ABSTRACT

An analytical study was undertaken to determine the two-dimensional wall conduction effects in an internally finned, rotating heat pipe. The finite element method was employed to generate computer results for a copper condenser with triangular fins. Heat transfer rates were shown to be approximately seventy-five percent greater than that predicted by an earlier, one-dimensional analysis. Heat transfer rates were found to be insensitive to rotational speed and fin half-angle. Due to numerical difficulties within the finite element program, no data was obtained for the finned, stainless steel condenser.

I. INTRODUCTION

A. THE ROTATING, NON-CAPILLARY HEAT PIPE

The rotating, non-capillary heat pipe is a self-contained device designed to transfer large quantities of heat in a rotating system. The heat pipe contains an evaporator, a condenser, and a working fluid as shown in Figure 1. The working fluid is vaporized by heat addition at the evaporator. The vapor flows toward the condenser end as a result of a vapor pressure differential. There, the vapor condenses on the inner wall, releasing its latent heat of vaporization. The condensate then returns to the evaporator where the cycle is repeated.

The difference between the conventional heat pipe and the rotating, non-capillary heat pipe is the condensate return mechanism. A conventional heat pipe employs the capillary pumping action of an internal porous wick to transport the condensate to the evaporator. The disadvantage of this scheme is the resistance to condensate flow through the wick. Additionally, the presence of nucleate boiling in the evaporator could create bubbles inside the wick structure, reducing the effectiveness of the pumping action [1]. In the rotating heat pipe, rotation about its longitudinal axis establishes a centrifugal force field which, when combined with a slight

1 Numbers in brackets indicate references listed in the Bibliography.
taper of the condenser section, forces the condensate toward
the evaporator. At high rotation rates, the heat transfer
rate is significantly increased over the rate achieved in
conventional heat pipes of similar dimensions.

B. BACKGROUND

Previous analyses [2-9] of the rotating heat pipe have
been conducted to determine its performance characteristics.
These studies determined, among other things, that under
normal circumstances, the heat transfer rate is limited pri-
marily by the amount of heat which can be transferred through
the condenser wall.

In an effort to improve the condenser heat transfer per-
formance, Schafer [8] estimated and compared the thermal
resistances across the condensate film, the wall, and the
outside convective film using Woodard's earlier data [9].
He showed that with the use of outside spray cooling and a
thin copper wall, the controlling resistance is the inside
film resistance. Schafer suggested that this resistance can
be reduced (1) by the proper selection of working fluid, and
(2) through the use of internal axial fins as sketched in
Figure 2a.

Machining axial fins into the inner surface of the con-
denser would improve heat transfer performance through two
mechanisms: a decrease in condensate film thickness near
the apex of each fin, and an increase in inner wall surface
area. However, with the addition of fins, the wall thermal
resistance would also increase due to the increase in effective wall thickness. Of course, the use of copper as the wall material, because of its high thermal conductivity, would minimize the added wall resistance.

Schafer then developed an analytical model of the internally finned condenser for the case of fins of triangular profile (Figures 2a, 2b). In the analysis, he assumed one-dimensional heat conduction through the wall and assumed a linearly decreasing temperature profile from the fin apex (point A) to the midpoint of the trough (point C). Results from the analysis indicated significantly improved heat transfer rates for the finned condenser compared to the smooth condenser. He pointed out, however, that two-dimensional conduction effects may be significant so that a more detailed analysis of the heat conduction problem within the wall was necessary.

C. OBJECTIVES

The objectives of this study were, therefore, to (1) develop an analytical solution to account for two-dimensional conduction effects within the wall for the triangular fin profile, and (2) compare this solution with the solution derived by Schafer.
II. THEORETICAL PROGRAM

A. REVIEW OF SCHAFER ANALYSIS [8]

Schafer's study considered an internal fin geometry represented by Figure 2a. Since the sum of wall thickness and fin height was assumed to be much smaller than condenser radius, an average radius from any point on the axis to the condenser wall was taken to be the distance from the axis to a position midway between the base of the fin and the apex of the fin, $r_1$. The centrifugal acceleration term was then evaluated at this average radius, $r_1 \omega^2$.

