FOREWORD

This research was sponsored jointly by the Massachusetts Institute of Technology's Lincoln Laboratory under P.O. No. CC-164 and the United States Air Force, Office of Scientific Research under Contract F44620-76-C-0049.

This material was submitted by Marshall D. Solomon as a thesis for the Degree of Master of Science in Aeronautics and Astronautics in May of 1977.

LIST OF SYMBOLS (continued)

- \( C_{fL}(x) \) Local laminar skin friction coefficient
- \( C_{ft}(\ell) \) Average turbulent skin friction coefficient on flat plate of length \( \ell \)
- \( c \) Constant in equation of a plane
- \( \bar{c} \) Two-thirds of the root chord
- \( E_L \) Area of projection of lower surface onto plane \( \perp \) to free stream
- \( E_U \) Area of projection of upper surface onto plane \( \perp \) to free stream
- \( h \) Semi-span in plane of wing panel
- \( \hat{i} \) Unit vector in \( x \)-direction
- \( L/D \) Lift-to-drag ratio
- \( l_1 \) Caret wing length measured from apex to base plane
- \( l_2 \) Length of internal rib
- \( l_3 \) Length of upper surface rib
- \( l(z) \) Distance from leading-to-trailing edge measured parallel to internal or upper surface rib
- \( \lambda, m, n \) Direction cosines
- \( M \) Mach number
- \( P_b \) Base pressure
- \( P_L \) Lower surface pressure
- \( P_U \) Upper surface pressure
LIST OF SYMBOLS (continued)

$q_{\infty}$ Free stream dynamic pressure

$Re$ Reynolds number

$S$ Plan area

$T$ Static temperature

$V$ Velocity

$x,y,z$ Coordinates in free stream, vertical and horizontal directions

$x,z$ Coordinates parallel and $\perp$ to internal or upper surface ribs in skin friction calculations

$\beta$ Angle between $M_1$ and $\overrightarrow{ABC}$

$\beta'$ Angle between $M_1$ and $\overrightarrow{ABC'}$;

$\Gamma_1$ Wedge angle normal to leading edge (lower surface)

$\Gamma'_1$ Expansion angle normal to leading edge (upper surface)

$\Gamma_{\text{max}}$ Maximum stream deflection angle

$\delta$ Angle between internal rib and free stream direction

$\delta'$ Angle between upper surface rib and free stream direction

$\eta_L$ Correlation parameter for laminar base pressure data

$\eta_T$ Correlation parameter for turbulent base pressure data

$\Theta$ Angle between plane spanning leading edges and free stream direction

$\mu$ Viscosity

</table>
Aircraft designed for flight at low supersonic Mach numbers have, for a long time, employed the swept wing with subsonic leading edge to prevent the appearance of shock waves in the flow field (at least ahead of the trailing edge) and thereby avoid the losses associated with them. At higher Mach numbers, say above 3, such a wing would be so highly swept that its low speed performance is unacceptable. One must therefore go to either a variable geometry wing or a wing with a supersonic leading edge. In the latter case, it is desirable from the standpoint of lifting efficiency to have the shock waves attached to the leading edge and confined to the flow over the lower surface. Wings supporting a flow of this type are known collectively as waveriders (1).

The general problem of calculating the flow field about an arbitrary three-dimensional body in a supersonic stream is unmanageable. Thus another approach is usually taken with waveriders, the inverse method, wherein one starts with a simple known flow field and constructs a body to fit it by replacing stream surfaces with the solid walls of the body. The flows which have been used in this context are two-dimensional wedge flow, two-dimensional Prandtl-Meyer expansion and axi-symmetric cone flow.
The first published report of a body of this type is by G. I. Maikapar (2) of the U.S.S.R. in which a pyramid whose base is a polygon with concave (reentrant) sides is surrounded by \( n \) regions of wedge flow with the plane oblique shocks spanning the \( n \) corners of the polygon. A lifting body derived from wedge flow was first reported by T. Nonweiler (3,4) and is actually \( \frac{1}{n} \)th of the Maikapar body. This body, the caret wing, has an inverted V cross section from which it received its name (Figure 1). J. W. Flower (5) has described upper expansion surfaces derived from a Prandtl-Meyer expansion and the combination of these with caret wing lower surfaces. A survey of much of the work done in Great Britain using the inverse method has been presented by J. Seddon (1) and A. Spence.

