Abstract

Procedures are presented for the systematic design of digital filters that contain poles and zeros. The procedures are simple, fast, and effective. All of the important algorithms are of the Levinson-type. The first key idea in the paper is that one may begin a design by posing a linear prediction problem for a stochastic sequence. The second is that a high-order "whitening" filter may be constructed for this sequence and "inverted" to yield a high-order all-pole filter whose spectrum approximates the spectrum of the stochastic sequence. The third key idea is that the all-pole filter may be used to generate consistent unit pulse and covariance sequences for use in the Mullis-Roberts algorithm. This algorithm is then used to obtain a low-order digital filter, with poles and zeros, that approximates the high-order all-pole filter. The results demonstrate that the Mullis-Roberts algorithm, together with the design philosophy of this paper, may be used with profit to reduce filter complexity and to design spectrum-matching digital filters.
I. Introduction

This is a paper about the systematic design of autoregressive-moving average (ARMA) digital filters. There are three key ideas in the paper. The first is that one may begin the design of an ARMA digital filter by specifying the power spectral density of a stochastic sequence and then posing a classical linear prediction problem for the stochastic sequence. The second is that this prediction problem may be solved by designing a high-order moving average (MA) prediction filter. This prediction filter is related to an MA whitening filter which may, in turn, be "inverted" to give an autoregressive (AR) filter termed an inverse filter. Identical argumentation lies at the heart of AR or maximum entropy (ME) spectrum analysis and explains why the magnitude-squared frequency response of the AR filter should approximate the power spectrum of the stochastic sequence [1]. The appropriate design equations are linear equations (termed normal equations) that may be efficiently solved using Levinson-type algorithms. For our purposes the value of the high-order AR filter is simply that it provides a handy mechanism for generating consistent unit pulse and covariance sequences \( \{h_k\}_0^\infty \) and \( \{r_k\}_{-\infty}^\infty \), respectively. These sequences approximate the unit pulse and covariance sequences of an idealized, unrealizable, digital filter.

The third key idea is that the sequences \( \{h_k\}_0^\infty \) and \( \{r_k\}_{-\infty}^\infty \) may be used in the approximation algorithm published by Mullis and Roberts in their remarkable paper on the use of first- and second-order information in discrete-time system design [2]. From \( \{h_k\}_0^\infty \) and \( \{r_k\}_{-\infty}^\infty \) for the high-order AR, the finite-length sequences \( \{h_k\}_0^M \) and \( \{r_k\}_0^N \) are used in the Mullis-Roberts algorithm to design an ARMA \( (N,M) \) digital filter. The notation ARMA \( (N,M) \) denotes a digital filter with \( N \) poles and \( M \) zeros. Correspond-
ingly, AR \((N_1)\) will denote an all-pole digital filter with \(N_1\) poles and 
MA \((M_1)\) will denote an all-zero digital filter with \(M_1\) zeros.

Our results indicate that the design procedure outlined above is 
simple, effective, and fast. All of the important algorithms are Levinson-
type algorithms. Moderate-order filters (e.g., \(N=16\) and \(M=16\)) may be de-
signed in approximately 8 seconds of CDC 6400 CPU time. Design parameters 
are center frequency, bandwidth, and stopband rejection. Even for low-
order filters (e.g. \(N=8\) and \(M=8\)) one may achieve 60 dB rejection over a 
transition band that is a small percentage of the foldover frequency with 
approximately 3dB passband ripple.

As an approximation tool the Mullis-Roberts algorithm is very effec-
tive: for example, an ARMA \((N,M)\) filter of complexity \(C = N + M\) is shown in 
many instances to be a very good approximation to an AR \((N_1)\) filter for 
\(C << N_1\). Designs for \(N_1=256\) and \(C=32\), and \(N=64\) and \(C=16\) illus-
trate the point. Our experience indicates that the designs presented 
here are superior to those achieved by simply matching the impulse sequence 
\(\{h_k\}_{k=0}^{N+M}\) using the Burrus-Parks algorithm [3]. Furthermore there is no 
difficulty with stability because both the AR \((N_1)\) and ARMA \((N,M)\) filters 
are guaranteed to be stable.