The thin wall assumption also allowed the curvature of the wall to be neglected. The problem could then be analyzed using a planar conduction heat transfer model as shown in Figure 2b. Furthermore, because of repetitive geometry the problem could be reduced to the simpler geometry shown in Figure 3. Cartesian coordinates were then selected, as shown, to permit a simplified fin condensation analysis.

Assumptions in the analysis were based upon the earlier work of Ballback [2]. These assumptions were similar to those used in the Nusselt analysis of film condensation on a wall. The more important of these assumptions are:

(1) steady state operation,

(2) film condensation, as opposed to dropwise condensation,

(3) laminar condensate flow along both the fin and the trough,

(4) static balance of forces within the condensate,
(5) one-dimensional conduction heat transfer through the film thickness (no convective heat transfer),
(6) no liquid-vapor interfacial shear stresses, and
(7) no condensate subcooling.

Additional assumptions in the analysis are noted later.

The complete development of Schafer's finned condenser heat transfer theory is presented in his thesis [8]. However, since the fluid flow and heat transfer theory was applicable to the two-dimensional conduction heat transfer analysis, a summary of his work is presented here, prior to the development of the two-dimensional conduction model.

1. Fin Condensate Mass Flow

A Nusselt analysis was performed for film condensation on the wall of the fin. In this analysis, the fluid momentum equation was constructed to account for the effects of condenser cone half-angle, $\phi$, fin half-angle, $\alpha$, and the centrifugal force field. The pressure differential term was neglected. Condensate flow on the fin was assumed to be in the $z$-direction only.

An expression for fluid velocity, $w(y,z)$, was then derived by substituting the shear stress equation for laminar flow, $\tau_z = \mu_f \frac{\partial w}{\partial y}$, into the momentum equation and solving for $w(y,z)$. Average velocity, $\bar{w}(z)$, was then found by integrating $w(y,z)$ over $y$ from $y = 0$ to $y = \delta(z)$, the local film thickness. This average velocity was then placed in the fin mass flow equation to yield an expression for fluid mass flow rate along the fin per unit condenser length as a function of $\delta(z)$,
\[
M_1(z) = \frac{\rho_f^2 \omega^2 (R_2 + x \sin \phi) \cos \phi \cos \alpha \delta^3(z)}{3 \mu_f}.
\]

(1)

2. Trough Condensate Mass Flow Equation

Fluid flow within the trough was assumed to be one-dimensional in the x-direction and of constant velocity across the width of the trough. Therefore, condensate flowing from the fins into the trough was assumed to accelerate immediately to the velocity of the trough fluid. Cross-sectional area of the trough condensate region was twice the area shown in Figure 4.

The x-direction momentum equation for an infinitesimal fluid element in the trough was constructed with the pressure differential term neglected. The trough mass flow expression was then developed in a manner similar to the development of the fin mass flow equation (1). The average trough velocity was derived and substituted into the trough mass flow equation to yield total mass flow through the trough region,

\[
M_{\text{tot}}(x) = \frac{\rho_f^2 \omega^2 (R_z + x \sin \phi) \delta^*(x) \sin \phi}{3 \mu_f}
\]

\[
(\varepsilon \delta^*(x) + \sin \alpha \cos \alpha \delta^2(x)),
\]

(2)

where the expression in the second parenthesis is the cross-sectional area of the trough condensate region.

Total condensate mass flow was identical to trough condensate mass flow since all condensate eventually flowed to the trough. Therefore, once the total mass flow rate at
any position x was known, through condensate thickness, $\delta^*(x)$, could be determined using equation (2).

3. Condenser Heat Transfer Determination

Schafer assumed zero heat flux boundary conditions on both sides of the wall section shown in Figure 4. Temperature at the fin apex was taken to be fluid saturation temperature since film thickness at this position was assumed to be zero.

He then imposed a linearly decreasing temperature on the inner wall surface from the apex of the fin to the mid-channel position. The surface temperature expression became

$$T_s - T_w(z) = \beta z,$$

where $\beta$ was an unknown constant. This choice of temperature distribution was arbitrary but allowed a simplified one-dimensional conduction analysis of the condenser wall. He then imposed the restriction that no heat transfer would occur through section BE of the wall (Figure 3). All heat transfer through the fin surface, thus, flowed out of the wall through section FE.