All bodies derived from a known flow field necessarily have a "design point", the free stream Mach number of the deriving flow and the angle of incidence of the body to that flow. At other flight conditions the simple two-dimensional or axi-symmetric flow will not be maintained and some approximate method must be used to describe the off-design behavior. J. Venn (6) and J. W. Flower have given a qualitative description of the shock patterns for off-design caret wings and have shown that exact solutions other than at the design point exist for certain of these wings. The flow field of a body similar to the reentrant pyramid but with blunt rather
than sharp corners and a shock attached only at the apex has been solved numerically by B. Ziph (7) using a finite difference approximation to the equations governing conical flow. The approximate method used in this study will be described in Chapter II.

This study is concerned only with the caret wing wave-rider. The lower surface of the caret wing can be described by the three parameters \( \delta \), \( \theta \) and \( \phi \) (Figure 1). Delta is the angle between the internal rib and the free stream direction. Theta is the angle between the plane spanning the leading edges and the free stream direction. Phi is the angle between the two free stream surfaces containing the leading edges; i.e., the angle between the projection of the leading edges onto a plane perpendicular to the free stream. The volume in \( \delta, \theta, \phi \) space of all possible caret wing lower surfaces is shown in Figure 2 as the cylinder with triangular ends ABC and DEF. The ranges of the parameters are \( 0^\circ < \phi < 180^\circ \), \( 0^\circ < \theta < 90^\circ \) and \( 0^\circ < \delta < \theta \). Note that in the limit \( \phi = 180^\circ \) the caret wing becomes a two-dimensional wedge.

Caret wings for which a design Mach number, \( M_{\text{des}} \), exists form a more restricted class. At the design point a plane oblique shock spans the leading edges and \( \delta \) and \( \theta \) are the stream deflection angle and shock angle, respectively, of the corresponding wedge flow. For any given \( \theta \) there is a maximum \( \delta \), occurring at infinite Mach number, above which wedge flow
does not have an attached shock solution. Thus $M_{\text{des}}$ will exist only for those values of $\delta$ less than or equal this maximum. In Figure 2, the volume of all caret wings that have a design point is the cylinder with end surfaces AGB and DHE.

This volume can itself be divided into two parts, depending on whether the wedge flow corresponding to any $\delta, \theta$ pair is a weak or strong shock solution. For wedge flow, the strong shock is not observed in practice and it is therefore not expected to occur in the caret wing flow field either. Only caret wings derivable from wedge flow of the weak type will be considered in the remainder of this paper. In Figure 2, the volume in $\delta, \theta, \phi$ space of these caret wings is the cylinder with end surfaces AGIB and DHJE. The terms "weak" and "strong" are used above in the conventional sense and should not be confused with their use later on in discussions about the component of the free stream velocity normal to the leading edge.

The caret wing body studied here will be completed with an upper expansion surface defined in a manner analogous to the lower surface and a base surface normal to the free stream direction (Figure 3). Just as the lower surface is defined by the parameters $\delta$, $\theta$ and $\phi$, the upper surface will be defined by $\delta'$, $\theta$ and $\phi$ where $\delta'$ is the angle between the upper surface rib and the free stream direction and $\theta$ and $\phi$ are the
same as for the lower surface. The common values of $\Theta$ and $\phi$ guarantee that the leading edges of the lower and upper surfaces coincide. To reduce the number of independent variables, $\varepsilon$ will always be taken equal to 3° less than $\delta$. As a result, the thickness ratio will be about 0.05.

The main concern of this study is the estimation of the lift coefficient, drag coefficient and lift-to-drag ratio of caret wings and the identification of their dependence on body geometry, Mach number and Reynolds number. Mach numbers and Reynolds numbers considered range from 1.5 to 5.0 and from $10^5$ to $10^8$ respectively. The aerodynamic coefficients are calculated by combining estimates of the upper, lower and base surface pressures and estimates of the skin friction on the upper and lower surfaces. Calculations of the pressures on the upper and lower surfaces are based on supersonic, inviscid, perfect fluid gas dynamics and calculations of base pressures rely on published experimental data. The skin friction calculations are for flat plates with zero pressure gradient.