Preliminary design efforts along the lines of this paper were reported 
in [4]. The designs were begun with a moderate-order MA \((M_1)\) filter (e.g., 
\(M_1 = 32\)) designed using the methodology of [5]. The MA filter was used 
to generate consistent unit-pulse and covariance sequences for use in the 
Mullis-Roberts algorithm. The results reported were mixed because the 
unit-pulse and covariance sequences were not well-suited for subsequent 
approximation using the Mullis-Roberts algorithm. In our opinion, and 
the results seem to corroborate this view, one should begin ARMA \((N,M)\)
approximations with very high-order AR \((N_1)\) designs (e.g., \(N_1 = 256\)) rather than very long or short MA designs. The reasons are three-fold: (1) AR power spectrum approximations are well-understood [6] and virtually free in terms of numerical design effort, (ii) the sequences \(\{h_k\}_0^\infty\) and \(\{r_k\}_0^\infty\) are obtained from simple regression equations, and (iii) the AR sequences \(\{h_k\}_0^\infty\) and \(\{r_k\}_0^\infty\) are infinite-length and, therefore, apparently better suited to subsequent matching and approximation by infinite length ARMA unit-pulse and covariance sequences.

We remark that the approximation algorithm of Mullis and Roberts gives exact matching of the ARMA \((N,M)\) and AR \((N_1)\) unit pulse sequences over \(M + 1\) indices and only approximate matching of the covariance sequences over \(N + 1\) indices. When only a covariance sequence is to be matched, then the Mullis-Roberts algorithm reduces to the Levinson algorithm for obtaining an exact covariance match over \(N + 1\) indices.

We feel the statistically-related filter design procedures reported here and in [5] and [7] are becoming well-enough understood, and are yielding attractive-enough designs, to warrant serious attention from designers. One needs only to view the digital filter design problem as a problem of statistically designing a linear minimum mean-squared error filter or predictor. Elegant solutions abound. An added dividend paid by this way of thought is that a class of digital filter designs becomes a logical branch of linear minimum mean-squared error filtering theory. Some find this comforting. Others don’t need it.
II. Beginning the Design

The design begins with specification of a bandlimited power spectrum \( G(f) \) of the type illustrated in Figure 1a. It may be helpful to visualize the spectrum on the passband interval \(-W < f < W\) as a signal spectrum \( S(f) \) and the spectrum on the remainder of the frequency interval (the stopband) as a noise spectrum \( N(f) \). See [5]. Then \( S(f) \) corresponds to the desired passband characteristic and \( N(f) \) corresponds to the desired stopband characteristic. Center frequency \( f_0 \) (\( f_0 = 0 \) in Figure 1), signal bandwidth \( W \), stopband rejection \( \eta \), and total bandwidth \( 1/2T \) are design parameters. The rejection \( \eta \) may be visualized as a signal-to-noise ratio \( \eta = A_s / A_n \). In the design of MA filters it has been found useful to include a transition band [5]. In the design of ARMA filters beginning with AR filters we have not discovered a useful way to specify a transition band.

The next step is to periodically extend the spectrum \( G(f) \) using period \( 1/T \) (or foldover frequency \( 1/2T \)) and scale it by \( 1/T \) to obtain a periodic spectrum \( \tilde{G}_p(f) \):

\[
\tilde{G}_p(f) = \begin{cases} 
\frac{1}{T} G(f), & |f| < 1/2T \\
\frac{1}{T} G(f - \frac{m}{T}), & \frac{m}{T} - 1/2T < f < \frac{m}{T} + 1/2T, \quad m = 0, \pm 1, \pm 2, \ldots 
\end{cases}
\]

(1)

This is illustrated in Fig. 1b. The Fourier coefficients

\[
c_k = \frac{1}{2T} \int_{-1/2T}^{1/2T} \tilde{G}_p(f)e^{-j2\pi kfT} df, \quad k = 0, \pm 1, \pm 2, \ldots
\]

(2)

specify a covariance sequence \( \{c_k\} \) with \( c_k = c_{-k} \). The sequence \( \{c_k\} \) may be thought of as the covariance sequence of a zero-mean sampled data sequence \( \{x(kT)\} \) obtained by sampling a continuous-time random process \( \{x(t)\} \) that has bandlimited power spectral density \( G(f) \). Then,
of course, $c_k = c(t=kT)$ where

$$c(t) = \int_{-1/2T}^{1/2T} G(f)e^{-j2\pi ft} df$$

is the covariance of the process $\{x(t)\}_{-\infty}^{\infty}$.

