In our scheme of things, however, this type of "built-in" values is not possible, since our only means of computation is through substitutions, and we should blame inefficiencies on the program, not on the computation rule.

/* Strictly speaking, we are using the full substitution only on simplified terms, otherwise the computation would always be infinite.
3.2 Optimality of the Delay Rule

So far, we know that the delay rule is safe, and that it never recomputes copies of the same term. Using the same labelling as before, we say that a label \( F_\alpha \) is maximal in a term if \( \alpha \) is not a proper initial segment of \( \beta \) for any label \( F_\beta \) in the term. A term is simple if all of its labels are maximal. In other words, a term is simple if all computations of various copies of subterms have been pushed to the same point. For example, if \( T_0 = F(F(X)) \) and \( T_0 = G(X,F_1(F_2(X))) \) then \( G(G(X,F_1(F_2(X)),F_1(F_2(F(X)))))) \) is not simple while \( F(G(X,F_1(F_2(X)))) \) is simple.

A computation is simple if all \( F \)'s with the same labels are all treated alike in all substitutions (if one of them is to be substituted, all of them are to be substituted). All terms in a simple computation are necessarily simple. If we are to count for one a substitution of all \( F \)'s with the same labels, as justified by our previous exercise in data structuring, simple computations are more efficient than others. Namely, if we define \( \text{length}(T_0 \rightarrow A) \) as the total number of substitutions performed during the computation \( T_0 \rightarrow A \), we have

**Lemma E**

For any term \( A \), there exists a simple term \( \bar{A} \) with \( A \leq \bar{A} \) such that, for any computation \( T_0 \rightarrow A \) and simple computation \( T_0 \rightarrow \bar{A} \),

\[
\text{length}(T_0 \rightarrow \bar{A}) \leq \text{length}(T_0 \rightarrow A).
\]

**Proof.** Let \( r(C) \) be the number of maximal labels and \( s(C) \) be the sum of the lengths of the maximal labels in a term \( C \), while \( q \) and \( p \) mean respectively the number of occurrences of \( F \) in \( T_0 \) and \( P \). It
is easily proven by induction on \( \text{length}(T_0 \rightarrow^* C) \) that
\[
\text{length}(T_0 \rightarrow^* C) \geq \varphi(C, p, q) \quad \text{where} \quad \varphi(C, p, q) = \begin{cases} \frac{s(C)}{q} & \text{if } p = 1 \\ \frac{r(C)}{p-1} & \text{else} \end{cases}
\]
In a similar way, \((C \text{ simple})\) and \((T_0 \rightarrow^* C \text{ simple})\) imply
\[
\text{length}(T_0 \rightarrow^* C) = \varphi(C, p, q).
\]

Given any term \( A \), we can "complete" it into an \( \bar{A} \) by substituting \( P \) for all occurrences of \( F \) with non-maximal labels until there is none left. An \( \bar{A} \) constructed in this way will be simple and such that \( A \preceq \bar{A} \) while \( r(A) = r(\bar{A}) \). It follows that, for any computation \( T_0 \rightarrow^* A \) and simple computation \( T_0 \rightarrow^* \bar{A} \),
\[
\text{length}(T_0 \rightarrow^* \bar{A}) = \varphi(\bar{A}, p, q) = \varphi(A, p, q) \leq \text{length}(T_0 \rightarrow^* A).
\]

The intuitive meaning of this lemma is very simple: nothing is to be gained by working on individual copies of the same term. At the same price, we get more information by substituting all copies of the same occurrences. In particular, all the computation rules described so far will be improved by "lumping" together occurrences of \( F \) with the same labels, thus becoming simple rules. However they may still perform unnecessary substitutions unless

\textbf{Theorem 4}

Any computation rule which is simple, safe and performs at most one substitution at each computation step is optimal.

\textbf{Proof.} Let \( T_0 \) be a term, \( F(\bar{x}) \preceq P \) a program and \( C \) a safe and simple computation rule performing only one substitution at a time.

Let \( T_0 \Rightarrow T_1 \Rightarrow \ldots \Rightarrow T_n \Rightarrow T_{n+1} \Rightarrow \ldots \) the (simple) computation sequence of \( T_0 \) according to \( C \) for some input \( \bar{b} \).

46
If $T$ is a term in the computation lattice of $T_0$ by $P$, let us consider an arbitrary computation $T_0 \ast T$, and prove that whatever approximation $t(n)(\bar{d})$ of $t_0(f_p)(\bar{d})$ is computed by $T$ will be computed faster by $C$. For this purpose, we construct $\bar{T}$ as in Lemma E, and consider a simple computation $T_0 \Rightarrow \bar{T}$ (the argument in Lemma E not only proves the existence of $\bar{T}$ but also that of a simple computation $T_0 \Rightarrow \bar{T}$).

Let $i$ be some natural number such that $T_i \leq \bar{T}$ and $T_{i+1} \not\leq \bar{T}$.

Since $C$ performs only one substitution at the time, this implies $T_i = \min(T_{i+1}, \bar{T}) = \min(T_i, \bar{T})$. By Lemma S, we then know that $t(n)(\bar{d}) \leq t_i(n)(\bar{d})$. Using Lemmas E and C now, $T \leq \bar{T}$ implies $t(n)(\bar{d}) \leq t(n)(\bar{d})$ and $\text{length}(T_0 \Rightarrow \bar{T}) \leq \text{length}(T_0 \Rightarrow T)$. Since both $T_0 \Rightarrow \bar{T}$ and $T \Rightarrow T_i$ are simple and $T_i \leq \bar{T}$, we have $\text{length}(T_0 \Rightarrow T_i) \leq \text{length}(T_0 \Rightarrow \bar{T})$ hence $t(n)(\bar{d}) \leq t_i(n)(\bar{d})$ while $\text{length}(T_0 \Rightarrow T_i) \leq \text{length}(T_0 \Rightarrow T)$.

We shall derive two applications of this theorem.

**Corollary 1**

The delay rule is optimal in $\text{lang } S$.

**Proof.** The delay rule has all the properties required by Theorem 4.

**Corollary 2**

In $\text{lang } S$, "call by value" is optimal whenever the least fixed-point $f_p$ corresponding to the program $F(x) <= P$ is a strict function.

(The function $f_p$ is strict if $f_p(..., w, ...) = w$.)
Proof. Since "call by value" is clearly a simple rule and performs at most one substitution at each step, we only need proving that it is safe whenever \( f_p \) is strict. We prove that the substitution \( B \rightarrow B' \) is safe in that case by induction on \( |C| \) where \( C = \text{simp}(B) \):

Case \( C = A_i \). Any rule is safe.

Case \( C = G (C_1, \ldots, C_p) \). Same argument as for the safeness of "call by name".

Case \( C = F(C_1, \ldots, C_n) \). If \( F \) does not occur in any of the \( C_i \)'s, then the outermost substitution is performed, which is clearly safe. Otherwise, let \( C_1 \) be the leftmost term in which \( F \) occurs. Then,
\[
C_1[\alpha/f_1, \beta/f_2](\bar{a}) = w \quad \text{and} \quad C[\alpha/f_1, \beta/f_2](\bar{a}) = f_p(\ldots, w, \ldots) = w = C[\alpha/f_1, \alpha/f_2](\bar{a}).
\]

\( \square \)

3.3 Sequential Functions

The applications of Theorem 4 given in the previous section do not quite match with the generality of the result. In particular, the data-type on which \( \text{lang} \ S \) is computing has no chain of length more than two. What we shall now sketch is a theory of sequential functions, where Theorem 4 finds its full application.

The relevant notion here seems to be

Definition

A function \( \lambda x_1, \ldots, x_n.g(x_1, \ldots, x_n) \) in \( [D_1 \times \ldots \times D_n \rightarrow D] \) is sequential if, for all \( x_1 \in D_1, \ldots, x_n \in D_n \), there exists an \( i \in [1, n] \) such
that, for all \( y_1, \ldots, y_n \) such that \( x_j \subseteq y_j \) for \( j \in [1, n] \) and \( x_1 = y_1 \) we have \( g(x_1, \ldots, x_n) = g(y_1, \ldots, y_n) \).

Intuitively, \( g \) is sequential if, at any given moment, the value of (at least) one of its arguments is crucially needed in order to better approximate the value of the result. For the purpose of our theory, we need to check that sequentiality has the correct closure property, namely

**Proposition S**

**Sequentiality is preserved by composition of functions and fixed-point operators.**

**Proof.**

--- **Composition.** If \( \lambda z_1, \ldots, z_n g(z_1, \ldots, z_n) \) and \( \lambda x_1, \ldots, x_m f_i(x_1, \ldots, x_m) \) for \( 1 \leq i \leq n \) are sequential, then

\[
\varphi = \lambda x_1, \ldots, x_m g(f_1(x_1, \ldots, x_m), \ldots, f_m(x_1, \ldots, x_m))
\]

is also sequential: for any \( x_1, \ldots, x_m \) and \( i \in [1, n] \), let

\( z_i = f_i(x_1, \ldots, x_m) \); since \( g \) is sequential \( z_1, \ldots, z_n \) determines some \( i_0 \in [1, n] \) and, \( f_i \) being also sequential, \( x_1, \ldots, x_m \) determine some \( j \in [1, m] \) which can then be used for the sequentiality of \( \varphi \).

--- **Fixed-point operator.** If the functions \( \lambda x_1, \ldots, x_n f_i(x_1, \ldots, x_n) \) are sequential for any natural number \( i \), the function

\[
\varphi = \lambda x_1, \ldots, x_n \bigcup_{i \geq 0} f_i(x_1, \ldots, x_n)
\]

is also sequential: for any \( x_1, \ldots, x_n \) sequentiality of the \( f_i \)'s determines a sequence \( j_0, j_1, \ldots \) where \( j_i \in [1, n] \). At least one of
the $j_i$'s must occur infinitely often in this sequence, and it can be
used for proving that $\varphi$ is sequential.

For example, over a discrete data-type, conditional and strict
functions are sequential; hence, by Proposition S, all functions
definable in $\text{lang } S$ are sequential.

In a data-type which is a lattice, the functions $\lambda x, y \sup(x, y)$
and $\lambda x, y \inf(x, y)$ are not sequential in general.

The set $\Sigma^\omega$ of finite or infinite words over some vocabulary $\Sigma$
becomes a data-type under the partial ordering: $x \leq y$ whenever $x$
is an initial segment of $y$.