A comparison of the performance of caret wings to delta wings will also be made.
CHAPTER II

A MODEL OF THE CARET WING FLOW FIELD

2.1 Analysis of the Caret Wing Flow Field at Design Conditions

It is well known that the velocity component parallel to an oblique shock wave passes through unchanged and that the shock acts as a normal shock to the normal velocity component. Except for relations involving ratios of static-to-total conditions, the changes in properties across an oblique shock are the same as for the normal velocity components and a normal shock. On this basis the use of normal shock tables is extended to oblique shock waves (8). More generally, one can take any oblique shock flow, add or subtract a velocity component of any magnitude which is tangent to the shock and calculate - based on the new velocities, shock angle and stream deflection angle - the change in properties across the shock in the original flow.

An interesting phenomenon associated with this calculation procedure is that, while the changes in properties across the shocks are the same for both flows, the shock type ("weak" or "strong") may change. In a simple case, for example, to find the pressure ratio across a weak oblique shock in two-dimensional wedge flow one might calculate the Mach number of the velocity component normal to the shock and look up the
pressure ratio in a normal shock table. However, the normal shock is of the strong type (the weak solution corresponding to the normal shock is a Mach wave) and thus the question arises, whether to use the weak or strong solution. Clearly, the spatial location of the shock cannot change. In the example under discussion, the Mach number component used in the table look up is normal to the shock and the solution which preserves this orientation, the strong solution, is the desired one.

A slightly different application of the concept of subtracting velocity components tangent to a shock wave is found in the analysis of the swept wedge of infinite span. The component of the free stream velocity which is parallel to the leading edge of the wedge will also be tangent to any shock attached to the leading edge. Therefore, this velocity component can be subtracted from the flow field by a Galilean transformation of coordinates leaving an upstream velocity which is normal to the leading edge and which is deflected by the wedge through the angle the wedge makes as measured in a plane perpendicular to the leading edge. This is just two-dimensional wedge flow. If the normal velocity component is supersonic and the wedge angle normal to the leading edge is small enough, weak and strong attached shock solutions are mathematically possible. In practice the weak shock is always observed in two-dimensional wedge flow and the
existence of crossflow in the swept wedge problem will not alter this, even though the strong shock with respect to the normal velocity component is, in some cases, weak with respect to the free stream. If the normal velocity component is subsonic or the wedge angle is too large, no attached shock solution exists.

These ideas will now be applied to the caret wing flow field. The caret wing's lower surface is formed from sections of two swept wedges which are joined at the vertical symmetry plane of the wing. At the design point, a plane shock spans the leading edges and deflects the free stream through the angle δ, the angle between the free stream and the internal rib. In the same manner as the swept wedge of infinite span, the component of the free stream velocity parallel to either of the caret wing's leading edges, $\vec{V}_{cf}$, must be tangent to the design point shock and, therefore, can be subtracted from the free stream, $\vec{V}_\infty$. The shock can then be analyzed using the component of the free stream velocity normal to the leading edge, $\vec{V}_\perp$, and the wedge angle normal to the leading edge, $\Gamma_\perp$, just as well as from the point of view of $\vec{V}_\infty$ and δ.

Consider a family of caret wings, all derivable from the same two-dimensional wedge flow. They will have the angles δ and θ in common while φ varies from zero to 180 degrees
(Figure 4). A single design Mach number determined by \( \delta \) and \( \theta \) will also be common to the members of this family.

In the limit \( \theta = 180^\circ \) the caret wing is a two-dimensional wedge. The velocity component normal to the leading edge is equal to the free stream velocity and the wedge angle normal to the leading edge is equal to \( \delta \). As mentioned in the introduction, only caret wings whose design point shocks are weak with respect to the free stream are being considered. So when \( \theta \geq 180^\circ \) the design point shock is also weak with respect to \( \overline{V}_L \).