Another connection between $\{c_k\}$ and the periodically extended spectrum $G_p(f)$ is

$$G_p(f) = M(z)M(z^{-1})|_{z=\exp(j2\pi fT)}$$

$$M(z)M(z^{-1}) = \sum_{k=-\infty}^{\infty} c_k z^{-k}$$

This says $\{c_k\}_{-\infty}^{\infty}$ is the covariance of the output of a digital filter $M(z)$ that is driven by a white sequence with unit variance and that the periodically-extended spectrum $G_p(f)$ is the magnitude-squared frequency response of the digital filter $M(z)$.

The periodic spectrum $G_p(f)$ illustrated in Figure 1 is a legitimate discrete-time spectrum. However, it is not rational and is, therefore, not the spectrum of an autoregressive moving average digital filter. This is another way of saying the $M(z)$ of (4) is not a transfer function for a filter that can be realized using a finite number of multipliers, adders, and delays (memory). Thus the approximation problem is one of designing an ARMA filter $H(z)$ whose rational spectrum $H(z=\exp(j2\pi fT))$.

$H(z=\exp(j2\pi fT))$ approximates the irrational spectrum $G_p(f)$. Of course, $H(z=\exp(j2\pi fT))H(z^{-1}=\exp(-j2\pi fT))$ is simply the magnitude-squared frequency response of the filter $H(z)$. This brings us to the next step in our design procedure.
III. Designing an Autoregressive Approximation

The problem now is the following: given a covariance sequence \( \{c_k\}_{-\infty}^{\infty} \) corresponding to the desired spectrum \( G_p(f) \), find a realizable filter \( H(z) \) whose periodic spectrum well-approximates \( G_p(f) \). Call \( \{r_k\}_{-\infty}^{\infty} \) the covariance sequence of the filter \( H(z) \). The following relationships are in force:

\[
H(z)H(z^{-1}) = \sum_{k=-\infty}^{\infty} r_k z^{-k}
\]

\[
r_k = \frac{1}{2\pi j} \oint_C H(z)H(z^{-1})z^{-k-1} dz
\]

\[
H(z=e^{j2\pi fT})H(z^{-1}=e^{j2\pi fT}) = \sum_{k=-\infty}^{\infty} r_k e^{-j2\pi f k T}
\]

It is clear that for purposes of matching spectra, the covariances come into play in a more fundamental way than do the unit pulse sequences. In (5) the contour \( C \) lies within the annulus of uniform convergence of \( H(z)H(z^{-1}) \).

One approach to the approximation problem is to design an AR \( (N_1) \) filter

\[
H(z) = \frac{k}{N_1} 1 - \sum_{k=1}^{\infty} a_k z^{-k}
\]

in such a way that

\[
r_k = c_k \quad k = 0, \pm 1, \ldots \pm N_1
\]

For large values of \( N_1 \), the matching of \( \{r_k\}_{0}^{N_1} \) and \( \{c_k\}_{0}^{N_1} \) provides effective approximation of \( G_p(f) \) by \( H(z=e^{j2\pi fT})H(z^{-1}=e^{j2\pi fT}) \). See equations (2) and (5). The result of (7) is achieved with the filter of (6) by solving the normal equations.
\[ \bar{\mathbf{C}} \mathbf{a} = \bar{\mathbf{c}} \]

\[
\begin{bmatrix}
  c_0 & c_1 & \cdots & c_{N_1-1} \\
  c_1 & c_0 & & \\
  \vdots & & \ddots & \\
  c_{N_1-1} & \cdots & c_0
\end{bmatrix}
\]

\[ \bar{\mathbf{c}} = (c_1, c_2, \ldots, c_{N_1}) \]

\[ \bar{\mathbf{a}} = (a_1, a_2, \ldots, a_{N_1}) \]

\[ \kappa^2 = c_0 - \sum_{\ell=1}^{N_1} a_\ell c_\ell \]

Here the prime denotes matrix transpose.

These normal equations arise over and over again in speech processing and autoregressive spectrum analysis. When statistically fluctuating data enters the picture these equations are replaced by the famous Yule-Walker equations involving estimates of \( c_k \).

Due to the Toeplitz nature of \( \mathbf{C} \) and the relation \( \bar{\mathbf{c}} \) bears to \( \mathbf{C} \), the linear equation \( \bar{\mathbf{C}} \mathbf{a} = \bar{\mathbf{c}} \) may be solved very efficiently using a Levinson-type algorithm. In the FORTRAN program of Appendix I, the subroutine TPLSLV implements such an algorithm. See [8] for a listing of the algorithm and a discussion of computational demands.