In $\Sigma^\omega$, the functions

\begin{align*}
\lambda x.\text{first}(x) & \quad \text{(take the first letter of } x \text{),} \\
\lambda x.\text{rest}(x) & \quad \text{(erase the first letter of } x \text{),} \\
\lambda x, y. x \otimes y & \quad \text{(append the first letter of } x \text{ to } y \text{) are}
\end{align*}

sequential. */

This is clear enough for first and rest since any function of one argu-
ment is sequential. For $x \otimes y$, if $x = \Lambda$, i.e., $x$ is the empty word, then
the first argument is to be chosen for sequentiality since $\Lambda \otimes y = \omega$;
otherwise, $x \neq \Lambda$ and any $x'$ such that $x \sqsubseteq x'$ will have the same first
letter so that we can use the other argument $y$ for sequentiality.

Yet another programming language. We define a new language $\text{lang } GS$
similar to our previous ones except that all base functions must be
sequential.

*/ The relevance of these functions and data-type to parallel programs
is shown in Kahn [11].
Let $\varepsilon$ be a computation rule, called the generalized delay rule (GDR) defined as follows:

First, using the same type of data-structuring as for the delay rule, $\varepsilon$ will be simple.

In any term $T$, rule $\varepsilon$ will select at most one $F$ (or rather set of $F$'s with the same labels) as follows:

- If $T = A_i$, no $F$ is chosen.
- If $T = G_i(T_1, \ldots, T_p)$, the $F$ will be the $F$ chosen by $\varepsilon$ in $T_j$ where $j$ is the index corresponding to the sequentiality of $G_i$ with the arguments $t_1(\bar{a}), \ldots, t_p(\bar{a})$. Of course, this requires the choice of $j$ to be effective; also, since we want $\varepsilon$ to be simple, all $F$'s with the same labels occurring in other subterms are also to be substituted.
- If $T = F(T_1, \ldots, T_n)$ the outermost $F$ is selected by $\varepsilon$.

We can apply Theorem 4 again in order to prove

**Corollary 3**

The generalized delay rule is optimal in Lang GS.

**Proof.** Since the GDR is simple and performs at most one substitution at each step, all we need to prove is that it is safe.

The proof is by induction on $|B|$ where $B$ is any term in the computation lattice of

$$T_0 = T[\bar{B}/\bar{X}] \text{ by } P.$$

The cases $B = A_i$ or $B = F(B_1, \ldots, B_n)$ are easy.

If $B = G_i(B_1, \ldots, B_p)$ and $j$ is the sequentiality index of
\[ g_1(b_1(\Omega)(\bar{d}), \ldots, b_p(\Omega)(\bar{d})) \text{, then } b_j(\Omega/f_1, f_2/f_2)(\bar{d}) = b_j(\Omega)(\bar{d}) \text{ by induction. Since } b_k(\Omega)(\bar{d}) \equiv b_k(\Omega/f_1, f_2/f_2)(\bar{d}) \text{, the very definition of sequentiality gives us } b(\Omega/f_1, f_2/f_2)(\bar{d}) = b(\Omega/f_1, \Omega/f_2)(\bar{d}). \]

\[ \square \]

Conclusion

The results of this chapter generalize quite nicely to a programming language where we introduce assignments, goto's and while statements. What is less clear to the author is how to perform computation in a "typeless" recursive language where procedures can be passed as arguments, say in a full LISP for example. It might also be interesting to study (or prove the non-existence of) optimal computation rules when the simplifications allowed are less restrictive than the ones we chose.
Chapter 3. PROOFS BASED UPON MONOTONICITY

In this chapter, we investigate how far into the theory of computation can one get from the mere hypothesis that programs represent monotone mappings between data-types, thus ignoring continuity.

For this purpose, we introduce a formal system in which the methods of "inductive assertions" and "structural induction" for proving properties of programs can be expressed and justified.

The reader interested in the logic developed here is expected to be familiar with the work of Milner [19]. However, a detailed knowledge of the formalism should not be necessary for understanding the various uses we make of it. In particular, the examples given are described informally, despite the fact that all the proofs can be expressed within the logical system.

1. A Formal System for the Time Being

1.1 Syntax

Terms, which are meant to denote monotone functions of some type, are defined as follows:

(i) Typed identifiers are terms. (We shall almost always omit the type subscript.)

(ii) If \( s \) is a term of type \( \alpha \rightarrow \beta \) and \( t \) a term of type \( \alpha \), then \( s(t) \) is a term of type \( \beta \).

(iii) If \( x \) is of type \( \alpha \) and \( t \) of type \( \beta \), then \( \lambda x. t \) is a term of type \( \alpha \rightarrow \beta \).
(iv) If P is a wff, t a term of type α and x a variable, then \[ U_t \] and \[ n_t \] are terms of type α.

A well-formed-formula P is a conjunction of equalities or inequalities between terms of the form \( p \leq q, r = s, \ldots, u \leq t \).

A proof is a sequence of implications between wffs \( P \vdash Q \), each being derived from the preceding implication by an axiom or a rule of inference.

Variables are bound by \( \lambda, \cup \) and \( \cap \). We write \( s[t/x] \) and \( P[t/x] \) to denote the result of replacing all free occurrences of \( x \) in \( s \) and \( P \) by \( t \), after renaming the necessary bound variables.

1.2 Semantics

A standard model is a denumerable family of complete lattices \( D_\alpha \), one at each type \( \alpha \). Each \( D_\alpha \) has a minimal element \( \underline{U}_\alpha \) and maximal element \( \underline{0}_\alpha \). The two base types are I and B. The domain of individuals \( D_I \) can be any complete lattice while \( D_B \) is the set of monotone mappings from \( D_\alpha \) into \( D_\beta \). It is easily checked that, whenever \( D_\alpha \) and \( D_\beta \) are complete lattices, \( D_{\alpha\rightarrow\beta} \) is itself a complete lattice. Terms of type \( \alpha \) are intended to denote elements of \( D_\alpha \).

1.3 Axioms and Rules of Inference

Here \( x, y, z, f \) represent variables \( s, t \) terms and \( P, Q, R \) wffs. Axioms and rules are meant at all syntactically correct types.
(a) **Axioms**

(Reflexivity) \[ D_1: \quad x \equiv x \]

(Transitivity) \[ D_2: \quad x \equiv y, y \equiv z \Rightarrow x \equiv z \]

(Antisymmetry) \[ D_3: \quad x \equiv y, y \equiv x \Rightarrow x = y \]

(Minimality) \[ D_4: \quad x \equiv y, y \subseteq x \Rightarrow x \subseteq y \]

(Maximality) \[ D_5: \quad x \subseteq y, y \subseteq x \Rightarrow x = y \]

(Monotonicity) \[ F_1: \quad x \subseteq y \Rightarrow f(x) \subseteq f(y) \]

(\(\lambda\)-conversion) \[ F_2: \quad f(x) \equiv g(x) \land x \not\in \text{free in } P \Rightarrow f(x) \equiv g(x) \]

(bottoms-tops) \[ F_3: \quad f(x) \equiv g(x) \land x \not\in \text{free in } P \Rightarrow f(x) \equiv g(x) \]

(joins) \[ F_4: \quad P[y/x] \cup \{x|P\} \Rightarrow t[y/x] \subseteq \cup \{x|P\} \]

(meets) \[ F_5: \quad P[y/x] \cap \{x|P\} \Rightarrow t[y/x] \subseteq \cup \{x|P\} \]

(Inclusion) \[ W_1: \quad P \cup Q \quad (Q \text{ is a sub-conjunct of } P) \]

(b) **Rules of inference**

(Conjunction) \[ R_1: \quad \frac{P \cup Q \quad P \cup R}{P \cup Q, R} \]

(Cut) \[ R_2: \quad \frac{P \cup Q \quad Q \cup R}{P \cup R} \]

(Substitution) \[ R_3: \quad \frac{P \cup Q}{P[s/x] \cup Q[s/x]} \]

(Extensionality) \[ R_4: \quad \frac{P \cup f(x) \equiv g(x)}{P \cup f \subseteq g} \quad (x \text{ not free in } P) \]

(Cases) \[ R_5: \quad \frac{P[\text{false/x}] \cup Q \quad P[\text{true/x}] \cup Q}{P \cup Q} \]

Here, \text{false} and \text{true} are abbreviations for \(UU_B\) and \(OO_B\) respectively.
(meets) \[ \frac{Q, P \vdash y \subseteq t}{Q \vdash y \subseteq \bigcap_{[x] P} t} \quad (x \text{ not free in } Q) \]

(joins) \[ \frac{Q, P \vdash t \subseteq y}{Q \vdash \bigcup_{[x] P} t \subseteq y} \quad (x \text{ not free in } Q) \]

1.4 Soundness

In order to establish validity of the axioms and rules of inference, one first ought to make sure that terms without free variables indeed denote elements of the complete lattice of the corresponding type. This is easy for application and \( \lambda \)-abstraction (see Milner [19]). For meets and joins, we have to prove in essence that if for each \( i \in I \) the function \( f_i \) is monotonic then \( \bigcap_{i \in I} f_i \) and \( \bigcup_{i \in I} f_i \) are also monotonic.

Let \( x \subseteq y \). For all \( i \in I \), we have

\[ \bigcap_{i \in I} f_i(x) \subseteq f_i(x) \subseteq f_i(y) \subseteq \bigcup_{i \in I} f_i(y) \]

It follows by definition of \( \bigcap \) and \( \bigcup \) that

\[ \bigcap_{i \in I} f_i(x) \subseteq \bigcap_{i \in I} f_i(y) \quad \text{and} \quad \bigcup_{i \in I} f_i(x) \subseteq \bigcup_{i \in I} f_i(y) \]

and by definition again

\[ \bigcap_{i \in I} f_i(x) \subseteq \bigcap_{i \in I} f_i(y) \quad \text{and} \quad \bigcup_{i \in I} f_i(x) \subseteq \bigcup_{i \in I} f_i(y) \]

Using exactly the same approach as Milner [19], one can then go through the axioms and rules of inference, and justify their validity.
1.5 **Pragmatics**

We shall use the following abbreviations:

(1) By the Knaster-Tarski theorem, we can characterize the least-fixpoint of \( \lambda x. f(x) \) as the greatest-lower-bound of \( \{ x \mid f(x) \subseteq x \} \). We shall therefore use \( \mu x. f(x) \) as an abbreviation for \( \bigcap \{ x \mid f(x) \subseteq x \} \). The equivalents of rules R8 and R9 are then:

\[
\text{R8: } f(\mu x. f(x)) \subseteq \mu x. f(x) \\
\text{R9: } f(y) \subseteq y \quad \mu x. f(x) \subseteq y
\]

The rule R9 was named fixed-point induction by Park [26].