In the limit \( \theta = 0^\circ \) the velocity component normal to the leading edge is also perpendicular to the design point shock. Thus the shock must be strong with respect to \( \overline{V}_L \). As explained earlier, this shock is never found on the swept wedge of infinite span and therefore doubt is cast on the existence of the caret wing's design point flow as \( \theta \) approaches zero. However, the fact that the strong shock is never observed on an isolated swept wedge is not sufficient grounds for dismissing the possibility of its occurrence here, since each leading edge of the caret wing lies within the Mach cone of influence of the opposite wing panel. More will be said about the tenability of these strong shock solutions in the next section.
Evidently, at some value of $\phi$ between zero and 180 degrees the design point shock's type with respect to $\overline{V}_\perp$ undergoes a transition from weak to strong. The value of $\phi$ at which this occurs, $\phi_{\text{trans}}$, must be characterized by a smooth transition between types because physically the shock is the same regardless of $\phi$, only the velocity component being analyzed changes with $\phi$. For any given Mach number there is a maximum angle, $\Gamma_{\text{max}}$, through which a streamline can be deflected by a single oblique shock wave and at which the weak and strong shocks coincide (the governing cubic equation has a double root). Thus $\phi_{\text{trans}}$ is that value of $\phi$ where $\Gamma_{\text{max}}$ equals $\Gamma_\perp$. This is illustrated in Figure 5 for the particular caret wing family $\delta = 5.0^\circ$ and $\theta = 34.0^\circ$, where $\Gamma_{\text{max}}$, $\Gamma_\perp$ and $\Gamma_{\text{max}} - \Gamma_\perp$ are plotted as functions of $\phi$. $\Gamma_{\text{max}} - \Gamma_\perp$ goes to zero at $\phi = \phi_{\text{trans}} = 42.29^\circ$.

Caret wings whose design point shocks are weak with respect to $\overline{V}_\infty$ can now be further classified according to whether the shock is weak or strong with respect to $\overline{V}_\perp$. Wings with $\phi$ greater than $\phi_{\text{trans}}$ have the weak solution and those with $\phi$ less than $\phi_{\text{trans}}$ the strong one. $\phi_{\text{trans}}$ is plotted as a function of $\theta$ with $\delta$ as a parameter in Figure 6. Using the curve corresponding to the value of $\delta$ one is interested in, caret wings lying to the left of the curve have design point shocks that are weak with respect to $\overline{V}_\perp$ and those lying to the right,
strong shocks. The range of $\theta$ for a given $\delta$ varies from a minimum when $M_{des} = \infty$ to a maximum when $\Gamma_{max} (M_{des}) = \delta$.

It is interesting to plot, for the flow normal to the leading edge of a family of caret wings, the pressure ratio of both the weak and strong shocks as a function of $\phi$. This is done for the family $\delta = 5.0^\circ$ and $\theta = 34.0^\circ$ at $M = M_{des} = 2.02$ in Figure 7. Starting at $\phi = 180^\circ$ and down to $\phi = \phi_{trans} = 42.29^\circ$ the weak shock gives the design point pressure ratio which is a constant independent of $\phi$. At $\phi = \phi_{trans}$ the strong shock picks up where the weak shock leaves off and continues the design point pressure ratio down to $\phi = 0^\circ$. The weak and strong solutions, patched together at $\phi = \phi_{trans}$, give the flow field the family of caret wings was derived from.

2.2 Extension of the Swept Wedge Analysis to Off-Design Conditions

Schlieren photographs taken in wind tunnel studies of Maikapar bodies at Mach numbers below $M_{des}$ indicate that a convex curved shock attached to the leading edges replaces the plane shock found at the design point (9). For $M_{\infty} < M_{des}$ and $\phi > \phi_{trans}$, Venn (6) and Flower suggest a convex shock composed of a curved central section joined to plane shocks emanating from the leading edges (Figure 8). The shock is plane outside the Mach cone from the caret wing's apex and is the weak shock calculated using $\overline{V}$ and $\Gamma$. 
For $M_\infty > M_{\text{des}}$, Venn (6) and Flower suggest either a bifurcated shock pattern or a pattern where plane shocks from the leading edges intersect at the vertical symmetry plane and are followed by a complex system of shocks further inside the wing (Figure 8). In either case the leading edge shocks are plane outside the Mach cone from the wing's apex, are inclined inside the plane spanning the leading edges and are the weak shock calculated using $\bar{V}_\perp$ and $\Gamma_\perp$.