In summary, the AR \( (N_1) \) coefficients \( \{a_k\}_{1}^{N_1} \) are obtained by solving (8) with the \( \{c_k\}_{0}^{N_1} \) obtained from the desired spectrum \( \mathbf{G}_p(f) \) according to (2). For all of our designs the \( c_k \) may be obtained analytically as follows:

\[ C_k = A_s 2TW \text{sinc}[2\pi WkT] + A_n [1-2TW] \cos[(2TW+1)\frac{n}{2}k] \text{sinc}[(1-2TW)\frac{n}{2}k] \]

(9)
Figure 2 shows the results of several AR designs. Each design
was begun with a $G_p(f)$ of the form illustrated in Fig. 1. The idealized
$G_p(f)$ is superimposed on each design. Important parameters are included
in the figures.

There is one other interpretation of the $H(z)$ given in (6) that is
worth noting, even though it has been noted many places. The filter
\[
L(z) = \sum_{\ell=1}^{N_1} a_{\ell} z^{-\ell} \tag{10}
\]
with the \{a_{\ell}\} given by (8) is the linear MA filter of order $N_1-1$ that
minimizes the mean squared prediction error
\[
\zeta^2 = E[x(mT) - \sum_{\ell=1}^{N_1} a_{\ell} x((m-\ell)T)]^2 \tag{11}
\]
Here \{x(\ell T)\}_{-\infty}^{\infty} is the sampled-data sequence that has spectrum $G_p(f)$.

The filter
\[
K(z) = 1 - \sum_{\ell=1}^{N_1} a_{\ell} z^{-\ell} \tag{12}
\]
is the corresponding "whitening" filter. Of course $H(z) = 1/K(z)$.
Therefore, to the extent that $K(z)$ whitens $G_p(f)$, $H(z)$ inherits the
spectral properties of $G_p(f)$. It is well-known that an $H(z)$ designed
as outlined above is stable [9].
IV. Obtaining Unit—Pulse and Covariance Sequences from the AR Design

No one wants a high—order AR filter, regardless of its frequency response characteristics. However, the high—order AR design serves another very useful purpose: it provides a ready—made generator for a covariance sequence \( \{r_k\}_k \) and a causal unit pulse sequence \( \{h_k\}_k \) that are consistent in the sense that

\[
    r_k = \sum_{\ell=0}^{\infty} h_{\ell} h_{\ell+k}, \quad k = 0, 1, 2, 
\]

\[
    r_{-k} = r_k
\]

The appropriate equations for the generation of the unit pulse sequence \( \{h_k\}_k \) are

\[
    h_k = \begin{cases} 
    0, & k < 0 \\
    \sum_{\ell=1}^{N_1} \alpha_{\ell} h_{k-\ell}, & k \geq 0 
    \end{cases}
\]

Here the coefficients \( \{\alpha_{\ell}\}_1^{N_1} \) are the feedback coefficients of \( H(z) \). See equations \( (6) - (8) \). The symbol \( \delta_k \) denotes the Kronecker delta.

The generating equations for \( \{r_k\}_k \) are not much more difficult. The following linear relationship holds:

\[
    r_k = \sum_{\ell=1}^{N_1} \alpha_{\ell} r_{k-\ell}
\]

\[
    r_{-k} = r_k
\]

So, given the \( N_1 \) covariances \( \{r_{\ell}\}_1^{N_1} \), for example, one may solve for \( r_{N_1+1}^{N_1} \) and so on. Of course, the \( \{r_{\ell}\}_1^{N_1} \) are available as \( r_{\ell} = c_{\ell} \), \( \ell = 0, 1, \ldots, N_1 \), from the AR design procedure of Section III. For
completeness we show in Appendix I how to solve for \( r_0 \) in terms only of the \( \{a_k\}_1 \), and thereby completely characterize the covariance sequence \( \{r_k\}_0^\infty \). We re-iterate that the calculation of Appendix II is not required in our design procedure because the \( \{r_0\}_0^N \) are available as \( r_0 = c_0 \), \( k = 0, 1, \ldots, N \) with the \( c_k \) given by (2).