Heat transfer through the fin was equated with one-dimensional heat transfer through a rectangular geometry of the same width as section FE, and of height, $t^*$, equal to t plus one-half the fin height (Figure 4). Temperature of the upper surface of the rectangle was set equal to the temperature at a point midway between positions A and B. The expression for heat transfer rate per unit condenser length through the wall and outer convective thermal resistance
of the fin became
\[ \dot{Q}_1(z) = \frac{[(T_s - \frac{\beta z \rho}{2}) - T_\infty]}{(\frac{k_f T}{k_w} + \frac{1}{h_{out}})} \dot{e}_O \varepsilon O. \] (4)

It was then desired to develop an expression for \( \dot{Q}_1(z) \) in terms of the heat transfer rate through the fin condensate film. First, the equation for fin condensate film thickness was derived by differentiating (1) with respect to \( z \) and substituting the result into the differentiated equation for mass flow rate per unit condenser length,

\[ dM_1(z) = \frac{dQ_1(z)}{h_{fg}} = \frac{1}{h_{fg}} [k_f (\frac{T_s - T_w(z)}{\delta(z)})] dz. \] (5)

The expression produced was algebraically rearranged to form a differential equation in \( \delta(z) \),

\[ \delta^3(z) d(\delta(z)) = \frac{k_f (T_s - T_w(z)) \mu_f \frac{1}{\rho_f^2 \omega^2 (R_2 + x \sin \phi) h_{fg} \cos \phi \cos \alpha}} dz. \] (6)

Equation (3) was then substituted in (6) and the result integrated over \( z \) from \( z = 0 \) to \( z \) to give an equation for \( \delta(z) \),

\[ \delta(z) = [\frac{2 k_f \beta \mu_f}{\rho_f^2 \omega^2 (R_2 + x \sin \phi) h_{fg} \cos \phi \cos \alpha}]^{1/4} z^{1/2}. \] (7)

The value for fin heat transfer rate per unit condenser length was then evaluated using

\[ \dot{Q}_1(z^*) = h_{fg} \dot{M}_1(z^*) \] (8)
where \( z^* \) is defined in Figure 4. This expression was set equal to (4) to yield a transcendental equation in \( \beta \),

\[
\frac{[T_s - \frac{\beta z^*}{2} - T_\infty]}{(\frac{t^*}{K_w} + \frac{1}{h_{out}})} = \frac{[1 - (R_2 + x \sin \phi)] h_{fg} \cos \phi \cos \alpha}{3\mu_f^{\frac{1}{4}}} \left( \frac{T_s}{T_{avg}} - \frac{T_{avg}}{2} \right)
\]

where \( \varepsilon_0 \) was the width of the base of the fin. The expressions on the left and right hand sides of this equation were equivalent only when all boundary conditions were satisfied. The task was then to solve iteratively for \( \beta \) until equation (9) was satisfied. \( Q_1(z^*) \) was then determined in equation (4) using the final iterated value of \( \beta \).

Heat transfer rate from the trough region was evaluated using

\[
\dot{Q}_2(x) = k_f \frac{(T_s - T_{avg})}{\delta^*(x)} \frac{\varepsilon}{2}
\]

where \( T_{avg} \) was calculated as an average temperature of the trough wall and \( \varepsilon \) was the total trough width (Figure 4).

A flowchart description of the computer program used in the Schafer analysis is given in Figure 5. The axial length of the condenser was first divided into increments of equal length, \( \Delta x \). Solution of the heat transfer problem was then started by assuming an initial trough condensate thickness, \( \delta^*_1 = 0.00006752 \) feet. This initial value was based upon a mass flow analysis by Sparrow and Gregg of condensation on a rotating disk [10]. It was assumed in
Schafer's analysis that the effect on the Sparrow and Gregg solution of enclosing the disk within the condenser would be minimal. A study of the effects of a ten-fold increase or decrease from the above value of $\delta^*_1$ indicated that the initial $\delta^*_1$ assumption would not affect the heat transfer solution by more than ten percent. Therefore, the determination of an exact value of initial trough condensate thickness was not crucial to the problem.