We shall use the notations \( f \leq \tau(f) \) and \( f \) as alternatives to \( [\tau(f)] \).

(2) One should not confuse the domain \( D_B \): true \quad false \)

data-type with the boolean range of some semi-decision procedure.

Let us now suppose that the domain \( D_\alpha \) is characterized by a semi-decision predicate \( \lambda x. \beta(x) \) mapping \( D_\alpha \) into \( D_B \) such that \( \beta(x) = \text{false} \) if and only if \( x = \text{null} \). We can then interpret the logical formula \( \forall y \in B: P(y) \) as \( \bigcap \{ y \mid \beta(y) = \text{true} \} \), where \( P \)

belongs to \( D_\alpha \rightarrow D_B \). This justifies using \( \forall y \in B. P(y) \),

or, when no confusion can arise, \( \forall y. P(y) \) as an abbreviation for

\( \bigcap \{ y \mid \beta(y) = \text{true} \} \). Similarly, \( \exists y. P(y) \) will abbreviate

\( \bigcup \{ y \mid \beta(y) = \text{true} \} \).
Rules $F_4$, $F_5$, $R_6$ and $R_7$ then translate into the following equivalents to the rules of first-order logic:

(i) $\forall y. P(y) \equiv \text{true}, B(a) \equiv \text{true} \vdash P(a) \equiv \text{true}$

(ii) $P(a) \equiv \text{true}, B(a) \equiv \text{true} \vdash \exists y. P(y) \equiv \text{true}$

(iii) from $Q, B(y) \equiv \text{true} \vdash P(y) \equiv \text{true}$

\[ (y \text{ not free in } Q) \]

\[ \text{infer } Q \vdash \exists y. P(y) \equiv \text{true} \]

(iv) from $Q, B(y) \equiv \text{true} \vdash P(y) \equiv \text{false}$

\[ (y \text{ not free in } Q) \]

\[ \text{infer } Q \vdash \exists y. P(y) \equiv \text{false} \]

Examples of Proofs

Example 1. The proof that

\[
[\text{ if } (i)](x) \equiv \text{ } [\text{ if } (i)](x)
\]

is quite instructive, and we sketch it here:

\[
\begin{align*}
\text{First} & \quad I \vdash f(i) \equiv \text{ } \cup f(i) \quad (F_4) \\
& \quad I \vdash f(i) \equiv \text{ } [\cup f(i)](x) \quad (Appl)
\end{align*}
\]

(The rule $(Appl)$ $f \equiv g \vdash f(x) \equiv g(x)$ is derivable from $F_1$ and $F_2$.)

\[
\begin{align*}
& \quad \vdash \cup f(i)(x) \equiv \text{ } [\cup f(i)](x) \\
& \quad \vdash \text{ } \cup f(i)(x) \equiv \text{ } \cup f(i)(x) \quad (R_7)
\end{align*}
\]

then \[
\begin{align*}
I \vdash f(i)(x) \equiv \text{ } \cup f(i)(x) \quad (F_4) \\
& \quad I \vdash f(i) \equiv \text{ } \lambda x. \cup f(i)(x) \\
& \quad I \vdash f(i) \equiv \text{ } \lambda x. \cup f(i)(x) \quad (R_4) \\
& \quad \vdash \cup f(i) \equiv \text{ } \lambda x. \cup f(i)(x) \\
& \quad \vdash \text{ } \cup f(i)(x) \equiv \text{ } \cup f(i)(x) \quad (Appl) \text{ and } (F_2).
\end{align*}
\]
Example 2. Let us prove that

(a) \( \mu f. s(f, f) = \mu f. s(f, \mu f. s(f, f)) \)

(b) \( \mu f. s(f, f) = \mu f. s(f, s(f, f)) \).

In other words, we must establish the equivalence of the following three programs:

\[
\begin{align*}
& f \leftarrow s(f, f) \\
& g \leftarrow s(g, f) \\
& h \leftarrow s(h, s(h, h))
\end{align*}
\]

Proof of (a). Since \( s(f, f) \leq f \), we know by fixed-point induction that \( g \subseteq f \). By monotonicity of \( s \), this implies \( s(g, g) \subseteq s(g, f) \).

Since \( g = s(g, f) \), we have \( s(g, g) \subseteq g \) and \( f \subseteq g \) follows by fixed-point induction again.

Proof of (b). By definition, \( f = s(f, f) = s(f, s(f, f)) \) and therefore, \( h \subseteq f \) by fixed-point induction.

In order to prove that \( f \subseteq h \), let us use the auxiliary program

\[
\begin{align*}
& k \leftarrow s(h, s(h, k)) 
\end{align*}
\]

Since \( s(h, s(h, s(h, h))) = s(h, h) \), the rule of fixed-point induction tells us that

\[
k \subseteq s(h, h) \quad (1)
\]

but we know by (a) that \( k \equiv h \), and (1) becomes \( h \subseteq s(h, h) \).

By monotonicity of \( s \), this implies \( s(h, h) \subseteq s(h, s(h, h)) \) which, by definition of \( h \), reduces to \( s(h, h) \subseteq h \). One last application of fixed-point induction and we prove \( f \subseteq h \).
Example 3. For any functions $s$ and $t$,

$$f_{st} = s(f_{ts}).$$

That is, the programs $f \subseteq s(t(f))$ and $g \subseteq t(s(f))$ are related by $f = s(g)$ and $g = t(f)$. Since $f_{st} = s(t(f_{st}))$ we have $t_{st} = t_{st}f_{st}$ and, by fixed-point induction, $f_{ts} \subseteq t_{st}$. By symmetry $f_{st} \subseteq s_{ts}$ hence $f_{st} \subseteq t_{st}f_{ts} \subseteq f_{ts}$. 

Example 4. Let $f(x) \subseteq g(f(h(x), f(k(x)))$ and $y \subseteq g(y, y)$. We prove that $f(x) = y$. Since

$$g([\lambda x.y](h(x)), [\lambda x.y](h(x))) = g(y, y) = y = [\lambda x.y](x),$$

we know by fixed-point induction that $x \subseteq [\lambda x.y]$ hence $f(x) \subseteq y$. On the other hand, $g(f(UU), f(UU)) \subseteq g(f(h(UU)), f(k(UU)))$ by monotonicity, and $g(f(UU), f(UU)) \subseteq f(UU)$ follows from $f(UU) = g(f(h(UU), f(k(UU))))$. We conclude $y \subseteq f(UU)$ by fixed-point induction and, since $f(UU) \subseteq f(x)$, we proved that $y \subseteq f(x)$.

Example 5. If the two functions $\lambda f.s(f)$ and $\lambda f.t(f)$ commute, i.e., $st = ts$ then Example 2 tells us that $f_{st} = s(f_{st})$ and $f_{ts} = t(f_{ts})$ so that $f_{s} \subseteq f_{st}$ and $f_{t} \subseteq f_{st}$. (We can say that $f_{s}$ and $f_{t}$ are weakly equivalent.)

The similarity between some of those results and better known ones in linear algebra should not surprise us since linear algebra can be used as a model of our formal system. The base domain $D_{I}$ will be the set of vector-space over some space $V$. The natural ordering
is inverted: \( V_1 \subseteq V_2 \) holds whenever \( V_2 \) is a subspace of \( V_1 \).
The minimal element \( \mathcal{U} \) corresponds to the space \( V \) itself while
the vector space containing only \( 0 \) corresponds to \( 00 \). Linear
transformations over \( V \) are then monotone mappings in \( D_1 \to D_1 \) with
respect to that ordering, and, if the dimension of \( V \) is infinite, they
are not continuous in general. The least fixed-point of a linear
transformation \( A \in D_1 \to D_1 \) is then the eigenspace of \( A \) having
maximal dimension.

1.6 A Possible Weakness of the System

Let us consider the inference rule

\[
\text{RT: } \frac{P, x \subseteq g(x) \quad f(x) \subseteq g(f(x))}{P \quad \mu x. f(x) \subseteq g(\mu x. f(x))} \quad (x \text{ not free in } P)
\]

Is RT provable or not within our system? Although we have not
been able to settle this question, we shall be able to show that rule RT
must be valid in any standard model of our formal system.

Before doing so, let us point out that fixed-point induction can
be derived from RT and that using RT would somewhat simplify the
proofs in the previous examples. For instance, the proof that \( f \subseteq h \),
where \( f = \mu x. s(x, x) \) and \( h = \mu x. s(x, s(x, x)) \) could go as follows:
Let us assume \( y \subseteq h \) and \( y \subseteq s(y, y) \). In order to apply rule RT,
we shall prove that

\[
y \subseteq h, y \subseteq s(y, y) \quad s(y, y) \subseteq h, s(y, y) \subseteq s(s(y, y), s(y, y))
\]

and therefore conclude that \( f \subseteq h, f \subseteq s(f, f) \) so, a-fortiori
\( f \subseteq h \).
By monotonicity $y \subseteq s(y,y) \uparrow s(y,y) \subseteq s(s(y,y),s(y,y))$ and $y \subseteq s(y,y) \uparrow s(y,y) \subseteq s(y,s(y,y))$. Therefore, using monotonicity three times again $y \subseteq s(y,y), y \subseteq h \uparrow y \subseteq s(h,s(h,h))$. But $h = s(h,s(h,h))$ and, putting everything together, we get $y \subseteq h, y \subseteq s(y,y) \uparrow s(y,y) \subseteq h, s(y,y) \subseteq s(s(y,y),s(y,y))$.

We shall now justify the rule. To each monotone function $t$ mapping $\beta \rightarrow \beta$ and ordinal number $\alpha$, we associate an element $t^\alpha(UU) \in \beta$ as follows:

(i) $t^0(UU) = UU$

(ii) $t^{\alpha+1}(UU) = t(t^\alpha(UU))$

(iii) If $\alpha = \lim(\beta)$ is a limit ordinal, $t^\alpha(UU) = \bigcup_{\beta < \alpha} \{t^\beta(UU)\}$.

More concisely, $t^\alpha(UU) = t(\bigcup_{\beta < \alpha} \{t^\beta(UU)\})$, if we agree that $\bigcup(\emptyset) = UU$.

This sequence has the properties that $\beta < \gamma$ implies $t^\beta(UU) \subseteq t^\gamma(UU) \subseteq f_t$ for all ordinals $\beta$ and $\gamma$, and $t^\alpha(UU) = t^{\alpha+1}(UU)$ implies $t^\alpha(UU) = f_t$ for any ordinal $\alpha$.