Here is where we stand: we have at our disposal a systematic technique for generating a high-order AR \( (N_1) \) filter that "approximates" the idealized spectrum \( G_p(f) \). This AR \( (N_1) \) filter is characterized by its impulse and covariance sequences \( \{h_0\}_0^\infty \) and \( \{r_0\}_0^\infty \) which are easily obtained as outlined above. The sense of the approximation is that 
\[
r_k = c_k, \quad k = 0, 1, 2, \ldots, N_1.
\]

In the following section we use the algorithm of Mullis and Roberts to approximate this generally high-order AR \( (N_1) \) filter with a much lower order ARMA \( (N, M) \) filter.

V. Designing with the Mullis-Roberts Algorithm

Call \( H(z) \) the transfer function of our AR \( (N_1) \) design. Let \( \hat{H}(z) \) be the transfer function of an ARMA \( (N, M) \) filter:
\[
\hat{H}(z) = \frac{Q(z)}{A(z)}
\]
\[
Q(z) = q_0 + q_1 z^{-1} + \ldots + q_M z^{-M} \tag{16}
\]
\[
A(z) = 1 + a_1 z^{-1} + a_2 z^{-2} + \ldots + a_N z^{-N}
\]

The problem studied by Mullis and Roberts is one of minimizing the approximation error
\[
e^2 = T \int_{-1/2T}^{1/2T} |A(z = e^{j2\pi fT})|^2 |H(z = e^{j2\pi fT}) - \hat{H}(z = e^{j2\pi fT})|^2 df \tag{17}
\]
In the general case $H(z)$ is arbitrary. For our purposes it will always be the transfer function of a high-order AR $(N_1)$ filter. The error $\varepsilon^2$ may be written

$$\varepsilon^2 = T \int_{-1/2T}^{1/2T} |H(z=e^{j2\pi fT})A(z=e^{j2\pi fT}) - Q(z,e^{j2\pi fT})|^2 df$$  \hspace{1cm} (18)$$

The main virtue of this error measure is that it leads to a tractable minimization problem [2]. It is a straight-forward exercise to define $A(z) = H(z)A(z) - Q(z)$, invoke Parseval's Theorem, and use (13) and (18) to write

$$\varepsilon^2 = \sum_{l=0}^{N} \sum_{m=0}^{N} a_l a_m |l-m| - 2 \sum_{k=0}^{M} q_k \sum_{l=0}^{N} a_l h_{k-l} + \sum_{k=0}^{M} q_k^2$$ \hspace{1cm} (19)$$

The minimization problem is one of minimizing $\varepsilon^2$ with respect to the ARMA parameters $(q_k)_0^M$ and $(a_k)_0^N$, subject to the constraint that $a_0 = 1$. Write this as

$$\min_{a,q} [\varepsilon^2 - 2\lambda(a \cdot \tilde{\psi} - 1)]$$  \hspace{1cm} (20)$$

where $\lambda$ is a Lagrange multiplier and

$$\tilde{a} = (a_N, a_{N-1}, \ldots, a_0)'$$
$$\tilde{q} = (q_M, q_{M-1}, \ldots, q_0)'$$
$$\tilde{\psi} = (0, 0, \ldots, 1)$$

Note $\tilde{a} \cdot \tilde{\psi} = a_0$.

First minimize with respect to $\tilde{q}$. The constraint plays no role and the result is

$$q_k = \sum_{l=0}^{N} a_l h_{k-l}, \quad k = 0, 1, \ldots, M$$ \hspace{1cm} (22)$$

with the $\{h_k\}$ corresponding to $H(z)$ and the $(a_k)_0^N$ yet to be determined.
Substitute this result into (19) to obtain

\[ \varepsilon^2 = \tilde{a}^T K \tilde{a} \]  

\[ K = \{ r_{|l-m|} - \sum_{k=0}^{M} h_{k-l} h_{k-m} \} \]  

Here the notation \( K = \{ d_{\ell,m} \} \) denotes that \( d_{\ell,m} \) is the \((\ell,m)\)-th term of the \((N+1) \times (N+1)\) matrix \( K \). The matrix \( K \) is positive semi-definite if and only if \( \{ r_k \}_\infty \) and \( \{ h_k \}_0 \) are consistent, as they are by virtue of our construction method.