These complicated shock patterns will be approximated here by two plane shocks, one from each leading edge, that intersect at the wing's vertical symmetry plane (Figure 8). It was shown in the previous section that the on-design caret wing can be treated as a swept wedge. The model of the caret wing's off-design behavior adopted here will be to extend the use of the swept wedge calculations to all conditions, except for $\phi < \phi_{\text{trans}}$. Within this approximation, the pressure on the caret wing's lower surface is a constant determined by the pressure ratio across the leading edge shocks.

The model just described for the caret wing's lower surface flow field gives the exact solution under the assumptions of steady, supersonic, inviscid, perfect fluid aerodynamics when the free stream Mach number, $M_\infty$, is equal to the design Mach number. It also gives the exact solution in the limits $\phi = 180^\circ$ or $\delta = 0^\circ$. 
Under the same assumptions, the model gives a shock tangent to the actual shock at the leading edges regardless of the influence of the opposite wing panel. This is because the Mach number and stream deflection angle at the leading edges are known and are sufficient to determine the shock. Furthermore, the shocks given by the model will also be correct outside of the Mach cone from the apex of the caret wing. It should be noted that this model of the flow field violates the boundary condition that there be no flow across the vertical symmetry plane.

The average pressure on the lower surface of a caret wing is approximated by the pressure downstream of the model's leading edge shocks. Useful bounds on the magnitude of the error in this approximation are not known. However, something can be said about the sign of the error. A method of determining the magnitude of the error will be suggested in Chapter V.

For cases where $M_\infty < M_{\text{des}}$, the model's shocks are inclined outside of the plane spanning the leading edges. Therefore, they direct the flow away from the vertical symmetry plane and expansions will be present in the actual flow which curve the shock toward the internal rib so that it is perpendicular to the symmetry plane at their intersection (6). Thus the model gives too high a pressure in this case.
For cases where \( M_\infty > M_{des} \), the model's shocks are inclined inside the plane spanning the leading edges. Therefore they direct the flow toward the symmetry plane and further compression will be present in the actual flow (6). In this case the model gives a pressure below the correct value.

More can now be said about the strong shock solutions for \( \phi < \phi_{trans} \). At the design Mach number it was possible to make a smooth transition from the weak to strong cases. This transition occurred at \( \phi_{trans} \), where \( \Gamma_{max} \) is equal to \( \Gamma_\perp \) and the weak and strong solutions coincide. \( \Gamma_\perp \) is a geometric property of the caret wing and does not change with \( M_\infty \). However, \( \Gamma_{max} \) is a monotonically increasing function of \( M_\infty \). If \( M_\infty \) is raised above \( M_{des} \), then there will no longer be any value of \( \phi \) for which \( \Gamma_{max} \) is equal to \( \Gamma_\perp \) and no smooth transition from the weak to the strong cases is possible. In Figure 5 the entire curve for \( \Gamma_{max} \) vs. \( \phi \) is shifted upwards when \( M_\infty > M_{des} \) and \( \Gamma_{max} - \Gamma_\perp \) never goes to zero. It is not likely that a discontinuous change in shock pattern or lower surface pressure will occur with an infinitesimal change in body geometry or flight conditions and for this reason the strong shock solutions must be considered untenable. Other possibilities include a weak shock at the leading edge followed by a complicated system of shocks further inside the wing, unsteady behavior or detachment. Venn (6) and Flower suggest the first of these on the
grounds that weak shocks are always observed on two-dimensional wedges. Because of the uncertainty here, caret wings with design point shocks that are strong with respect to $V_\perp$ will not be considered in calculations of lift, drag and lift-to-drag ratio.

One additional generalization about the caret wing's off-design behavior will be made. When $M_{\infty}$ is reduced below $M_{\text{des}}$, the entire curve for $\Gamma_{\text{max}}$ vs. $\phi$ in Figure 5 is shifted downward. This leaves a neighborhood about $\phi_{\text{trans}}$ in which $\Gamma_{\text{max}}$ is less than $\Gamma_\perp$, and consequently, the shock is detached.