Hence, if we choose $\alpha$ to be the first ordinal not embeddable in $\beta \rightarrow \beta$, the sequence $t^0(UU), t^1(UU), \ldots, t^\alpha(UU)$ has "too many" elements and $t^\alpha(UU) = f_t$. (See Cadiou [2] or Hitchcock-Park [8].)

Now, from the hypothesis $F \subseteq s(F) \uparrow t(F) \subseteq s(t(F))$, we can deduce that, for all ordinals $\alpha$,

$$t^\alpha(UU) \subseteq s(t^\alpha(UU)) \quad (1)$$

If $\alpha$ is not a limit ordinal, (1) is easy to establish. If $\alpha$ is a limit ordinal $\alpha = \lim(\beta)$, then for all $\beta < \alpha$ we know that $\ldots$
\[ t^\beta(UU) \subseteq s(t^\beta(UU)) \]. Since \[ t^\beta(UU) \subseteq t^\alpha(UU) \] we know that \[ t^\beta(UU) \subseteq s(t^\alpha(UU)) \] and therefore \[ t^\alpha(UU) = \bigcup_{\beta < \alpha} \{ t^\beta(UU) \} \subseteq s(t^\alpha(UU)) \].

Choosing \( \alpha \) such that \( t^\alpha(UU) = f_t \) then yields the conclusion of rule RT.
$t^\beta(UU) \subseteq s(t^\beta(UU))$. Since $t^\beta(UU) \subseteq t^\alpha(UU)$ we know that
$t^\beta(UU) \subseteq s(t^\alpha(UU))$ and therefore $t^\alpha(UU) = \bigcup_{\beta < \alpha} \{t^\beta(UU)\} \subseteq s(t^\alpha(UU))$.

Choosing $\alpha$ such that $t^\alpha(UU) = f_t$ then yields the conclusion of rule RT.
2. Justification of Some Proof Techniques

Suitable choices of the semantic definition of programming languages allow to reduce most of the proof techniques described in the literature to the rule of fixed-point induction. In particular, this applies to the methods described in McCarthy [13], Naur [24], Floyd [7], Manna [14], Manna-Pnueli [16], and Hoare [9]. Since Hoare's technique has been justified in Manna-Vuillemin [17], and the connections between fixed-point induction and the Manna-Pnueli method have been explicited by Park [26], we shall limit ourselves to first indicating how the Floyd-Naur method can be explained within our formal system and then sketch the connections with structural induction. The basic ideas in this section are from Park [26].

2.1 Description of a Flowchart-language

A flowchart is a connected graph, with two distinguished nodes

\[ \text{START} \quad \text{and} \quad \text{HALT} \]

Nodes can be of the type assignment

\[ x_i \leftarrow F(\bar{x}) \]

or test

\[ \begin{cases} F(\bar{x}) & \text{T} \\ T(\bar{x}) & \text{F} \end{cases} \]

Following Floyd [7], the "meaning assigned" to such a program will be a relation \( \psi(\bar{x}_H) \) over the values of the program variables, at the \( \text{HALT} \) node. This output relation is obtained by "carrying along" an input relation \( \varphi(\bar{x}_S) \), holding of the program variables at the \( \text{START} \) node. The notation \( \psi = \Sigma \varphi \) therefore means that, whenever we start
the execution of $\mathcal{F}$ with inputs satisfying $\varphi$, the outputs, if any, must satisfy $\psi$.

As in Chapter 2, syntactic objects are represented by upper-case letters and associated semantic objects by the corresponding lower-case letters.

The semantic function $\Sigma$ is defined recursively as:

(i) $\Sigma \left( \pi, x_1 \leftarrow F(x) \right) = \lambda x (\exists y)[\pi(\vec{y}) \land x_1 = f(\vec{y}) \land (\land_{j \neq i} x_j = y_j)]$

(ii) $\Sigma \left( \pi, \begin{array}{c} B_1 \\ B_2 \end{array} \right) = \Sigma \left( \pi, \begin{array}{c} B_1 \\ B_2 \end{array} \right)

(iii) $\Sigma \left( \pi, \begin{array}{c} \text{if } q \text{ then } \pi \land q, \begin{array}{c} B_1 \\ B_2 \end{array} \\ \text{else } \pi \land \neg q, \begin{array}{c} B_1 \\ B_2 \end{array} \end{array} \right)$

(iv) $\Sigma \left( \pi, \begin{array}{c} \text{if } q \text{ then } \mu \sigma. \pi \lor \Sigma \left( \sim q \land \sigma, \begin{array}{c} B_1 \\ B_2 \end{array} \right) \right)$

\[ \begin{array}{c}
\end{array} \]
Equation (iv), expressing the semantics of goto's, defines the "minimum valid inductive assertion" described in Manna [14]. There will be essentially one such equation per loop in the program; this may lead to systems of mutually recursive relations, depending on the nature of nesting of the loops. According to this definition, we have for example:

\[ \sum \lambda y_1, y_2. \text{true,} \]

\[ = [\lambda y_1, y_2. (y_1 \geq a) \land r_t(y_1, y_2)] , \]

where \( t(r)(y_1, y_2) = [(y_1 = 0) \land (y_2 = 1)] \lor \]
\[ [\lambda x_1, x_2. (x_1 < a) \land r(x_1, x_2) \land (y_1 = x_1 + 1) \land (y_2 = (x_1 + 1) \cdot x_2)] . \]

Note that, in order to simplify our semantic description, we have in effect limited ourselves to considering a flowchart in block-form. If loops do not have this nice nested structure, the description would be slightly more complex, and we would need to express the semantics of ill-nested loops by systems of mutually recursive equations.
2.2 The Inductive Assertions Technique

The meaning of a flowchart program is now a (partial) predicate, defined as the least-fixed point of some equation, say \( r = t(r) \). If we can find an "inductive assertion" \( q \) such that \( t(q) \subseteq q \), the rule of fixed-point induction allows us to infer that \( r \subseteq q \). This shows that whenever the program terminates, that is, if \( r_t(\bar{a}) = \text{true} \) for some input \( \bar{a} \), then we must also have \( q(\bar{a}) = \text{true} \).

This will be best understood by using the same example as above: The expression \( t(q) \subseteq q \) is

\[
[y_1 = 0) \land (y_2 = 1) \lor [(\exists x_1, x_2, (x_1 \neq a) \land q(x_1, x_2) \land (y_1 = x_1 + 1) \land (y_2 = (x_1 + 1) \cdot x_2)] \subseteq q(y_1, y_2).
\]

Using the inference rules corresponding to those of predicate calculus in Section 1, this formula is equivalent to

\[ q(0,1) = \text{true} \]

and

\[ q(y_1, y_2) \land y_1 \neq a = \text{true} \land q(y_1 + 1, (y_1 + 1) \cdot y_2) = \text{true} \].

This last formulation is the direct translation within our formalism of the verification condition derived by Manna [14]. This justification of the method gives us the additional insight that the inductive assertions one may use for proving the partial correctness of some program by the Manna-Floyd method are exactly the fixed-points of some algorithmically constructed functional.
2.3 Termination of Programs

Following Park [26], we shall now prove that the rule of fixed-point induction allows us to derive instances of (mathematical) transfinite induction.

Let $\mathcal{D}$ be a domain, and $<$ a partial ordering on $\mathcal{D}$. For any relation $R$ mapping $\mathcal{D}$ into $\{\text{true}, \text{false}\}$, let

$$t(R)(x) = \begin{cases} \text{true} & \text{if } y < x \text{ then } R(y) \text{ else true} \\ \text{false} & \end{cases}$$

The least fixed-point of $t$ is then the maximal well-ordered initial segment of the ordering $<$ over $\mathcal{D}$. (Note that this is the first time that we use a monotone function which is not continuous.)

Example. Let us consider some orderings over the integers, and the corresponding $R_t$.

If $<$ is $1 < 2 < 3 < \ldots$ then $R_t = t^\infty(UU)$ and $R_t(n)$ holds for every $n$.

If $<$ is $\ldots < 3 < 2 < 1$ then $R_t = UU$ never holds.

If $<$ is $1 < 3 < 5 \ldots 2 < 4 < \ldots$ then $R_t = t^{2\omega}(UU)$ and $R_t(n)$ holds for every $n$.

If $<$ is $1 < 3 < 5 \ldots 6 < 4 < 2$, then $R_t = t^\omega(UU)$ and $R_t(n)$ holds only of the odd natural numbers.

If $<$ is $1 < 3 < 5 \ldots 2 < 6 < 10 < \ldots 4 < 12 < 20 < \ldots \ldots$, then $R_t = t^\omega(UU)$ and $R_t(n)$ holds for every $n$.

If $<$ is a well-founded relation over $\mathcal{D}$, then $R_t(x)$ holds for any element $x$ of $\mathcal{D}$, in which case the "program" $R(x) \leq t(R)(x)$ can be thought of as defining recursively our domain.
In other words, if
\[ W_0 = \mu R. \lambda x. (\forall y) \text{ if } y < x \text{ then } R(y) \text{ else true} \],

the equality \( W_0(\prec)(x) = \mathcal{B}(x) \) characterizes the relation \( \prec \) as being well-founded. (See also Hitchcock-Park [8] for a more elegant formulation of this equality.)

No matter what kind of ordering \( \prec \) is, fixed-point induction translates into the following rule:

\[
(\forall y). \text{ if } y < x \text{ then } P(y) \text{ else true} \subseteq P(x) \land W_0(\prec)(x) \subseteq P(x).
\]

And in particular, if \( \prec \) is well founded over \( \mathcal{B} \), then \( P(x) = \text{true} \) will hold for any \( x \) in \( \mathcal{B} \). Depending on the interpretation of \( \prec \), this is a formulation of structural induction or transfinite induction (see Chapter 4, Section 3).

For example, the termination of the program

\[
\begin{align*}
F(n) & \leq \text{if odd}(n) \text{ then } n \text{ else } \\rule{0pt}{2ex} \\
& \quad \text{if } G(n) = 1 \text{ then } F(\frac{n}{2}) \text{ else } F(\frac{n}{G(n)}) \cdot F(n - \frac{2n}{G(n)}) + \frac{n}{G(n)} \\
G(n) & \leq \text{if even}(n) \text{ then } G(n/2) \text{ else } n
\end{align*}
\]

over the natural numbers can be established using the well ordering

\((1 < 3 < 5 < \ldots) < (2 < 6 < 10 < \ldots) < (4 < 12 < 20 < \ldots) < (\ldots) \ldots\)

More examples of applications of this technique will be given in the next chapter.
Chapter 4. PROOFS BASED UPON CONTINUITY

The previous chapter was a first attempt at proving properties of programs, based on a rather weak theory of computation. We shall now use our knowledge that programs are continuous functions, and justify some other proof techniques. The presentation will again be quite informal. However, it should soon be apparent that all the proofs given can be formalized in Milner's Logic for Computable Functions (LCF), as described in Section 1 of this chapter.

