### ABSTRACT

An analytical solution to the vibrational characteristics of a rectangular cantilever plate with a discontinuous boundary condition (crack) at the root is presented. Mechanical damping which may exist as a result of the contact between the crack's free surfaces during vibration has been eliminated by assuming the crack surface to be a free boundary. The approach to solution involves the use of the method of Ritz applied to Hamilton's Law of Varying Action. A comparison is made to the solution as obtained from conventional methods.
finite element theory (NASTRAN). No exact solution is available for comparison. The assumptions which underlie both theories are outlined. A comparison is made to the experimental results for a cantilever plate with a narrow slot of varying lengths at the root. Indications are that significant frequency deterioration and nodal pattern variations occur with increasing crack length. Further work on the effect of cracks/flaws on plate response is warranted. The author considers this work a step forward in determining and understanding the effects of flaws/cracks on blade response (i.e., high cycle fatigue, flutter) in gas turbine engines today. Further investigation is warranted.
FORWARD

This technical report was prepared in the Directorate of Engineering and Test, Structural Durability Division, Deputy for Propulsion, Aeronautical Systems Division, Wright-Patterson Air Force Base, Ohio. The work was accomplished under ASDD 0011 during the period between September 1976 through May 1977.

J. S. Ogg acknowledges the support of both Dr. James MacBain and his assistant, Bruce Tavner, for their services, thus making the experimental portion of this report possible.

</table>
At the present time, a great deal of attention is being directed to turbine engine structural durability. Emphasis is now placed on either extending or extracting the maximum useful life from engine hardware. With major advances being made in fracture mechanics, the day may soon arrive when an engine's structural components will be designed to satisfy a damage tolerance criteria similar to that employed on air-frames today. Therefore, total understanding of the effect of discrepancies, i.e., flaws and cracks on engine hardware, is necessary before such an approach to design can be feasible.

One area which may be especially sensitive to these discrepancies is turbine engine blades (i.e., fan, compressor, and turbine). Engines are designed to meet certain requirements which are determined by blade response (i.e., flutter boundaries, engine order blade excitations, etc.). Both blade flutter and frequency response are dependent upon material and mechanical damping characteristics, blade mode shapes, and natural frequencies of excitation. This paper will explore the effects of cracks on the mode shapes and frequencies of blades. For the purpose of portraying the relative effects of cracks, a flat plate with an aspect ratio of two will serve as the blade model for this investigation.

Much work has been directed to the solution of the flat plate vibration problem. Extensive documentation (Reference 1) of upper and
lower bounds of solutions for various plate geometrics has meticulously defined what the exact value of solution would be, provided it could be obtained. Various techniques to solution have been employed yielding reasonable accuracy, however, no exact solution is available for the nonuniform (cracked) boundary value problem. Probably one of the most powerful tools for the solution of a problem of this nature is that of the finite element theory. The utility of such an approach to solution is questionable when a more direct, simplified, and economical means of solution is available; namely, the energy solution. It is unfortunate that some energy approaches to solutions (i.e., Rayleigh, Galerkin) have masked the power of this type of approach. The major drawback of these approaches has been the need of selecting "appropriate" shape functions which satisfy the geometrical constraints and approximate the modes of vibration. The accuracy of the solutions are primarily dependent on these assumed functions. Ritz (Reference 2) demonstrated that through the use of a truncated series, properly employed, an upper bound on the true solution to deformable body problems could be obtained. The benefits of using an approach to solution as eluded to by Ritz can best be summarized as follows (Reference 3). "Advantages of the Ritz method lie in the relative ease with which complex boundary conditions can be handled. It is a powerful tool yielding high accuracy in the deflection analysis . . . The Ritz method can be considered as one of the most usable methods of higher analysis for solving complex boundary value problems in the mathematical physics." The relative ease and accuracy of this approach combined with the concepts
associated with Hamilton's Law of Varying Action provides an analytical means of solution for a wide range of applications (i.e., conservative, nonconservative, stationary, and nonstationary motion of particles, beams, plates and shells (References 4 through 8).