Now our constrained minimization problem yields the following solution for \( \tilde{a} \):

\[ K \tilde{a}^* = \lambda \psi \]

\[ \tilde{a}^* = \lambda K^{-1} \psi \]  

(24)

Invoke the constraint to get

\[ \tilde{a}^* = (k^*_N/k_0, k^*_{N-1}/k_0, \ldots, 1) \]  

(25)

where \( \tilde{k} = (k^*_N, \ldots, k^*_0) \) is the last column of \( K^{-1} \). Substitution of \( \tilde{a}^* \) into (22) yields \( \tilde{q}^* \) and completes the design of the ARMA \((N,M)\) filter

\[ H(z) = \frac{q^*_0 + q^*_1 z^{-1} + \ldots + q^*_M z^{-M}}{1 + a^*_0 z^{-1} + \ldots + a^*_N z^{-N}} \]  

(26)

Call \( \{ \hat{h}_k \}_0^\infty \) the unit pulse sequence and \( \{ \hat{r}_k \}_\infty^\infty \) the covariance sequence corresponding to \( \hat{H}(z) \). Since \( \tilde{a}^* \) is simply the solution to a normal equation involving positive-definite \( K \), it follows that \( \{ \hat{h}_k \} \) is absolutely summable. That is \( \hat{H}(z) \) is stable. Further, as shown by Mullis and Roberts, \( \hat{h}_k = h_k \), \( k = 0, 1, \ldots, M \). The covariances \( \hat{r}_k \) and \( r_k \) are not equal.

All of the results of this section are contained in [2].
VI. Systematic Design Steps

The design steps are summarized below and illustrated in Figure 3.

1. Specify a periodic power spectrum $G_p(f)$.  
2. Invert $G_p(f)$ to get a design covariance sequence $\{c_k\}_{k=0}^{N_1}$.  
3. Solve the normal equations $Cu = c$ to obtain an AR ($N_1$) approximation. Typically choose $N_1$ large (e.g. $N_1 = 256$).  
4. Generate $\{r_k\}_0^{N_1} = \{c_k\}_0^{N_1}, N_1 < N$; generate $\{h_k\}_0^M$ using the AR generating equation (14).  
5. Construct the matrix $K$.  
6. Solve for $\tilde{a}^*$ and $\tilde{q}^*$.  
7. Scale $\tilde{H}(z)$ to get desired dc response $H_0(z=1) = H_0$.

Actually, steps 5 and 6 are replaced by a Levinson-type algorithm presented by Mullis and Roberts for efficiently obtaining $\tilde{a}^*$ and $\tilde{q}^*$.

The FORTRAN listing of Appendix II describes a program written for a CDC 6400 computer with SCOPE compiler to implement the design steps above. The program was used to generate all of the designs that follow in Section VII. The number of storage locations required for the TPLSV subroutine to solve (8) is $3N_1$. The number of multiplies is approximately $2N_1^2$ and the number of adds is approximately $N_1$. The number of storage locations required to solve for $\tilde{a}^*$ using the Mullis-Roberts algorithm is $O(N)$. The number of multiplies is $O(N^2)$. The notation $O(N)$ indicates here that $O(N)/N$ is a constant.
VII. Designs

The designs presented in Figures 4–8 all have a design cutoff frequency of 0.2Hz and a foldover frequency of 1.0Hz. This does not mean the 3dB point, for example, is under careful control. It only means the ideal spectrum with which the design was begun had a cutoff frequency of 0.2Hz. Our convention in the figures is that ARMA(N,M) always denotes a filter designed according to the procedure of Section VI. Of course, the Chebyshev and Butterworth design of Figures 7 and 8 are also autoregressive moving average filters. These filters are denoted CH(N,N) and BW(N,N), respectively.

The results of Figure 4 illustrate how low-order ARMA filters may be used to approximate high-order AR filters. Figure 4(a) illustrates that an ARMA (8,8) filter is a very effective approximation to an AR(64) filter when only 30dB stopband rejection is desired. The complexity of the ARMA (8,8) is one-fourth the complexity of the AR(64) and the passband ripple of the ARMA (8,8) is very low. Figure 4(b) illustrates that an ARMA (32,32) filter is an effective approximation to an AR(256) when 90dB rejection is desired. Figure 5(a) illustrates what happens when one fixes the number of poles (N=8) and the number of zeros (M=4) in a relatively low complexity design and then increases the stopband rejection. At 30dB rejection the filter characteristic is smooth in the stopband and cuts off sharply. At 90dB rejection the ripple in the passband is severe. Figure 5(b) illustrates that if additional zeros are added to increase the complexity, control is maintained over the passband ripple even as the stopband rejection is increased to 90dB.