Calculation of condensate mass flow contribution from the endplate then followed. Then, for each increment $\Delta x$, an initial value of $\beta$ was calculated by removing the $\frac{\beta z_0}{2}$ term from the left side of equation (9) and solving directly for $\beta$. The full equation was then employed to solve iteratively for $\beta$. Calculation of incremental fin heat transfer rate then followed by multiplying the value obtained in (4) by the incremental length, $\Delta x$. Incremental trough heat transfer rate was next evaluated by multiplying equation (10) by $\Delta x$. Incremental trough and fin heat transfer rates were then summed to yield the total incremental heat transfer rate for the geometry of Figure 4.

Total incremental mass flow rate was evaluated by dividing twice the sum of the incremental trough and fin heat transfer rates by the latent heat of vaporization of the fluid. As the incrementation progressed, incremental mass flow rates were added to mass flow from preceding increments to yield $M_{\text{tot}}(x)$. Equation (2) was then solved for $\delta^*(x)$ with the aid of a polynomial rootfinder subroutine. The new value of
\( \delta(x) \) was then used to begin the solution for the next increment. When the total length of the condenser had been traversed, total heat transfer rate was evaluated.

\[
Q_{\text{tot}} = 2 N_{\text{fin}} \sum_{i=1}^{100} \Delta x [Q_1(z^*)_i + Q_2(x)_i].
\]  

(11)

B. TWO-DIMENSIONAL HEAT TRANSFER SOLUTION

1. Introduction

In this study, two-dimensional conduction through the condenser wall was considered in the heat transfer analysis using a finite element solution. The finite element method was chosen over the method of finite differences because of considerations involving wall geometry and computer utilization time. Myers [11] has shown that when these methods are compared for the case of two-dimensional conduction in a rectangular block with heat generation, the finite element method more closely approximates the exact solution when the number of nodal points considered in each method are equal. This is particularly true when the nodal point meshes are coarse.

To achieve the same accuracy as with the finite element method, the finite difference method must use a finer nodal mesh, especially for non-rectangular geometries. Additionally, when fins of different shape are considered, the mesh of the finite difference model must be completely reconstructed for each new shape. In the finite element program, however, a simple change in nodal coordinates is all that is necessary
to accommodate the change in fin shape. Since future studies may analyze the use of varied fin shapes with the rotating heat pipe, it was desired to incorporate the more flexible finite element method in the computer program to avoid having to rearrange the program for each fin shape.

While the accuracy of the finite element method is superior, the finite difference method requires less computer utilization time for the same number of nodal points. If a finite difference model of finer mesh was chosen, the decrease in computer time due to the method might be offset by an increase in time required for the increased number of nodes. The overall improvement in computer utilization time might, therefore, be minimal. As a result, in this study, the choice of method was not based upon computer time requirements. Also, a finite element computer program [12] was available which could be adapted for the purposes of this analysis. For the reasons outlined above, therefore, the finite element method was selected.

The steady state differential equation for conduction heat transfer is given in Arpaci's text [13] as

$$\frac{\partial}{\partial y} (k_y \frac{\partial T}{\partial y}) + \frac{\partial}{\partial z} (k_z \frac{\partial T}{\partial z}) = 0. \tag{12}$$

Boundary conditions are normally of two kinds; those of specified temperature on a boundary,

$$T = T_b, \text{ (boundary } b \text{ only)} \tag{13}$$

and those of specified heat flux or convective condition
on the boundary,
\[
(k_y \frac{\partial T}{\partial y} l_y)_b + (k_z \frac{\partial T}{\partial z} l_z)_b
\]
\[+ [h(T - T_\infty)]_b + q_b = 0, \text{ (boundary } b \text{ only)}
\]
(14)

where \( l_y \) and \( l_z \) are direction cosines of the outward normal to the boundary's surface.