Obviously we wish to preserve all the results obtained in the previous chapter. As far as formal systems are concerned, one could achieve this by embedding LCF in the logic described in Chapter 3. In this mixed system, terms would be (syntactically) recognizable as being monotone or continuous, and the appropriate rules of inference could be applied accordingly. The logic would not be very different from the other two we describe in this work. For example, a good candidate for the induction rule would be

\[ \text{rule M: } \frac{P \vdash g(UU) \subseteq h(UU) \quad P, g(x) \subseteq h(x) \quad g(f(x)) \subseteq h(f(x))}{P \vdash g(\mu x. f(x)) \subseteq h(\mu x. f(x))} \]

where \( x \) must not be free in \( P \) and \( g \) must be continuous, while \( h \) and \( f \) only need be monotone. (This rule was independently suggested by Hitchcock-Park [8].) Its justification is very similar to that of rule RT in the preceding chapter.

Remarkably enough, there seems to be no real need to get involved in this rather complex mixed system: as long as all the terms used in the proofs denote computable functions, any of the results of Chapter 3
will still hold in LCF. For example, if we restrict ourselves to using only computable assertions, the inductive assertions method can be justified in exactly the same way. The only technique for which this constitutes a real problem is transfinite induction, and we shall give it special attention in Section 2.1.

1. Description of LCF

The formal system that we shall use is, except for some trivial changes, taken from Milner [18]. It is a typed λ-calculus version of a logic designed by Scott [50]. (We assume the reader who is interested in the technical details to be familiar with Milner's work.)

1.1 Syntax

The terms of the logic are intended to denote the computable functions of various types. Each term should therefore be subscripted with its type, but we shall almost always omit this subscript.

Terms are defined recursively as:

(1) Identifiers: $g, p, F, r, s, x, y \ldots$ (at each type) or constants:
    
    $\text{UU}$ (at each type) $\text{TT, FF}$ (at the type Boolean) are terms.

(2) If $s$ is of type $\alpha \rightarrow \beta$ and $t$ of type $\alpha$, then $s(t)$ is a term of type $\beta$.

(3) If $s$ is of type $\alpha$, and $x$ of type $\beta$, then $[\lambda x. s]$ is a term of type $\beta \rightarrow \alpha$.

(4) If $p$ is of type Boolean, $s$ and $t$ of type $\alpha$, then
    
    $\text{if } p \text{ then } s \text{ else } t$
    
    is a term of type $\alpha$.

71
(5) If \( f \) and \( s \) are of type \( \alpha \), then \([\mu f.s]\) is a term of type \( \alpha \).

As an alternative to \([\mu f.s]\), we shall also use the notations \( f \), \( f \leq \tau(f) \) and \( \tau: f \leq s \), where \( \tau = [\lambda f.s] \).

A wff is a conjunction of equalities \( s = t \) or inequalities \( s \leq t \) between terms, separated by commas.

A proof is a sequence \( \phi_0 \vdash \psi_0, \ldots, \phi_n \vdash \psi_n \) of implications between wffs, each of which is obtained by application of the rules of inference, or use of the axioms.

For any term \( s \) or wff \( \phi \), we write \( s[t/x] \) and \( \phi[t/x] \) to designate the result of substituting \( t \) for all the free occurrences of \( x \) in \( s \) and \( \phi \). An occurrence of \( x \) is not free if it is bound by \( \lambda x \) or \( \mu x \).

1.2 Axioms and Rules of Inference

In this description, \( x, y, z, f \) denote variables, \( s \) and \( t \) terms, \( P, Q, R \) wffs.

(a) Axioms

About the Domains

(Reflexivity) \( D_1: \quad \vdash x \leq x \)

(Transitivity) \( D_2: \quad x \leq y, y \leq z \vdash x \leq z \)

(Antisymmetry) \( D_3: \quad x \leq y, y \leq x \vdash x \equiv y \)

(Minimality) \( D_4: \quad \vdash UU \leq x \)
### About the Functions

**Monotonicity**
- **P1:** \( x \leq y \Rightarrow f(x) \leq f(y) \)

**Fixed point**
- **P2:** \( f(\mu x. f(x)) \leq \mu x. f(x) \)

**\(\lambda\)-conversion**
- **P3:** \( \lambda x.s(t) = s[t/x] \)

**Bottoms**
- **P4:** \( \text{bottoms} \)

**Conditionals**
- **P5:**
  - \( \text{if} \ UU \ \text{then} \ x \ \text{else} \ y = UU \)
  - \( \text{if} \ TT \ \text{then} \ x \ \text{else} \ y = x \)
  - \( \text{if} \ FF \ \text{then} \ x \ \text{else} \ y = y \)

### About Formulae

**Inclusion**
- **W1:** \( P \vdash Q \) (\( Q \) is a subset of \( P \))

### (b) Rules of Inference

**Conjunction**
- **R1:** \( P, Q \vdash P, Q \)

**Cut**
- **R2:** \( P, Q \vdash R \)

**Substitution**
- **R3:** \( P, Q \vdash P[s/x], Q[s/x] \)

**Extensionality**
- **R4:** \( P, f(x) \leq g(x) \)

**Cases**
- **R5:** \( P[UU/x], Q, P[TT/x], Q, P[FF/x], Q \)

**Computation induction**
- **R6:** \( P, Q[UU/x], P, Q[f(x)/x], Q[\mu x. f(x)/x] \) (\( x \) not free in \( P \))
1.3 Some Remarks About the Logic

Incompleteness

Using the fact that natural numbers can be defined implicitly within the system, Scott [30] showed that the set of valid implications $P \Rightarrow Q$ is not recursively enumerable, i.e., the logic is incomplete. It also follows directly from the undecidability of equivalence between program schemas that the set of valid theorems $\vdash P$ is not recursively enumerable.

On the other hand, if we just consider terms which correspond to Ianov-schemas (Ianov [10]), the logic becomes complete. (This was proved independently by J. W. deBakker and R. Milner.) Another decidable sub-theory of LCF is described in Courcelles-Kahn-Vuillemin [5].

The Induction Rule is a Generalization of McCarthy's Recursion Induction

We shall use the fixed-point induction formulation of McCarthy's rule: $f(y) \equiv y \vdash \mu x. f(x) \equiv y$. This rule is easily derivable from computation induction. In order to show that computation induction cannot be derived from fixed-point induction, we shall exhibit a theorem of the logic which cannot be proved by fixed-point induction. One such theorem is:

$$\sigma(\tau(x)) \equiv \tau(\sigma(x)), \sigma(UU) \equiv \tau(UU) \vdash \mu x. \sigma(x) \equiv \mu x. \tau(x).$$

In order to prove that it cannot be derived using only fixed-point induction, notice that after removing the induction rule, neither the

* More precisely, if we replace the induction rule of LCF by fixed-point induction, the set of theorems of this modified logic is a strict subset of the theorems of LCF.
axioms, nor the inference rules require continuity in order to be valid. We can thus define the following countermodel:

Terms will denote the hierarchy of monotone functions constructed over the following base domain:

The counterexample to our theorem is provided by the functions $f$ and $g$ defined by

$$f(a_1) = g(a_1) = a_{i+1}; f(a) = f(b) = b;$$

$$f(c) = f(d) = g(b) = g(d) = d; g(a) = g(c) = c.$$ 

These two functions satisfy the hypothesis but not the conclusion -- $f(UU) = g(UU)$, $fg = gf$ while $\mu x f(x) \neq \mu x g(x)$ -- of our theorem, which is therefore not provable within this system.* Actually, the same example can be used to prove that rule $RT$ (see Chapter 3, Section 1.6) is also less powerful than computation example.

The theorem is in itself an interesting one and gives in some cases an elegant way for proving equivalence between programs. For example, the functionals

---

* With some slight changes, this counterexample can be used to answer a question raised by Scott [30].
\[ P_1(F)(x,y) = \text{if } x = 0 \text{ then } y \text{ else } F(x-1,y+1) \]
\[ P_2(F)(x,y) = \text{if } x = 0 \text{ then } y \text{ else } F(x-1,y)+1 \]

and
\[ P_3(F)(x,y) = \text{if } x = y \text{ then } y \text{ else } x.F(x+1,y) \]
\[ P_4(F)(x,y) = \text{if } x = y \text{ then } x \text{ else } y.F(x,y-1) \]

over the natural numbers are such that:
\[ P_1(\mathord{\text{U}}) \equiv P_2(\mathord{\text{U}}) , \ P_1 P_2 \equiv P_2 P_1 \ \text{and} \ \ P_3(\mathord{\text{U}}) \equiv P_4(\mathord{\text{U}}) , \ P_3 P_4 \equiv P_4 P_3 . \]

The proofs of equivalence between \( F \leq P_1(F) , \ F \leq P_2(F) \) and \( F \leq P_3(F) , \ F \leq P_4(F) \) respectively then follow.

1.4 Some Examples of Proofs

In order to demonstrate some practical aspects of the method, we shall present some examples of proofs by computation induction.

To improve readability, the following conventions will be adopted from now on:

(1) We shall omit the proofs that \( f(...,\text{U},...) \equiv \text{U} \) whenever they are straightforward.

(2) We shall use freely the equality
\[ f(..., \text{if } p \text{ then } a \text{ else } b, ...) = \text{if } p \text{ then } f(...,a,...) \]
\[ \text{else } f(...,b,...) \]
whenever it is easy to establish that \( f(...,\text{U},...) \equiv \text{U} \).

(3) In the arguments by cases on some variable \( p \), we shall omit the case \( p = \text{U} \) whenever it causes no problem.
(4) We shall use the parallel induction rule for systems of mutually recursive definition. Let us describe the situation on the example \[ F \subseteq \sigma(F, G) \quad \text{and} \quad G \subseteq \tau(F, G) \], the generalization to more complex systems being straightforward. The rule we wish to use is

\[
P \vdash Q\{UU/x\}\{UU/y\}
\]

\[
P, Q \vdash Q\{\sigma(x, y)/x\}\{\tau(x, y)/y\}
\]

\[
P \vdash Q\{F/x\}\{G/y\}
\]

\((x, y\text{ not free in } P)\)

Actually, a more accurate notation would be \( F \equiv \mu f. \sigma(f, \mu g. \tau(f, g)) \)

and \( G \equiv \mu g. \tau(\mu f. \sigma(f, g), g) \).