2.3 The Upper Surface Flow Field

The model for the upper surface flow field is analogous to the model for the lower surface. Corresponding to the shock on the lower surface is a Prandtl-Meyer expansion of the flow normal to the leading edge for the upper surface. The component of the free stream velocity normal to the leading edge, $\bar{V}_\perp$, is the same as before and the expansion angle is calculated in the same way as $\Gamma_\perp$ except that $\delta'$ is used instead of $\delta$. The average pressure on the upper surface of a caret wing is approximated by the pressure downstream of the Prandtl-Meyer expansion at the leading edge. Since the expansion at the leading edge directs the flow toward the vertical symmetry plane, additional compression will take place in the actual flow and the model's estimate of the upper
surface pressure must be too low. This model also violates
the boundary condition of no flow across the symmetry plane.

2.4 Estimate of Skin Friction

An approximation of the skin friction drag consistent
with the constant pressure surfaces of the upper and lower
surface flow field models is employed here. The calculation
is for a two-dimensional flat plate with zero pressure
gradient. The Mach numbers and Reynolds numbers downstream
of the lower surface shock and upper surface expansion are
used as the free stream conditions in the calculation of the
skin friction on the lower and upper surfaces respectively.
A power law for the variation of viscosity with temperature
valid in the range 300°R to 900°R is used to calculate the
Reynolds numbers downstream of the shock and expansion (8).
Skin friction estimates for both laminar and turbulent
boundary layers are made.

The local value of the skin friction coefficient for
laminar, incompressible flow based on distance from the leading edge in the direction of the external flow (parallel to
the internal rib for the lower surface and parallel to the
upper surface rib for the upper surface) is integrated over
the lower and upper wetted surfaces to obtain the average
skin friction coefficients on the lower and upper surfaces.
These are multiplied by the ratio of compressible to incompressible skin friction coefficients based on an adiabatic wall, Prandtl number equal to one and exponent in the viscosity law equal to 0.765 given by Schlichting (10) for the Mach number range zero to ten.

Schlichting (10) found an empirical equation which, in the range $5 \times 10^5 < \text{Re}_l < 10^9$, fits the exact formula for the turbulent, incompressible skin friction coefficient based on a logarithmic velocity profile. This is integrated over the lower and upper wetted surfaces to give the average skin friction coefficients on the lower and upper surfaces. These are then multiplied by the ratio of compressible to incompressible skin friction coefficients from the theory of R. E. Wilson as reported by Schlichting (10). This ratio is valid for the Mach number range zero to ten.

2.5 Estimate of Base Pressure

The calculations of caret wing base pressure rely on published experimental data. The main source of this data is Chapman (11), Wimbrow and Kester's wind tunnel study of blunt trailing edge wings at Mach numbers 1.5, 2.0 and 3.1 for both laminar and turbulent boundary layers. Base pressure data taken on the vertical fin of the X-15 at Mach 5 has been used to extend the Mach number range of the turbulent boundary layer data (12). The work of Rom (13), Gadd (14) and Korst (15) have been compared to Chapman's data. Base pressure data
taken on Maikapar bodies at the Aerophysics Laboratory (16,17) have also been compared to the other data. Chapman's graphs of base pressure ratio vs. ratio of boundary layer thickness to trailing edge thickness appear in Figure 9 with the other authors' data added for comparison. The Maikapar body base pressures tend to be higher than the other data. This is apparently due to the lower aspect ratio.

Chapman (11) found that base pressure data at a given free stream Mach number is correlated to the ratio of boundary layer thickness at the trailing edge to trailing edge thickness. This variable depends on the thickness ratio and Reynolds number based on wing chord. The thickness ratio of a caret wing is constant at all spanwise locations. The free stream Reynolds number based on half the length is used as an average value over the span.