2. The Finite Element Method

Many references including [11], [14], and [15] develop the concept of using material elements of finite dimensions within a structure to model the differential equation and its boundary conditions. The steady-state field equation, (12), may be discretized by considering that the temperature at any point within an element is a function of the temperatures of specified nodes on that element,
\[
T = \langle N \rangle \{ T \}^e,
\]
(15)
where \( \langle N \rangle \) is the row matrix shape function of position and \( \{ T \}^e \) is the nodal temperature vector for the element. The field equation and boundary equations for each element may be mathematically rearranged and integrated to yield a matrix system of equations for that element,
\[
[H]^e \{ T \}^e = -\{ F \}_b^e,
\]
(16)
where
\[
[H]^e = \int_{s_e} k \left( \frac{\partial N}{\partial z} \left< \frac{\partial N}{\partial z} \right> + \left< \frac{\partial N}{\partial y} \right> \frac{\partial N}{\partial y} \right) dz \, dy,
\]
(17)
and
\[ \{F\}_b^e = - (\int_{c_e} q \{N\} dc)_b + (\int_{c_e} \{N\} h \langle N \rangle dc)_b - h\{T\}_b c_b. \] (18)

Equation (18) is applied only over relevant boundaries. The element matrix equations are then assembled into a master matrix equation for the entire structure. Solution by numerical methods then follows.

The convective boundary conditions were applied in the finite element solution of the finned condenser using a lumped convective condition formulation. Average nodal convective coefficients, \( h_{avg} \), were determined for each node subject to a convective environment. The nodal \( h_{avg} \) values were then considered to be constant over the boundary region associated with the node. The method of determination of these coefficients is described in a later section.

Equation (18) was, thus, reduced to the following form,

\[ \{F\}_b^e = (\{h_{avg} T\}_b^e - \{h_{avg} T\}_b^e) c_b. \] (19)

This lumping procedure reduced the complexity of the convective condition calculations and did not seriously affect the values within the master matrix, \([H]\).

Reference [15] presents a development of the isoparametric finite element concept. This concept allows the solution of equations (12), (13), and (14) for elements of non-uniform shape. The application of the method of finite elements is, therefore, extended to a wider range of physical problems.
The eight-nodal finite element mesh used in the two-dimensional analysis of the axially finned condenser is shown in Figure 6. A computer program for the case of two-dimensional conduction was developed using a modified version of the three-dimensional, isoparametric finite element program assembled by Lew [12].

3. Test Cases

Before the finite element solution was applied to the condenser problem, a series of test cases were analyzed. These cases allowed a comparison of analytical solutions to results obtained using the finite element program. The two-dimensional heat conduction problems studied were

(1) a rectangular block with specified surface temperature,
(2) a rectangular block in a uniformly convective environment,
(3) a rectangular block with a triangular fin in a uniformly convective environment,
(4) a rectangular block with a convex parabolic fin in a uniformly convective environment, and
(5) a rectangular block with a concave parabolic fin in a uniformly convective environment.

Results of the test cases are presented in Figures 7-11 with values obtained using the finite element program placed in brackets. For the first two cases, the heat transfer rates calculated with the aid of the finite element computer program agreed well with the exact, two-dimensional solutions. Although finite element heat transfer solutions were relatively accurate, nodal temperature values were slightly different from the exact values. This temperature discrepancy
led to numerical difficulties when the finite element solution was applied to the stainless steel condenser. These difficulties will be discussed more fully in Chapter III.

For the finned block cases, analytical expressions were derived for heat transfer rates through extended surfaces using the one-dimensional fin analysis as described in [16]. Heat transfer rates calculated by the finite element program for this uniformly convective environment did not vary significantly from the one-dimensional results. Since test case results from the finite element program agreed favorably with the derived results, the program was assumed to be operating properly and was applied to the condenser heat transfer problem.

4. Condenser Boundary Condition Application

The axially finned condenser problem was analyzed by considering the geometry of Figure 6. Boundary conditions for the problem were considered to be the same as those in the Schafer analysis with the exception of the inner surface temperature distribution. Instead of using a linearly decreasing temperature profile along the wall from the apex of the fin to the midpoint of the channel, a parabolic distribution was assumed and used to calculate average nodal convective coefficients.