The justification of this rule in the general case can be found in deBakker-Scott [6] or Hitchcock-Park [8].

If \( F \) and \( G \) happen to have the same type, we can also use the following more intuitive justification of the rule:

Using the pairing function \( \pi = \lambda x, y. [\lambda p. \text{if } p \text{ then } x \text{ else } y] \),
we can define \( \mathcal{F} = \pi(F, G) \). The components are then retrieved as \( F \equiv \mathcal{F}(\text{TT}) \) and \( G \equiv \mathcal{F}(\text{FF}) \), and \( \mathcal{F} \) can be defined by \( \mathcal{F} \subseteq \pi(\sigma(\mathcal{F}(\text{TT}), \mathcal{F}(\text{FF})), \tau(\mathcal{F}(\text{TT}), \mathcal{F}(\text{FF}))) \). The previous rule is then a direct translation of the ordinary computation induction as applied to \( \mathcal{F} \).

(5) For all the examples where computations are meant over some specific data-type -- integer, natural numbers, sets, lists, etc. ... -- we assume implicitly that the axioms for the corresponding data-types are put as premises of the Ways to axiomatize those various domains are described in Milner-Weyrauch [21] and in Newey [25].
Example 1. Let us consider the program schema

\[ \tau_n: f(x) \leftarrow \text{if } p(x) \text{ then } x \text{ else } f^n(h(x)) \],

where \( f^n(x) = f(f(\ldots(f(x)\ldots)) \) (\( n \) times), and \( f^0(x) = x \).

We wish to prove that the equality \( \tau_n \equiv \tau_m \) holds for all natural numbers \( n \geq 1 \) and \( m \geq 1 \).

We shall first prove that

\[ f_{\tau_n}^{k+1} \equiv f_{\tau_n}^k \quad \text{for any } k \geq 0 \quad \text{(a)} \]

Let \( P[f] \) be \( f_{\tau_n}^k f \equiv f \). We shall prove \( P[f_{\tau_n}] \) by computation induction.

**Base** If \( f \equiv UU \) then \( P(UU) \) is \( f_{\tau_n}^k (UU) \equiv UU \), i.e.,

\[ f_{\tau_n}^k (UU(x)) \equiv UU(x) \]

which is easily verified, assuming

\[ p(UU) \equiv UU \quad \text{(b)} \]

**Induction** Assuming that \( P(f) \) is true,

\[ f_{\tau_n}^k (\tau_n(f)(x)) \equiv f_{\tau_n}^k (\text{if } p(x) \text{ then } x \text{ else } f^n(h(x))) \]

(definition of \( \tau_n \))

\[ = \text{if } p(x) \text{ then } x \text{ else } f_{\tau_n}^k (h(x)) \]

(properties of \( f_{\tau_n} \))

\[ = \text{if } p(x) \text{ then } x \text{ else } f_{\tau_n}^n(h(x)) \]

(induction hypothesis)

\[ = \tau_n(f)(x) \quad \text{(c)} \]
Now that equation (a) has been proved, let us consider

\[ \tau_m(f^n)(x) = \begin{cases} p(x) & \text{if } p(x) \\ x & \text{else} \end{cases} f^n h(x) \]

\[ = \begin{cases} p(x) & \text{if } p(x) \\ x & \text{else} \end{cases} f^n h(x) \quad \text{(by (a))} \]

\[ = \begin{cases} p(x) & \text{if } p(x) \\ x & \text{else} \end{cases} f^n h(x) \quad \text{(by (a) again)} \]

\[ = \tau_n(f^n)(x) = f^n(x). \]

It follows by fixed-point induction that \( f^n \equiv f^n \) and by symmetry \( f^n \equiv f^n \).

**Example 2.** Let us consider the two "squaring" programs

\[ \tau: F(x,y,z) \leq \begin{cases} 0 & \text{if } x = 0 \\ y & \text{else} \end{cases} F(x-1,y+z,z) \]

and

\[ \sigma: G(x,y) \leq \begin{cases} 0 & \text{if } x = 0 \\ y & \text{else} \end{cases} G(x-1,y+2x-1) \]

over the natural numbers. We wish to show that \( f^n(x,0,x) = g(x,0) \).

Let \( P(f,g) \) be \( f(y,x(x-0),x) = g(y,x^2-0^2) \). If we can prove \( P(f^n,g_n) \), the desired conclusion will follow by choosing \( x \) equal to \( y \).

**Base** Proving \( P(UU,UU) \) is straightforward.

**Induction** Assuming \( P(f,g) \), consider

\[ \tau(f)(y,x(x-0),x) = \begin{cases} y = 0 & \text{if } y = 0 \text{ then } x(x-0) \text{ else } f(y-1,x(x-y)+x,x) \\ \text{definition of } \tau \end{cases} \]

\[ = \begin{cases} y = 0 & \text{if } y = 0 \text{ then } x^2 \text{ else } f(y-1,x(x-(y-1)),x) \\ \text{induction hypothesis} \end{cases} \]

\[ = \begin{cases} y = 0 & \text{if } y = 0 \text{ then } x^2-0^2 \text{ else } g(y-1,(x^2-0^2)+2y-1) \\ \text{induction hypothesis} \end{cases} \]

\[ = \sigma(g)(y,x^2-0^2). \]
Example 3. (S. Ness) Let us consider the following two LISP functions

\[ F(x) \triangleq \begin{cases} \text{if } \text{atom}(x) \text{ then } x \cdot \text{NIL} & \text{else } F(\text{car}(x)) \ast F(\text{cdr}(x)) \end{cases} \]

and

\[ G(x, y) \triangleq \begin{cases} \text{if } \text{atom}(x) \text{ then } x \cdot y & \text{else } G(\text{car}(x), G(\text{cdr}(x), y)) \end{cases} \]

where \( \ast \) represents the append function. We shall prove by computation induction that \( G(x, y) \equiv F(x) \ast y \) (over the domain of lists).

**Base** The equality \( UU \equiv UU \ast y \) is a consequence of the definition of \( \ast \).

**Induction** If

\[ A(x, y) \equiv \begin{cases} \text{if } \text{atom}(x) \text{ then } x \cdot \text{NIL} & \text{else } f(\text{car}(x)) \ast f(\text{cdr}(x)) \ast y \end{cases} \]

then

\[ A(x, y) \equiv \begin{cases} \text{if } \text{atom}(x) \text{ then } (x \cdot \text{NIL}) \ast y & \text{else } (f(\text{car}(x)) \ast f(\text{cdr}(x))) \ast y \end{cases} \]

\[ \equiv \begin{cases} \text{if } \text{atom}(x) \text{ then } x \cdot y & \text{else } f(\text{car}(x)) \ast (f(\text{cdr}(x)) \ast y) \end{cases} \]

(LISP axioms)

The conclusion

\[ A(x, y) \equiv \begin{cases} \text{if } \text{atom}(x) \text{ then } x \cdot y & \text{else } g(\text{car}(x), g(\text{cdr}(x), y)) \end{cases} \]

follows then by using the induction hypothesis twice. \( \square \)
2. Modelling Some Proof Techniques Within LCF

Looking back at Chapter 3, we realize that Section 2.3 on termination of programs is the only place where we actually used functions which are not continuous. We therefore have to demonstrate how the technique of structural induction, as described for example, in Burstall [1] or Manna-Ness-Vuillemin [15] can be modelled within LCF.

Finally, a method which was not accounted for in Chapter 3, since its justification requires continuity, is that of Morris [25] and we shall study it in Section 2.2.

2.1 Structural Induction

Actually, the word structural induction covers two rather different techniques. The first one is a simple generalization of the induction principle on natural numbers, while the other one is a statement of Noetherian induction applied to arbitrary well-founded sets, which is the most general induction principle known to man.

Simple Structural Induction

(a) Mathematical Induction

The usual formulation of this principle for natural numbers is:

\[
\begin{align*}
\text{from} & \quad p(0) \quad \text{and} \quad \forall x (p(x) = p(x+1)) \\
\text{infer} & \quad \forall x p(x) .
\end{align*}
\]

Let the predicate \( n(x) \leq \text{if } x = 0 \text{ then T T else } n(x-1) \) characterize the natural numbers in our system. (We assume the usual axioms about 0, 1, =, +, - as described in Newey [25].) Let \( p(x) \) be any predicate which can be expressed as a term of the \( \mu \)-calculus.
From the premises
\[ p(x) \equiv \text{TT}, \quad \text{if } x = 0 \text{ then } \text{TT else } p(x-1) \equiv p(x) \]
we can infer by fixed-point induction that \( n(x) \equiv p(x) \), i.e., that \( p(x) \) holds for any natural number \( x \).

In other words,

\[
\text{from } p(0) = \text{TT and } p(x) = \text{TT then } p(x+1) = \text{TT}
\]
\[
\text{infer } n(x) = \text{TT } \land \ p(x) = \text{TT}.
\]

This method applies to any data-type which is recursively defined by a semi-computable predicate. For example, the domain \( \Sigma^* \) of words over some vocabulary \( \Sigma \) can be characterized by

\[
\text{word}(x) \equiv \text{if } x = \text{\texttt{A}} \text{ then } \text{TT else } \text{word}(t(x))
\]

and the corresponding principle is:

\[
\text{from } \text{if null}(x) \text{ then } p(A) \text{ else } p(t(x)) = \text{TT } \land \ p(h(x),t(x)) = \text{TT}
\]
\[
\text{infer } \text{word}(x) = \text{TT } \land \ p(x) = \text{TT}.
\]

(We are again assuming axioms about \( \Lambda, =, \cdot, h, t \).)

**Example 4.** Let us consider two programs for computing the factorial function:

\[
F(x) \equiv \text{if } x = 0 \text{ then } 1 \text{ else } x \times F(x-1)
\]
\[
G(x,y) \equiv \text{if } x = y \text{ then } 1 \text{ else } (y+1) \times G(x,y+1).
\]

In order to show that \( G(x,0) = F(x) \), we shall prove that \( n(x-y) \equiv p(x,y) \)
where \( p(x,y) \) is \( G(x,y) \times F(y) = F(x) \). Let \( r \) be defined as

\[
r(x,y) \equiv \text{if } x = y \text{ then } \text{TT else } r(x,y+1).
\]
We first prove that \( r(x,y) = n(x-y) \). Then, since
\[
p(x,y) = \text{if } x = y \text{ then } F(x) = F(y) \text{ else } (y+1)G(x,y+1) \cdot F(y) = F(x)
\]
\[
= \text{if } x = y \text{ then } \text{TT} \text{ else } p(x,y+1)
\]
we can conclude that \( r(x,y) \subseteq p(x,y) \), i.e., \( n(x-y) \subseteq p(x,y) \). This last inequality is equivalent to \( y \leq x \Rightarrow \text{TT} \Rightarrow p(x,y) = \text{TT} \).