Figure 6 shows that when complexity is already high (N=16, M>8) and the stopband rejection moderate (60dB), the addition of zeros does not
dramatically influence the magnitude-squared response.

Figure 7 shows ARMA (8,M) approximations to ideal lowpass spectra and comparisons with Butterworth and Chebyshev designs of order 8 and complexity 16. If only 30dB stopband rejection is desired then an ARMA (8,4) filter can be designed that yields smoother passband characteristics than the Chebyshev filter and sharper cutoff than either the Chebyshev filter or the Butterworth filter. Of course, the passband ripple is larger than that of the Butterworth filter. The ARMA (8,4) filter is less complex than the Chebyshev and Butterworth filters by a factor of 3/4. As rejection is increased to 60dB, the passband ripple of an ARMA (8,8) increases, but remains smaller than the Chebyshev ripple everywhere in the passband except near cutoff. The cutoff is comparable.

Figure 8 shows ARMA (16,M) approximations to ideal lowpass spectra and comparisons with Butterworth and Chebyshev designs of order 16 and complexity 32. If only 60dB stopband rejection is required, then an ARMA (16,8) provides cutoff comparable to that of the Chebyshev with smaller ripple except near cutoff. For 90dB rejection an ARMA (16,16) provides cutoff comparable to the Chebyshev filter of the same complexity with less passband ripple except near cutoff.

In all of our designs run to date, well-conceived ARMA designs exhibit relatively little passband ripple, except very near the cutoff frequency, and cutoff characteristics comparable to Chebyshev characteristics. When filter complexity is high and stopband rejection low, then the filter characteristics can approximate ideal lowpass characteristics much more closely than equivalent-complexity Butterworth or Chebyshev designs. Reference the ARMA (8,8) filter of Figure 4(a), the ARMA (8,12) - 30dB filter of Figure 5(a), and the ARMA(16,24) filter of Figure 6.
VIII. Conclusions

The results presented here are only representative of what one may achieve. Extensions to bandpass, high-pass, band reject, and comb filters are straightforward. Several points should be made: (i) there is no requirement in these designs to begin with a rational analog filter; (ii) there is nothing fundamental about the shape of the $G(f)$ we have started with - an inventive designer may experiment with his own choices; (iii) the procedures presented here permit the designer to exercise implicit control over center frequency, bandwidth, and stopband rejection; and (iv) one may systematically design filters with arbitrary numbers of poles and zeros.

The results of Section VII do not say the statistical designs of this paper are better or worse than more classical designs. Only different. The new designs do, however, offer much more flexibility.

We speculate that the fitting of long AR models and subsequent approximation with the Mullis-Roberts algorithm may provide a useful method of fitting ARMA spectral models to random data. The question of order determination would, of course, be crucial here as it is in AR model-fitting [6].
APPENDIX I: Generating a Covariance Sequence from an AR Model

Write out (15) for \( k = 1, 2, \ldots, N_1 \) and order the equations in the following way:

\[
Q\vec{r} = \vec{r}
\]

\[
Q = \\
\begin{bmatrix}
0 & a_1 & a_2 & a_3 & \cdots & a_{N_1} \\
a_1 & a_2 & a_3 & \cdots & a_{N_1} & 0 \\
a_2 & (a_1+a_3) & a_4 & a_5 & \cdots & a_{N_1} & 0 & 0 \\
\vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\
a_{N_1} & a_{N_1-1} & \cdots & a_1 & 0
\end{bmatrix}
\]

\[
\vec{r} = (r_0, r_1, \ldots, r_{N_1})
\]

The matrix \( Q \) is generated as follows: begin with the first row \((0, a_1, a_2, \ldots, a_N)\); left-shift this row \((n-1)\) times and add the \( m \)th overflow to the \((n,m+1)\) term to get the \( n \)th row. For example, the fourth row is generated in the following way:

\[
0 \quad a_1 \quad a_2 \quad a_3 \quad a_4 \quad a_5 \quad a_6 \quad a_7 \quad \cdots \quad a_{N_1} \\
0 \quad a_1 \quad a_2 \quad a_3 \quad a_4 \quad a_5 \quad a_6 \quad a_7 \quad \cdots \quad a_{N_1} \\
0 \quad a_1 \quad a_2 \quad a_3 \quad a_4 \quad a_5 \quad a_6 \quad a_7 \quad \cdots \quad a_{N_1} \\
0 \quad a_1 \quad a_2 \quad a_3 \quad a_4 \quad a_5 \quad a_6 \quad a_7 \quad \cdots \quad a_{N_1} \\
\vdots \quad \vdots \quad \vdots \quad \vdots \quad \vdots \quad \vdots \quad \vdots \quad \vdots \quad \ddots \quad \vdots \\
a_{N_1} \quad a_{N_1-1} \quad \cdots \quad a_1 \quad 0
\]