The Nusselt analysis of the fin condensation problem yielded a differential equation in $\delta(z)$, fin condensate thickness, which is identical to equation (6) used in Schafer's analysis.
Consistent with the eight-nodal finite element concept, a parabolic temperature distribution was then assumed to exist along the fin surface using the boundary condition, $T = T_s$ at $z = 0$, since $\delta(0) = 0$. Therefore,

$$T_w(z) = a_1 z^2 + b_1 z + T_s,$$

or

$$T_s - T_w(z) = -a_1 z^2 - b_1 z,$$

where $a_1$ and $b_1$ were unknown constants.

When (21) was substituted into equation (6) and the result integrated from $z = 0$ to $z$, the expression for $\delta(z)$ became

$$\delta(z) = \left[ \frac{4k_f}{\rho_f^2 \omega^2 (R_z + x \sin \phi) h_{fg} \cos \phi \cos \alpha} \left( -a_1 \frac{z^3}{3} - b_1 \frac{z^2}{2} \right) \mu_f \right]^{1/4}.$$

The local convective heat transfer coefficient, assuming one-dimensional heat conduction through the thin condensate film, was then

$$h(z)_{\text{fin}} = \frac{k_f}{\delta(z)} = \left[ \frac{k_f^3 \rho_f^2 \omega^2 (R_z + x \sin \phi) h_{fg} \cos \phi \cos \alpha}{4\mu_f \left( -a_1 \frac{z^3}{3} - b_1 \frac{z^2}{2} \right)} \right]^{1/4},$$

and was applicable from $z = 0$ to $z = z^* = z_o - \delta^*/\cos \alpha$ (Figure 6).

Across the width of the trough, from $z = z_o$ to the mid-channel position,

$$h(x)_{\text{trough}} = \frac{k_f}{\delta^*(x)}.$$

26
δ*(x) was considered constant across the trough width. Based upon a check of the wall temperatures generated from Schafer's computer program, the fluid temperature difference across the width of the trough was predicted to be small. Fluid thermal conductivity values were, therefore, assumed to remain relatively constant. As a result, h(x)_{trough} was assumed to be constant across the trough width and was calculated using equation (24) and a representative average inner wall temperature to determine k_f.

An h(z) temperature distribution was then needed between \( z = z^* \) and \( z = z_0 \). Since the thickness of condensate film increased linearly from the value at \( z^* \) to the value at \( z_0 \), the convective coefficient was assumed to decrease linearly from \( h(z^*)_{fin} \) to \( h(x)_{trough} \).

Other boundary conditions were then applied in accordance with the assumptions of Schafer, namely, zero heat flux through the sides of the geometry, \( T = T_s \) at the fin apex, and constant convective coefficient, \( h_{out} \), along the outside surface of the wall. Boundary conditions for the problem were, thus, completely specified.

In his expression for trough condensate cross-sectional area, Schafer assumed that the surfaces of the condensate flows from the fin and the trough were coincident at a position directly above the trough-fin wall juncture (Figure 4). For small fin film thicknesses and other than small fin angles, this assumption was not accurate. In this study, it was assumed that fin condensate thickness was much smaller than
trough condensate thickness. The trough condensate region could, therefore, be more accurately described as shown in Figure 6. The modified trough mass flow equation became

\[ \frac{M_{\text{tot}}(x)}{\rho_f^2 \omega^2 (R_x + x \sin \phi) \delta(x)^2 \sin \phi} = \frac{3 \mu_f}{(\delta(x) \epsilon + \delta(x)^2 \tan \alpha)}. \]  

(25)

It should be noted that this equation differs from equation (2) only in the expression for cross-sectional area of the trough condensate region. The change in cross-sectional areas involved the term, \(1/\cos^2 \alpha\), which for large fin angles, could make a significant difference in cross-sectional areas of the two equations.

5. Condenser Heat Transfer Solution

Within the computer program, the heat transfer rate for the entire condenser was determined by dividing its axial length into one hundred equal length increments of length, \(\Delta x\), solving for the incremental heat transfer rate using an iterative procedure, and summing those incremental rates to yield a total heat transfer rate. A flowchart description of the computer program used in this analysis is given in Figure 12.