This paper will concentrate on the stationary motion of the simple harmonic vibration of thin flat plates. Since no in-plane vibrations (membrane) will be considered, the out-of-plane deflection \( w \) can be written as a function of the in-plane coordinates \( x, y \), and time, \( t \). As will be shown, the assumptions associated with linear, plane stress solutions may no longer be valid to solve a highly nonuniform vibration problem such as in the crack plate response.
SECTION II
THEORY

It is often difficult to determine which equation will yield the best results when solving a particular problem using an energy approach. Therefore, it is best to start with the most fundamental equation which encompasses all other energy approaches to solution. Such an equation was postulated by Sir William Rowan Hamilton and was called by him the "Law of Varying Action" (Reference 9). It can be mathematically stated as,

\[ \delta \int_{t_0}^{t_1} (T + W) \, dt - \frac{\partial T}{\partial q_1} \bigg|_{t_0}^{t_1} \delta q_1 = 0 \]  

(1)

where \( T \) represents the total kinetic energy of the system and \( W \) is the total work of the forces acting on or within the system.

1. STRAIN-DISPLACEMENT RELATIONSHIPS

For the purpose of this analysis, the plate is considered to be composed of an isotropic continuum which obeys the elastic stress-strain relationships. In addition, the assumptions underlying thin plate theory (plane stress) are assumed valid for the vibrational analysis. From this assumption we have,

\[ \gamma_{yz} = \tau_{zx} = \sigma_z = 0 \]
which reduces the stress-strain relationships to,

\[
\sigma_x = \frac{E}{(1 - \nu^2)} (\epsilon_x + v \epsilon_y)
\]

\[
\sigma_y = \frac{E}{(1 - \nu^2)} (\epsilon_y + v \epsilon_x)
\]

\[
\tau_{xy} = \frac{E}{2(1 + \nu)} \gamma_{xy}
\]

Membrane stresses have not been considered for this analysis (inextensional plate theory) since there are no externally applied (thermal or mechanical) in-plane loads. From the assumption of small deflections during vibration, the corresponding strain-displacement equations reduce to a set of linear equations of the form,

\[
\epsilon_x = \frac{3u}{3x}
\]

\[
\epsilon_y = \frac{3v}{3y}
\]

\[
\gamma_{xy} = \frac{3v}{3x} + \frac{3u}{3y}
\]

With the two assumptions, plane stress and small deflections, the in-plane displacements, \( u, v \), can be expressed as functions of the out-of-plane deflection, \( w \).
Substituting Equations 4 into Equations 3 and combining with Equations 2 yields,

\[ u = -z \frac{\partial \bar{w}}{\partial x} \]

\[ v = -z \frac{\partial \bar{w}}{\partial y} \]

2. WORK

For the conservative, stationary problem of the free vibration where there are no external forces, the work of the internal stresses may be expressed as the volume integral of the strain energy density function,

\[ W = -\frac{1}{2} \iiint \left( \sigma_x \varepsilon_x + \sigma_y \varepsilon_y + \tau_{xy} \gamma_{xy} \right) \, dx \, dy \, dz \]  

(6)

3. KINETIC ENERGY

The contribution of rotary inertia to the total kinetic energy has been found to be insignificant for small vibrations of a thin
plate. Therefore, the kinetic energy can be expressed as,

\[ T = \frac{1}{2} \iiint \rho \dot{w}^2 \, dx \, dy \, dz \]  

(7)

As a result of \( \rho, w, \dot{w} \) satisfying natural continuity conditions within the region occupied by the plate material,

\[ \frac{\partial T}{\partial q_1} \bigg|_{t_0}^{t_1} = \iiint \rho \ddot{w} \, dx \, dy \, dz \]  

(8)

Taking the variation of Equation 7 and combining with Equation 8, as in Hamilton's Law,

\[ \int_{t_0}^{t_1} \delta T \, dt - \frac{\partial T}{\partial q_1} \bigg|_{t_0}^{t_1} = \iiint \rho \ddot{w} \, dx \, dy \, dz \]  

(9)

Integrating the first term of Equation 9 by parts with respect to time and carrying out the necessary algebraic operations yields,

\[ -\int_{t_0}^{t_1} \iiint \rho \ddot{w} \, dx \, dy \, dz \]  

(10)