The vector of covariances \( \vec{r} \) is obtained by solving the eigenvalue problem

\[
Q\vec{\lambda} = \lambda\vec{\lambda}
\]

for the eigenvector \( \vec{\lambda} \) (\( = \vec{r} \)) corresponding to \( \lambda = 1 \).
Appendix II: FORTRAN Program for Design of ARMA Filters

PROGRAM ARFILT (INPUT, OUTPUT, FILMPL, TAPES=INPUT, TAPES=OUTPUT)
  PROGRAM FOR STATISTICAL DESIGN OF AR AND ARMA DIGITAL FILTERS
  WRITTEN BY J. LUBY, COLORADO STATE UNIV., 1976-77.
  PROGRAM SET UP FOR LOWPASS DESIGNS AT PRESENT (AR OR ARMA).
  DATA READ IN SETS OF 6 CARDS. VARIABLE NOC TELLS PROGRAM

\( G(f) \)

(a)

\[
G(f) = \begin{cases} 
\sigma_n^2 & \text{if } -\frac{1}{2T} \leq f \leq \frac{1}{2T} \\
\sigma_s^2 & \text{if } \frac{1}{2T} < f < 1 \frac{1}{T} 
\end{cases}
\]

(b)

\[
G_p(f) = \begin{cases} 
\frac{\sigma_s^2}{T} & \text{if } -\frac{1}{2T} \leq f \leq \frac{1}{2T} \\
\frac{\sigma_n^2}{T} & \text{if } \frac{1}{2T} < f < 1 \frac{1}{T} 
\end{cases}
\]
N.B. Only the Stopband Characteristic of the AR(256) Filter is Plotted.

- AR(32)-30dB
- AR(64)-60dB
- AR(256)-90dB
Specify \( f_0, W, \eta \) and \( G(f) \)

Solve for \( \{ c_k \} \)

Use Levinson Algor. to Solve for \( \bar{\alpha} \):

\[ C\bar{\alpha} = \bar{c} \]

Construct AR \( H(z) \)

Generate \( \{ h_k \} \)

Use Mullis-Roberts Alg. to Solve for \( \bar{\alpha}, \bar{\alpha}^* \)

Normalize to Obtain ARMA Filter

\[ \hat{H}(z) = D \frac{Q(z)}{A(z)} \]
(a) ARMA (32, 32) - AR (256) - AR (64) - ARMA (8, 8)

(b) ARMA (32, 32) - AR (256)
Graph showing the magnitude-squared in dB versus frequency in Hz. The graph includes the following data points:

- ARMA(16,8)-60dB
- CH(16,16)
- ARMA(16,16)-90dB
- BW(16,16)

The x-axis represents frequency in Hz, ranging from 0 to 0.8, and the y-axis represents magnitude-squared in dB, ranging from -120 to 15 dB.

<tr>
<td>Procedures are presented for the systematic design of digital filters that contain poles and zeros. The procedures are simple, fast, and effective. All of the important algorithms are of the Levinson-type. The first key idea in the paper is that one may begin a design by posing a linear prediction problem for a stochastic sequence. The second is that a high-order &quot;whitening&quot; filter may be constructed for this sequence and &quot;inverted&quot; to yield a high-order all-pole filter whose spectrum approximates</td>

Abstract (cont.)

- the spectrum of the stochastic sequence. The third key idea is that the all-pole filter may be used to generate consistent unit pulse and covariance sequences for use in the Mullis-Roberts algorithm. This algorithm is then used to obtain a low-order digital filter with poles and zeros that approximates the high-order all-pole filter. The results demonstrate that the Mullis-Roberts algorithm, together with the design philosophy of this paper, may be used with profit to reduce filter complexity and to design spectrum-matching digital filters.