Straight lines have been fit to Chapman's (11) turbulent boundary layer base pressure curves and a line through the X-15 data point and parallel to Chapman's $M_\infty = 3.1$ line has been used for $M_\infty = 5.0$. Curves have been fitted to Chapman's laminar boundary layer base pressure curves. At intermediate Mach numbers linear interpolation between the curves is used.
CHAPTER III

CALCULATION OF THE LIFT COEFFICIENT, DRAG COEFFICIENT AND LIFT-TO-DRAG RATIO

3.1 Introduction

There are six independent variables in this problem. Four of them, $\delta$, $\delta'$, $\Theta$ and $\Phi$, define the caret wing's geometry and incidence to the free stream. The other two, the free stream Mach number, $M_\infty$, and the free stream Reynolds number, $Re_\infty$, specify the flight conditions. For convenience, the free stream Reynolds number has been based on the square root of the plan area, $S$, so that by holding $Re_\infty$ constant wings of the same plan area rather than length can be compared. A simple trigonometric formula which relates the Reynolds numbers based on $\sqrt{S}$ and length is presented in Section 3.6.

The lift coefficient, $C_L$, drag coefficient, $C_D$, and lift-to-drag ratio, $L/D$, are to be calculated as functions of the six independent variables. Five cases are considered: 1, no skin friction or base drag; 2, with laminar skin friction but no base drag; 3, with turbulent skin friction but no base drag; 4, with laminar skin friction and base drag; 5, with turbulent skin friction and base drag.
Given a set of values for the independent variables, a preliminary procedure must be undertaken to make sure the caret wing belongs to the group being considered in this study. To be a member of this group $M_{des}$ must exist, the design point shock must be weak with respect to the free stream and $\phi$ must be greater than or equal to $\phi_{trans}$.

If the above conditions are satisfied, the calculation of $C_L$, $C_D$ and $L/D$ can proceed. The equations for inviscid, compressible flow are taken from NACA Report 1135 (8). The ratio of specific heats, $c_p/c_v$, is assumed equal to 1.4.

3.2 Mach Number and Wedge Angle Normal to the Leading Edge

Formulas for $\tilde{M}_\perp$ and $\Gamma_\perp$ will be needed in three phases of the calculation of $C_L$, $C_D$ and $L/D$. They are necessary in the determination of $\phi_{trans}$, the pressure ratio across the lower surface shock and the pressure ratio across the upper surface expansion. In the derivation which follows, the Mach number will be treated as a vector.

Let the $x$-axis of a cartesian coordinate system be aligned with the free stream direction and the $y$ and $z$-axes be vertical and horizontal respectively. Also, let the origin of coordinates be located at the apex of a caret wing of unit length (Figure 3). Point A is the caret wing apex, point B is the left-hand wing tip and point C is the
intersection of the internal rib with the base. Vector \( \vec{B} \) is a vector pointing from the origin to point B.

The \((x,y,z)\) coordinates of points A, B and C are

\[
\begin{align*}
A &= (0,0,0) \\
B &= (1,b_2,b_3) \\
C &= (1,c_2,0)
\end{align*}
\]

where

\[
\begin{align*}
b_2 &= -\tan \theta \\
b_3 &= \tan \theta \tan \phi \\
c_2 &= -\tan \delta.
\end{align*}
\]

The component of \( \vec{M}_\infty \) parallel to the left-hand leading edge, \( \vec{M}_{cf} \), will be calculated by forming the dot product of \( \vec{M}_\infty \) and a unit vector parallel to the leading edge. The free stream Mach number in vector form is

\[
\vec{M}_\infty = M_\infty \hat{i} = (M_\infty,0,0).
\]

A unit vector parallel to the leading edge is

\[
\frac{\vec{B}}{|\vec{B}|} = \frac{(1,b_2,b_3)}{\sqrt{1+b_2^2+b_3^2}}.
\]
The Mach number parallel to the leading edge is

$$\bar{M}_{cf} = \left[ \bar{M}_\infty \cdot \frac{\bar{B}}{|\bar{B}|} \right] \frac{\bar{B}}{|\bar{B}|}$$

$$= \frac{M_\infty}{1+b_2^2+b_3^2} (1,b_2,b_3) \quad (3.2.9)$$

and its magnitude is given by

$$M_{cf} = |\bar{M}_{cf}| = \frac{M_\infty}{\sqrt{1+b_2^2+b_3^2}} \quad (3.2.10)$$

Calculation of the Mach number normal to the left-hand leading edge is now simply a matter of subtracting $\bar{M}_{cf}$ from $\bar{M}_\infty$.