4. HAMILTON’S ENERGY EQUATION

Substituting Equations 6 and 10 into Equation 1, Hamilton's Law, results in the time integral of the principle of virtual work,
\[ \int_{t_0}^{t_1} \left[ \int \int p \frac{\partial^2 \omega}{\partial t^2} dxdydz - \int \int \left( \sigma_x \delta^2 \epsilon_x + \sigma_y \delta^2 \epsilon_y + \tau_{xy} \delta^2 \gamma_{xy} \right) dxdydz \right] \, dt = 0 \]  

(11)

The resulting equation within the time integral in terms of the displacements of the system under consideration is well known,

\[ \int_{t_0}^{t_1} \left[ - \int \int \int D \left\{ \frac{\partial^2 w}{\partial x^2} \delta \frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial y^2} \delta \frac{\partial^2 w}{\partial y^2} + \nu \frac{\partial^2 w}{\partial x^2} \delta \frac{\partial^2 w}{\partial y^2} + \nu \frac{\partial^2 w}{\partial y^2} \delta \frac{\partial^2 w}{\partial x^2} + \right\} dxdy \right] \, dt = 0 \]

(12)

Assuming simple harmonic motion of the vibrating plate (free vibration), the displacement, \( w \), can be expressed as,

\[ \tilde{w}(x,y,t) = w(x,y) \sin \omega t \]  

(13)

Substituting this expression into Equation 12 and collecting terms yields,

\[ \left[ \omega^2 \int \int w \delta \omega dxdydz - \int \int D \left\{ \frac{\partial^2 w}{\partial x^2} \delta \frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial y^2} \delta \frac{\partial^2 w}{\partial y^2} + \right\} dxdy \right] \cdot \int \sin^2 \omega t dt = 0 \]  

(14)
Recognizing that the integral
\[ \int_{t_0}^{t_1} \sin^2 \omega t \, dt \]
cannot vanish for any time, \( t_1 \), larger than \( t_0 \), implies that the following condition must exist.

\[ \omega^2 \int \int_A \xi w \delta w \, dx \, dy - \int \int_D \left\{ \frac{\partial^2 w}{\partial x^2} \delta + \frac{\partial^2 w}{\partial y^2} \delta \right\} \frac{\partial^2 w}{\partial x^2} \delta + \frac{\partial^2 w}{\partial y^2} \delta + \nu \frac{\partial^2 w}{\partial x^2} \delta + \frac{\partial^2 w}{\partial y^2} \delta \right\} \, dx \, dy = 0 \quad (15) \]

Equation 15, as derived is applicable to only simple harmonic motion of the system.

5. PLATE COORDINATE CONFIGURATION

To aid in satisfying the necessary boundary conditions, the plate has been modeled as two discrete elements, one of which embodies the free surface of the crack. The coordinate system used for the analysis of the combined plate elements is shown in Figure 1. Dimensional characteristics of the elements served to model the root crack configuration for a series of crack depths (% chord). The nondimensionalization performed consisted of the following:
\[ \eta_1 = \eta_2 = y/a \quad \xi_1 = x_1/b_1 \quad \xi_2 = x_2/b_2 \]

\[ dy_1 = dy_2 = ad \eta \quad dx_1 = b_1 d\xi_1 \quad dx_2 = b_2 d\xi_2 \]

\[ \text{AR}_1 = a/b_1 \quad \text{AR}_2 = a/b_2 \]

\[ \text{Combined Plate AR} = \frac{\text{AR}_1 \cdot \text{AR}_2}{\text{AR}_1 + \text{AR}_2} \]

6. DISPLACEMENT FUNCTIONS

Based on the concepts as defined by Ritz (Reference 2) and knowledge gained from References 4 through 8, a set of admissible functions in the form of a simple truncated power series served as the deflection function for this analysis. The functions used for solving the crack plate problem are expressed in the nondimensional form,

\[
W_1 (\xi_1, \eta) = g_1 (\xi_1, \eta) \sum_{i=0}^{N} \sum_{j=0}^{M} A_{ij} \eta^i \xi_1^j \\
W_2 (\xi_2, \eta) = g_2 (\xi_2, \eta) \sum_{i=0}^{N} \sum_{j=0}^{M} B_{ij} \eta^i \xi_2^j
\]

where the term \( g(\xi, \eta) \) forces satisfaction of the prescribed geometrical boundary conditions. The most general form of this function for the coordinate system, Figure 1, chosen is,

\[
g(\xi, \eta) = \phi_1 (1 - \xi) \phi_2 \eta \theta_1 (1 - \eta) \theta_2
\]
The specific values of the $\phi$s and $\theta$s in Equation 17 for the two element solution are,