At each increment, constants \(a_1\) and \(b_1\) were determined using a Lagrangian interpolation fit of the temperatures calculated from the previous iterate at nodes 1, 3, and 6. For the first increment, \(a_1\) and \(b_1\) were initially calculated from an initial guess of the temperatures at those nodes. Convective coefficients at several locations along the fin were determined using equation (23) and the linearly decreasing
h(z) assumption from \( z = z^* \) to \( z = z_0 \). Next, average nodal values, \( h_{1\text{avg}}, h_{3\text{avg}} \), and the average \( h \) of the left hand boundary region associated with node 6, (Figure 13), were then calculated using the position dependent values of \( h(z)_{\text{fin}} \) in a Simpson's Rule approximation. \( h(x)_{\text{tough}} \) was then calculated from equation (24) using the \( \delta^* \) value calculated from the previous increment. This value was used as the average convective coefficient for nodes 9 and 12 and the right hand boundary region of node 6. The average convective coefficients calculated for the left and right hand boundary regions of node 6 were then weighted by their respective region lengths. The two values were then summed to yield the average convective coefficient for node 6, \( h_{6\text{avg}} \). The remaining boundary conditions were then applied and incremental heat transfer rate per unit condenser length, \( \dot{Q}_j \), and nodal temperature values were generated from the finite element subroutines.

If the resultant heat transfer rate converged to within the criteria of 0.05 percent change from the value of the previous iterate,

\[
\left| \frac{\dot{Q}_j - \dot{Q}_{j-1}}{\dot{Q}_j} \right| < 0.0005 ,
\]

the incremental problem was deemed solved and \( \dot{Q}_j \) set equal to the final iterate, \( \dot{Q}_j \). If, on the other hand, the convergence criteria was not met, the newly calculated nodal temperature values were used to establish a new set of inner wall convective coefficients. After the remaining boundary
conditions had been applied, the finite element solution was repeated until heat transfer rate converged to within the acceptable 0.05 percent tolerance. Because $\dot{Q}_j$ was initialized at zero for each increment, the iteration procedure was repeated at least twice for every increment.

Incremental mass flow rate was then calculated using

$$\Delta M_{tot_i} = 2 \frac{\dot{Q}_i}{h_{fg}} \Delta x.$$  \hspace{1cm} (27)

This value was then added to the mass flow rate from previous increments. The subsequent interval's trough condensate thickness was then calculated using a polynomial root-finder subroutine to solve equation (25). The incrementation continued until the entire length of the condenser had been traversed. Incremental heat transfer rates were then summed and a total heat transfer rate calculated from (3).

$$Q_{tot} = 2 N_{\text{fin}} \cdot \sum_{i=1}^{100} (Q_i \Delta x),$$  \hspace{1cm} (28)

where $N_{\text{fin}}$ was the number of fins along the inner wall circumference.

To start the incrementation, two initial assumptions were made. The initial increment's value of $\delta^* = \delta^*_1$ was taken from the analysis of Schafer as 0.00006752 feet. For reasons explained in the previous sub-chapter, a large variance in the accuracy of this value would not significantly affect the heat transfer results obtained from the computer program.
Additionally, at the first increment, initial guesses of fin temperatures at nodes 1, 3, and 6 were made in order to begin the solution. As an example, the temperatures used to begin the solution for the copper condenser with fluid saturation temperature of 200°F were $T_1 = 200°F$, $T_3 = 195°F$, and $T_6 = 191°F$.

For the copper condenser, the use of widely variant initial nodal temperature values, $T_1 = 200°F$, $T_3 = 191°F$, and $T_6 = 182°F$ had little effect on convergence to the heat transfer solution for the first increment. However, as will be discussed in Chapter III, the initial temperature guess, coupled with the slight inaccuracy of the finite element nodal temperature solution produced numerical difficulties within the computer program for the stainless steel condenser.
III. DISCUSSION OF RESULTS

Computer results for the finned copper condenser were generated for three outside convective coefficients, three fin angles, and five rotation rates. The working fluid used throughout the analysis was water. Representative results are presented in Figures 14 and 16, 17, 18.