This technique required \( p \) to be a computable predicate; if \( P \) is an arbitrary well-formed formula, a generalization (Milner [18]) yields:
\[
Q \vdash P[0/x] \quad Q, P \vdash P[(x+1)/x]
\]
\[
Q \vdash n(x) \Rightarrow P \quad (x \text{ not free in } Q)
\]
where \( q = s \equiv t \) means \( \text{if } q \text{ then } s \text{ else } \text{UU} \subseteq \text{if } q \text{ then } t \text{ else } \text{UU} \),
and \( q = w_1, w_2 \) means \( q = w_1 \), \( q = w_2 \).

Example 5. Let
\[
\text{rev}(x) \triangleq F(x, A)
\]
\[
F(x, y) \triangleq \text{if } x = A \text{ then } y \text{ else } F(t(x), h(x) \cdot y)
\]
In order to show that \( \text{rev}(\text{rev}(x)) = x \), one can prove that \( \text{word}(x) \Rightarrow P \), where \( P \) is \( \text{rev}(F(x,y)) = F(y,x) \).

(b) Course of Values Induction

Another formulation of the induction principle over the natural numbers is the following:
\[
\text{from } \forall x[\forall y[y < x \Rightarrow p(y)] \Rightarrow p(x)]
\]
\[
\text{infer } \forall x p(x) .
\]
Whenever \( p \) is computable, this course of value induction can also be modelled directly because the operation of bounded quantification is computable and can be defined as:

\[
\forall = \mu f. \left[ \lambda x, p. \begin{cases} \text{if } x = 0 \text{ then } \text{TT} & \text{else } \text{if } p(x-1) \text{ then } f(x-1) & \text{else } \text{UU} \end{cases} \right].
\]

According to this definition, \( \forall(x, p) \) "means" \( \forall y (y < x \Rightarrow p(y)) \). We can define the partial predicate \( m = \mu p. \lambda x [\forall(x, p)] \) and prove that \( m = n \) where \( n = \mu f. \left[ \lambda x. \begin{cases} \text{if } x = 0 \text{ then } \text{TT} & \text{else } f(x-1) \end{cases} \right] \) as follows.

(i) \( m \subseteq n \).

\[
\forall(x, n) = \begin{cases} \text{if } x = 0 \text{ then } \text{TT} & \text{else } \begin{cases} \text{if } n(x-1) \text{ then } \forall(x-1, n) & \text{else } \text{UU} \end{cases} \end{cases}
\]

\( \subseteq \begin{cases} \text{if } x = 0 \text{ then } \text{TT} & \text{else } n(x-1) \end{cases} \)  
(by cases using the fact that \( \forall(x-1, n) \subseteq \text{TT} \))  
\( \equiv n(x) \).

Hence, \( m \subseteq n \) follows by fixed-point induction.

(ii) \( n \subseteq m \).

Since \( x = 0 \equiv F \vdash m(x-1) = \forall(x-1, m) \) by definition of \( m \), we have \( x = 0 \equiv F \vdash (\text{if } m(x-1) \text{ then } \forall(x-1, m) \text{ else } \text{UU}) = m(x-1) \)  
(by cases again, using the fact that \( m(x-1) \subseteq \text{TT} \)). It follows that

\[
m(x) = \begin{cases} \text{if } x = 0 \text{ then } \text{TT} & \text{else } \begin{cases} \text{if } m(x-1) \text{ then } \forall(x-1, m) & \text{else } \text{UU} \end{cases} \end{cases}
\]

\( \equiv \begin{cases} \text{if } x = 0 \text{ then } \text{TT} & \text{else } m(x-1) \end{cases} \).

The conclusion \( n \subseteq m \) then follows by fixed-point induction again.

\[\square\]

Having established the equivalence \( n \equiv m \), we can justify the following rule of inference:
from $\forall (x,p) = TT \Rightarrow p(x) = TT$

infer $n(x) = TT \Rightarrow p(x) = TT$.

A similar rule can be derived for well-formed-formulas.

Example 6. Let us consider a modified version of McCarthy's 91-function:

$$F(x) \leq \text{if } x < 0 \text{ then } x+1 \text{ else } F(F(x-2)) .$$

In order to prove that $n(x) = TT \land (F(x) = 0) = TT$, let $p = \lambda x. [F(x) = 0]$.

The equalities $(F(0) = 0) = TT$ and $(F(1) = 0) = TT$ have to be checked first and then, assuming $\forall (x,p) = TT$ and $x > 1 = TT$, we prove $p(x)$:

$$p(x) = (F(x) = 0) = (F(F(x-2)) = 0)$$

$(x < 0 \equiv FF)$

$$= (F(0) = 0)$

$(p(x-2) = TT)$

$$= TT$$

(separate check)

Transfinite Induction

Let $<$ be a well-founded relation over the domain $\mathcal{D}$. We showed in Chapter 3 how to derive the following principle:

$$\text{from } \forall x \in \mathcal{D} \forall y \in \mathcal{D} (y < x \Rightarrow p(y)) \Rightarrow p(x)$$

infer $\forall x \in \mathcal{D} p(x)$.

The proof given precluded continuity and is therefore not applicable in the present context.

We shall describe a technique for deriving in LCF any instance of the above rule one may need in "practical" cases. Here, a "practical" well-founded relation is either one of the basic orderings described in the preceding section or an ordering constructed as a well-founded...
collection of well-founded relations.\(^*/\) 

Since we already know how to handle the "base" case, all we need to model is the construction of complex orderings from simpler ones.

Let \(<\) be a computable well-founded relation over the recursive domain \(B_1\), and, for any \(x \in B_1\), let \(<\) be a well-founded relation over \(B_2(x)\). We then consider the domain \(D = \{(x,y) | x \in B_1, y \in B_2(x)\}\) together with the ordering \(<\) where \((x,y) < (x',y')\) is equivalent to \(x \prec x'\) or \((x = x') \land (y < y')\). Assuming we already know that the rules

\[
\begin{align*}
(1) & \quad Q, x' < x \Rightarrow P[x'/x] \vdash P \\
& \quad \frac{Q \vdash B_1(x) \Rightarrow P}{(x \text{ and } x' \text{ free in } Q)}
\end{align*}
\]

and

\[
\begin{align*}
(2) & \quad Q, y' < y \Rightarrow P[y'/y] \vdash P \\
& \quad \frac{Q \vdash B_2(x,y) \Rightarrow P}{(y \text{ and } y' \text{ free in } Q)}
\end{align*}
\]

are valid, we want to justify the rule

\[
\begin{align*}
(3) & \quad Q, (x',y') < (x,y) \Rightarrow P[x'/x][y'/y] \vdash P \\
& \quad \frac{Q \vdash B(x,y) \Rightarrow P}{(x, x', y \text{ and } y' \text{ free in } Q)}
\end{align*}
\]

where \(B(x,y) = B_1(x) \land B_2(x,y)\). Assuming rules (1) and (2) and the hypothesis of rule (3), we shall prove that \(Q \vdash B_1(x) \land B_2(x,y) \Rightarrow P\) in two nested inductions, by distinguishing between the following cases:

\(^*/\) This is equivalent to multiplying the corresponding ordinals. The operation corresponding to ordinal exponentiation can be modelled just as well, although we could never find any practical application for it.
The hypothesis of (1) is then \( Q, x' < x \rightarrow P[x'/x] \rightarrow P \); hence rule (1) implies that \( Q \rightarrow B_1(x) = P \) and, a-fortiori, \( B(x,y) = P \).

2) \( x' < x \equiv FF \).

Since \( (x,x') < (y,y') = TT \) is the only interesting case, one can assume that \( x = x' \) and \( y' < y \). The hypothesis of (3) then becomes \( Q, y' < y \rightarrow x = P[y'/y] \rightarrow P \) which, by rule (2), implies that \( Q \rightarrow B_2(x,y) = P \) and the conclusion \( Q \rightarrow B(x,y) = P \) then follows.

Example 7. Using the technique we just described, we shall prove that Ackermann's function

\[
A(x,y) = \begin{cases} 
  y+1 & \text{if } x = 0 \\
  A(x-1, A(x,y-1)) & \text{if } y = 0 \\
  A(x-1, A(x,y-1)) & \text{else }
\end{cases}
\]

is defined over the natural number.

Let \( P \) be \( n(y) \leq n(A(x,y)) \), where

\[
n = \mu f. [\lambda x. \begin{cases} 
  TT & \text{if } x = 0 \\
  f(x-1) & \text{else }
\end{cases}].
\]

We shall prove that \( n(x) \vdash P \) which "means" that, whenever \( x \) and \( y \) are natural numbers, \( A(x,y) \) must also be a natural number, is true.

The main proof is by induction on \( x \).

Base: \( x = 0 \). In this case, \( P[0/x] \) is \( n(y) \leq n(y+1) \) which is always true, as a consequence of the axioms about \( 0, 1 \) and \( + \).

Induction. Assuming \( P[x-1/x] \), that is \( n(y) \leq n(A(x-1,y)) \) we must prove \( P \), i.e., \( n(y) \leq n(A(x,y)) \). Let us argue by cases on the predicate \( y = 0 \):
case \( y = 0 \equiv \text{TT} \). Since in this case \( A(x,y) = A(x-1,1) \), it is sufficient to prove that
\[
n(0) \subseteq n(A(x-1,1)) \tag{a}
\]
We know by the induction hypothesis that \( n(1) \subseteq n(A(x-1,1)) \) and equation (a) follows, since \( n(0) = n(1) \).

case \( y = 0 \equiv \text{FF} \). Choosing \( y = A(x,y-1) \) in the induction hypothesis \( P[x-1/x] \) gives us:
\[
n(A(x,y-1)) \subseteq n(A(x-1,A(x,y-1)) \).
\]
Since in this case \( A(x,y) = A(x-1,A(x,y-1)) \) the last inequality implies that \( n(A(x,y-1)) \subseteq n(A(x,y)) \). Hence, by a "nested" fixed-point induction applied to the predicate \( q(y) \equiv n(A(x,y)) \) we conclude that \( n(y) \subseteq n(A(x,y)) \).

\[\square\]

2.2 Truncation Induction

Recalling Kleene's first recursion theorem, we can characterize the least fixed-point of the program \( F \leftarrow \tau(F) \) as the least upper bound of the sequence of functions \( f_0, f_1, \ldots, f_n, \ldots \) defined by \( f_0 = \text{UU} \) and \( f_{n+1} = \tau(f_n) \). The rule of truncation induction, as Morris [23] named it, can be formulated as

Rule TI

from \( Q \vdash P[f_n/f] \) for any natural number \( n \)
infer \( Q \vdash P[f_/f] \).