Element 1: $\theta_1 = 2 \quad \phi_1 = \phi_2 = \theta_2 = 0$ \hspace{1cm} (18)

Element 2: $\phi_1 = \phi_2 = \theta_1 = \theta_2 = 0$

For the line of commonality between the two elements the following continuity conditions are required,

Displacement: $W_1 (1, \eta) = W_2 (0, \eta)$

Chordwise Slope: $W_{1x} (1, \eta) = W_{2x} (0, \eta)$ \hspace{1cm} (19)

Spanwise Slope: $W_{1y} (1, \eta) = W_{2y} (0, \eta)$

The author's experience (Reference 8) in performing these types of calculations for the case of beams with discontinuities has shown that satisfying only the slope and displacement conditions along the connecting boundary has provided excellent convergence on the higher order derivatives corresponding to the moments, shears, and forces.

Satisfying the three continuity requirements, Equations 19, and substituting the appropriate "$g$" functions, Equation 18, into Equations 16 yields,

$$W_1 (\xi_1, \eta) = \sum_{i=0}^{N} \sum_{j=0}^{M} A_{ij} \eta_i + 2 \xi_1 j$$
Replacing the deflection functions in Equations 18 with Equations 20 and performing the necessary operation with the operator, $\delta$, where

\[
\delta w_1 = \sum_{\lambda=0}^{k=0} \sum_{k=0}^{\infty} \eta^k \delta A_{k\lambda} \\
\delta w_2 = \sum_{\lambda=0}^{k=0} \sum_{k=0}^{\infty} \eta^k \delta A_{k\lambda} + \alpha \sum_{\lambda=0}^{k=0} \sum_{k=0}^{\infty} \eta^k \delta A_{k\lambda} + \sum_{\lambda=0}^{k=0} \sum_{k=0}^{\infty} \eta^k \delta A_{k\lambda}
\]

results in the set of equations of the form,

\[
\sum_{\lambda=0}^{k=0} \sum_{k=0}^{\infty} \sum_{j=0}^{i=0} A_{ij} \left( \left( K_{ij,k\lambda} - \lambda^2 M_{ij,k\lambda} \right) + B_{ij} \left( K_{ij,k\lambda} - \lambda^2 M_{ij,k\lambda} \right) \right) = 0 \quad (21)
\]

for $k = 0, 1, 2 \ldots M$

$\lambda = 0, 1, 2 \ldots N$

$j = 2, 3 \ldots N$
\[
\sum_{j=0}^{N} \sum_{i=0}^{M} \left[ A_{ij} (K_{2i,jk}^{T} - \lambda^2 M_{2i,jk}^{T}) + B_{ij} (K_{3i,jk}^{T} - \lambda^2 M_{3i,jk}^{T}) \right] = 0 \quad (22)
\]

for \( k = 0, 1, 2 \ldots M \)
\( j = 2, 3 \ldots N \)
\( \lambda = 2, 3 \ldots N \)

The recursion formulas for the matrix elements are presented in the Appendix. Equations 21 and 22 can be expressed in matrix form as,

\[
\begin{pmatrix} [K1] & [K2] \\ [K2]^{T} & [K3] \end{pmatrix} - \lambda^2 \begin{pmatrix} [M1] & [M2] \\ [M2]^{T} & [M3] \end{pmatrix} \begin{bmatrix} A \\ B \end{bmatrix} = 0 \quad (23)
\]

The \( 1K \) and \( 1M \) are square symmetric matrices of order \( M \cdot (2N - 2) \).