Figure 14 compares the heat transfer results of this study with the results of the analysis of Schafer for given operating conditions. It can be seen that the two-dimensional conduction analysis allowing a parabolic temperature distribution along the fin predicted heat transfer rates for the finned condenser which are approximately seventy-five percent greater than the rates predicted with the one-dimensional model with linear temperature profile along the wall. This rather significant change was unexpected, and may be somewhat in error due to numerical difficulties in the method. These numerical difficulties arose due to the boundary condition at node 1. The finite element boundary conditions are established for each node such that the condition is assumed to exist over the entire boundary region of the node. Therefore, the zero flux boundary condition could not be applied over the whole length of the left and right boundaries of the condenser geometry. This problem existed for nodes 1, 4, 11, and 12, but was most critical for node 1 since it was estimated that twenty to thirty percent of the total heat
flux through the inner wall passed through the region associated with this node.

An error of fifty percent in the calculation of node 1 heat transfer rate might then give a total heat transfer error of as high as fifteen percent. Two possible solutions to the boundary condition problem merit attention. The first is to increase the number of elements used in the solution of the geometry of Figure 6. However, a boundary region associated with node 1 would still exist on the left hand side of the geometry although reduced in size. The effects of the boundary condition problem would, therefore, be reduced but not eliminated.

The second solution would be to consider a wall geometry as shown in Figure 15. The zero flux boundary condition would then be forced along the boundary in question due to the symmetry of the problem. The use of one of these alternate solution methods might contain the added benefit of eliminating the numerical difficulties associated with the stainless steel condenser solution.

The heat transfer rate solution is generally affected in the same manner as with the analysis of Schafer when $h_{out}$, $\omega$, and $\alpha$ were varied. In Figure 16 the influence of outside convective coefficient, $h_{out}$, is shown. Figure 17 illustrates how the rate of heat transfer was relatively unaffected as fin half angle, $\alpha$, was varied. In addition, heat transfer rate was found not to vary significantly with rotation rate as shown in Figure 18. This result concurred with the results
obtained earlier by Schafer [8]. Schafer suggested that the invariance in heat transfer rate with the rotation rate was due to the cancelling effects of decreasing film thickness and decreasing temperature difference across the film thickness as rotation rate is increased.

Because of numerical difficulties in the program, no results were generated for the stainless steel condenser. With the solution of the first and second test cases, the nodal temperatures calculated were accurate only to within two or three degrees. In the condenser problem, this slight inaccuracy resulted in nodal temperatures along the fin wall which were slightly above the fluid saturation temperature. Computer output indicated that the wall temperature at node 3 was approximately 0.1°F above the saturation temperature when $T_s = 200°F$. As a result, the quantity within the brackets of equation (23) was a negative value. Error messages were generated when the computer attempted to evaluate the fourth root of this negative number.
IV. CONCLUSIONS

1. The addition of internal axial fins to the condenser surface of a rotating heat pipe significantly improves heat transfer performance.

2. Analysis of the condenser heat transfer problem using a two-dimensional wall conduction model and a parabolic temperature distribution along the fin yielded heat transfer rates about seventy-five percent above those predicted by the one-dimensional, linear temperature distribution analysis of Schafer [8].

3. For the geometrical cases studied in this thesis, the heat transfer rates calculated from the two-dimensional analysis are insensitive to changes in rotational speed and fin half-angle.

4. Boundary condition problems produced with the finite element solution for the copper condenser were the probable cause of solution inaccuracy on the order of fifteen percent.

5. Slight inaccuracy from the finite element calculation of nodal temperature values led to numerical difficulties in the heat transfer solution of the stainless steel condenser.
V. RECOMMENDATIONS FOR FURTHER STUDY

It is suggested that the following topics be considered for future study of the internally finned, rotating heat pipe:

1. Re-examination of the finite element analysis using either an increased number of elements for the geometry considered in this study or the mirror image geometry presented in Figure 15.

2. Use of twelve-nodal elements in the finite element analysis to allow the assumption of a cubic inner wall temperature profile in order to more closely approximate the actual temperature distribution.

3. Analysis of film condensation on a variety of fin shapes, and application of the solution to the two-dimensional model to determine the shape permitting optimum heat transfer rate.

4. An experimental program in order to compare theoretical and experimental heat transfer rates of the internally finned condenser.