Actually Morris [23] used the formulation

from \( Q, \forall m(m < n \Rightarrow P[f_m/f]) \vdash P[f_n/f] \)
infer \( Q \vdash P[f_n/f] \) for all \( n \)

88
which is equivalent to ours since Section 2.1 of this chapter shows
how to obtain the missing step, namely:

\[
\begin{align*}
& \text{from } q, \forall m (m < n \Rightarrow P[f_m/f] + P[f_n/f]) \text{ for all } n \\
& \text{infer } q + P[f_n/f] \text{ for all } n .
\end{align*}
\]

A first problem which arises with rule TI is that, since it
requires knowledge about the integers in its formulation, it cannot
even be expressed in pure LCF. (This should be regarded as an advantage
of Scott's formulation of the rule.)

More dramatic is the fact that, even in an LCF with integers
(where TI can then be expressed), there does not seem to be any way to
justify it, despite the fact that it is clearly valid in any standard
model. It is possible to get around this difficulty by slightly extending
the logic. What is needed is a formal way to talk about limits. This
can be achieved by embedding data-types into complete lattices, thus
going back to the original definition of data-types in Scott [29]. This
idea entails the following extensions to LCF:

1. Introduce constant terms \( \infty \) (for undefined) at each type. The
corresponding axioms are \( x \leq \infty \) and \( \infty \leq x \). In
the case-rule, the case \( P[\infty/x] + q \) should be added to the premise.

2. If \( s \) and \( t \) are terms of type \( \alpha \), then \( \text{sup}(s,t) \) should also be
a term of type \( \alpha \). It is axiomatized by \( x \leq \text{sup}(x,y) \),
\( y \leq \text{sup}(x,y) \) and \( x \leq z, y \leq z \Rightarrow \text{sup}(x,y) \leq z \).

3. We could introduce \( \text{inf}(x,y) \) in the same way, although we won't
need it. Also, one should make up his mind as to what
\( \text{if } \infty \text{ then } x \text{ else } y \) ought to mean. Two extreme possibilities are
\( \text{if } \infty \text{ then } x \text{ else } y = \infty \) or \( \text{if } \infty \text{ then } x \text{ else } y = \text{sup}(x,y) \).

89
In this extended logic (along with the natural numbers) we can then justify rule TI:

First of all, one needs to express the rule within the formal system, and we shall define \( f_n = \tau^n(UU) \) as \( \text{iter}(\tau)(n) \) where

**Definition 1.**

\[
\text{iter} = \mu f.[\lambda \tau, n. \text{if } n = 0 \text{ then } UU \text{ else } \tau(f(n-1))] .
\]

Using this definition, it is easy to prove that

**Lemma 1.**

\[
\text{iter}(\tau)(n) \subseteq \text{iter}(\tau)(n+1)
\]

and

**Lemma 2.**

\[
\text{iter}(\tau)(n) \subseteq f_\tau .
\]

We now wish to prove that \( f_\tau \equiv \bigcup_{n \geq 0} \{ f_n \} \) and, for this purpose, let

**Definition 2.**

\[
\bigcup = \mu f.[\lambda \beta, n. \sup(\beta(n), f(\beta(n+1)))] .
\]

Using an induction on this formal definition of \( \bigcup \), one can then prove that

**Lemma 3.**

\[
\beta(n) \subseteq g \vdash \bigcup(\beta, n) \subseteq g
\]

and

**Lemma 4.**

\[
\beta(n) \subseteq \beta(n+1) \vdash \gamma(\bigcup(\beta, n)) \equiv \bigcup(\lambda x. \gamma(\beta(x)), n) .
\]
Note that Lemma 4 is particularly interesting since it proves that any function \( \gamma \) which can be expressed within the logic must be continuous. Kleene's first recursion theorem may now be expressed as

\[
f_{\gamma} = \bigcup(\text{iter}(\tau),n) \quad \text{(K)}
\]

and proved in two steps.

Firstly, combining Lemmas 2 and 3 yields

\[
\bigcup(\text{iter}(\tau),n) \supseteq f_{\gamma}
\]

Then, the other half of the proof is a little bit more complicated.

\[
\tau(\bigcup(\text{iter}(\tau),n)) = \bigcup(\lambda x. \text{iter}(\tau)(x),n) \quad \text{(Lemmas 1 and 4)}
\]

\[
= \bigcup(\lambda x. \text{iter}(\tau)(x+1),n) \quad \text{(Definition 1)}
\]

\[
\supseteq \bigcup(\text{iter}(\tau),n) \quad \text{(Lemma 1)}
\]

The conclusion

\[
f_{\gamma} \supseteq \bigcup(\text{iter}(\tau),n)
\]

follows by fixed-point induction.

We now have all the machinery required for justifying truncation induction. Assuming for simplicity that the well-formed-formula we want to use is of the form \( \alpha(f) \subseteq \mathcal{G} \), we must prove that

\[
\alpha(\text{iter}(\tau)(n)) \subseteq \mathcal{G} \quad \alpha(f_{\gamma}) \subseteq \mathcal{G}.
\]

Lemmas 1 and 4 tell us that

\[
\bigcup(\lambda x. \alpha(\text{iter}(\tau)(x)),n) = \alpha(\bigcup(\text{iter}(\tau),n))
\]

and therefore

\[
\alpha(\text{iter}(\tau)(n)) \subseteq \mathcal{G} \quad \alpha(\bigcup(\text{iter}(\tau),n)) \subseteq \mathcal{G}.
\]
Since \( f^* = \mathcal{U}(\text{iter}(\tau), n) \) by Kleene's theorem, this last implication reduces to
\[
\alpha(\text{iter}(\tau)(n)) \subseteq g \implies \alpha(f^*_\tau) \subseteq g
\]
which is what we wanted to prove.

Applications

First of all, some equivalence proofs seem to be more natural (and may in fact require) using truncation induction.

For example, if two functionals \( s \) and \( t \) satisfy \( s(UU) = t(UU) \) and \( st = t^2s \), the natural truncation induction predicate would be \( \sum_{n=1}^{\infty} t^n(UU) = s^n(UU) \), and therefore \( \mu f. s(f) = \mu f. t(f) \). If one uses the machinery we just developed, this informal proof can very easily be carried through within the extended logic. Actually, a more elegant proof (not using natural numbers) would be the following:

Define
\[
M(g,f)(x) = \sup(f(x),M(g,f)(f(x)))
\]
and
\[
N(g,f)(x) = \sup(f(x),N(\lambda x. g(g(x)),f)(g(x))).
\]
(\( M(s,\lambda f.f)(UU) \) represents \( \cup_{n \geq 0} s^n(UU) \) and \( N(t,\lambda f.f)(UU) \) represents \( \cup_{n \geq 0} t^{2^n-1}(UU) \).) One can then prove that \( f^*_s = M(s,\lambda f.f)(UU) \) and
\[
f^*_t = N(t,\lambda f.f)(UU) \]
and finally that
\[
s(UU) = t(UU), \lambda f. s(t(f)) = \lambda f. t(t(s(f))) \implies M(s,\lambda f.f)(UU) = N(s,\lambda f.f)(UU).
\]

\(*\)
This example is due to J. W. de Bakker. Robin Milner has a proof of it in pure LCF. The reader may find out for himself how tricky it is, and further away from the intuitive proof than the one presented here.
Similarly, let us consider the following version of the induction rule

rule R6:

\[ Q \vdash h \subseteq f, P[h/f] \quad Q, P \vdash P[(f)/f] \quad \frac{Q \vdash P[f/f]}{Q \vdash P[f/f]} \quad (f \text{ not free in } Q) \]

where the base of computation induction is not taken at the undefined element \( \text{UU} \) but at any element \( h \subseteq f \).

Informally and assuming \( F \) to be \( a(f) \leq \beta(f) \) for simplicity, the hypothesis of the rule implies that \( a(\tau^n(h)) \leq \beta(\tau^n(h)) \) for any \( n \).

On the other hand, \( \text{UU} \subseteq h \subseteq f \) implies \( \tau^n(\text{UU}) \subseteq \tau^n(h) \subseteq f \) and therefore \( \bigcup_{n \geq 0} \{\tau^n(h)\} = f \). The conclusion \( a(f) \leq \beta(f) \) then follows easily from the continuity of \( a \) and monotonicity of \( \beta \).

This argument can be carried through formally within the extended LCF. In particular, it applies to the following theorem

\[ \vdash f \subseteq f \]

\[ \tau(f) \subseteq f \quad \vdash \tau(a(f)) \subseteq \sigma(f) \quad \frac{\vdash \tau(\sigma(f)) \subseteq \sigma(f)}{\vdash \tau(\sigma(f)) \subseteq \sigma(f)} \]

which is provable in the extended logic; the author does not know how to prove it (and conjectures are not provable) in pure LCF.
Conclusion

In the actual state-of-the-art, Scott's approach to the semantics of programming languages seems to be the most promising one. The theoretical foundations are sound, and a natural step would now be to describe fully the semantics of a full-size programming language, along the lines of Scott-Strachey [32], Milner-Weyrauch [21], or Reynolds [27].

Another wide open and promising area seems to be that of semantics of operating-systems and parallel processes. Steps in this direction were taken by Kahn [11], Milner [20], and others.

Finally, the question of a "best" logic for expressing a theory of computation remains. As alternatives to ICF, the systems of Hitchcock-Park [8] and deBakker-deRoever [5] have some interesting features; in an unpublished work, Scott and Milner also considered the possibility of extending ICF to a "type-free" logic whose semantic domain is one of Scott's models of the λ-calculus.

In any case, more efforts should be put in studying the existing systems. In particular, ICF provides a nice framework for the area of schematology, where existing results can be expressed and sometimes simplified, and where new and interesting questions arise. (See deBakker [4] and Courcelles-Kahn-Vuillemin [3].)