For a nontrivial solution to this set of homogeneous equations, the determinant of the coefficient matrix must vanish.

\[
\begin{vmatrix} [1K] & - \lambda^2 [1M] \end{vmatrix} = 0 \quad (24)
\]
SECTION III
RESULTS

Before attempting the solution to the nonuniform cantilever plate problem using the method of Ritz, a study of the rate and type of convergence possible was performed. The uniform cantilever plate vibration problem served to demonstrate the convergence possible using this approach. A great deal of data, both experimental and analytical, was available for comparison. Table 1 summarizes the eigenvalue comparisons for the various solution schemes.

A convergence study was conducted for the uncracked configuration on the effects of varying the aspect ratios of the two separate elements while maintaining the same combined aspect ratio of 2. Table 2 summarizes the results of this study for four different element combinations. As depicted, little variation was noted for the cases considered. In addition, Table 3 shows the results of a study conducted on the rate of eigenvalue convergence as a function of the number of terms used in the truncated power series. A study of this type was not performed on the effect of the number of elements in the finite element solution due to cost restraints. The average cost of extracting approximately 84 eigenvalues and their corresponding eigenvectors using the direct approach was $15.00. However, the cost of extracting the first 10 eigenvalues and mode shapes using the finite element program, NASTRAN, was $150.00. A study was performed and documented (Reference 10) which showed a sufficient lower bound convergence for a rectangular cantilever plate with an aspect ratio of 2 using the
same number and type of finite elements. In all cases, good agreement was obtained for the uniform cantilever plate solution schemes, Ritz, and finite element when compared to experimental and other analytical solutions.

With the good correlation between the experimental, direct, and finite element solutions for the uniform plate, the problem of the mixed boundary condition plate response was addressed. The crack was introduced into the analytical solutions as a free boundary with no surface interactions. For the experimental test, a narrow cut was made along the root of the plate attachment. The plate was not removed from its support throughout the entire testing sequence. An acoustical siren served as the excitation source. Resonant conditions were defined by two separate methods.

One approach employed the use of a laser interferometry technique to visually detect the resonant mode through the laser light interference patterns. The second method involved the use of an oscilloscope and a piezo-electric accelerometer. Resonant conditions were determined by plotting the input forcing function (sinusoidal) against the output signal as relayed by the accelerometer. The plate used for obtaining the experimental data consisted of an aluminum flat plate 1/8" x 3" x 6" rigidly constrained at one edge by two solid steel blocks. These blocks were attached to an air-damped (floating) table. Poisson's ratio (ν) of 0.3, mass density of 0.100 lb/in³, and elastic modules (E)
of $1.0 \times 10^7 \text{ lbf/in}^2$ were assumed for the analytical portion of the study.

Figures 2 through 9 portray the eigenvalue results for the first eight out-of-plane vibration modes. The data depicts the response as a function of root crack length for the three solution schemes. All eigenvalues have been normalized to the uniform (uncracked) configuration corresponding to each solution. In all cases, the experimental frequencies fall below the two analytical solutions. Reasonably good agreement can be seen in most instances between the finite element and energy solutions. In addition, Figures 10 through 16 show the variation in mode shapes as a function of crack length. The experimental mode shapes consist of the holograms taken from the laser setup previously mentioned. The finite element mode shape plots are contour surface diagrams, whereas the energy solution generated plots represent positive and negative out-of-plane displacements.
SECTION IV
CONCLUSIONS

The results of this work have demonstrated that a direct and economical solution to the nonuniform plate vibration can be obtained. Excellent agreement was shown for the uniform plate vibration solution when compared to those obtained from literature. Comparison of the results for the nonuniform vibration problem has indicated some differences between the theoretical and experimental solutions. Similar results were obtained for both the finite element and energy solutions. Figure 17 portrays the relative comparison between the uniform and nonuniform deviations from the experimental solution. As shown, a marked increase in the percent difference occurs for the cracked plate solution. This difference may possibly be explained by either a breakdown in the assumptions associated with thin plate vibration theory or the approach used in obtaining the experimental results. Both results indicate the same type of frequency decay with increasing crack length, but differ slightly in the absolute value of this decay. Additional experimental testing and analysis are necessary to resolve the problem of the noted difference.

This paper has presented an essential step towards the understanding of the effect of cracks on quasi-blade response. It is apparent from the results that further work in the area of nonuniform blade response is warranted before consideration is given to extending the damage tolerance criteria to gas turbine engine airfoils.