$$\bar{M}_\perp = \bar{M}_\infty - \bar{M}_{cf} = \frac{M_\infty}{1+b_2^2+b_3^2} (b_2^2+b_3^2, -b_2, -b_3) \quad (3.2.11)$$

$$M_\perp = |\bar{M}_\perp| = \frac{M_\infty \sqrt{b_2^4+2b_2^2b_3^2+b_3^4+b_2^2+b_3^2}}{1+b_2^2+b_3^2} \quad (3.2.12)$$
The wedge angle normal to the left-hand leading edge, $\Gamma_\perp$, is the angle between $\overline{W}_\perp$ and the plane containing the left-hand lower surface of the caret wing (Figure 3). It will be found using the dot product of $\overline{W}_\perp$ and a unit vector normal to the lower surface, $\overline{ABC}_\perp$.

The equation of a plane with normal vector $(l,m,n)$ is

$$lx + my + nz = c.$$  \hspace{1cm} (3.2.13)

Equation (3.2.13) can be solved for $l$, $m$, $n$ and $c$ subject to the condition that the plane contain the points $A$, $B$ and $C$ and that vector $(l,m,n)$ be of unit length. The solution is

$$l = -c_2^2m$$  \hspace{1cm} (3.2.14)

$$m = \pm \left[c_2^2 + 1 + \left(\frac{c_2-b_2}{b_3}\right)^2\right]^{-1/2}$$  \hspace{1cm} (3.2.15)

$$n = \left(\frac{c_2-b_2}{b_3}\right)m$$  \hspace{1cm} (3.2.16)

$$c = 0.$$  \hspace{1cm} (3.2.17)

Thus a unit vector normal to the caret wing's left-hand lower surface is
\[
\overline{ABC}_\perp = \left[ c_2^2 + 1 + \left( \frac{c_2^2 - b_2}{b_3} \right)^2 \right]^{-1/2} (-c_2, 1, \frac{c_2 - b_2}{b_3}). \tag{3.2.18}
\]

\(\overline{ABC}_\perp\) is the inward normal due to the selection of the positive sign in Equation (3.2.15).

The angle between \(\overline{M}_\perp\) and \(\overline{ABC}_\perp\), \(\beta\), satisfies the relation

\[
\overline{M}_\perp \cdot \overline{ABC}_\perp = \overline{M}_\perp \cos \beta \tag{3.2.19}
\]

and is equal to \(90^\circ - \Gamma_\perp\) (Figure 3). Solving Equation (3.2.19) for \(\Gamma_\perp\)

\[
\sin \Gamma_\perp = \frac{\overline{M}_\perp \cdot \overline{ABC}_\perp}{\overline{M}_\perp} \tag{3.2.20}
\]

\[
\Gamma_\perp = \sin^{-1} \frac{-c_2 (1 + b_2^2 + b_3^2)}{\sqrt{c_2^2 + 1 + \left( \frac{c_2 - b_2}{b_3} \right)^2} \sqrt{b_2^4 + 2b_2^2b_3^2 + b_3^4 + 2b_2^2 + b_3^2}} \tag{3.2.21}
\]

The preliminary procedure mentioned in Section 3.1 can now be carried out. Calculation of \(M_{\text{des}}\) is the first step.

At the design point, \(\delta\) and \(\Theta\) are the stream deflection angle and shock angle with respect to the free stream of the flow.
through an oblique shock. Thus the formula for the Mach number upstream of an oblique shock can be used to find \( M_{\text{des}} \). If \( M_{\text{des}} \) does not exist, Equation (3.2.22) will give a number less than 1.

\[
\frac{M^2}{M_{\text{des}}} = \frac{10 (\cot \theta + \tan \delta)}{5 \sin 2 \theta - \tan \delta (7 + 5 \cos 2 \theta)} \tag{3.2.22}
\]

The second step is to determine whether or not the design point shock is weak with respect to the free stream. For a given Mach number the shock angle can range from the Mach angle, \( \sin^{-1} \frac{1}{M} \), to 90°, depending on the stream deflection angle. At the maximum stream deflection angle the shock angle has some intermediate value. Below this are the weak shocks, above it the strong ones and exactly at this value the shock is both weak and strong. Thus the design point shock is weak with respect to the free stream if \( \theta \) is less than or equal to the shock angle which would give the largest possible deflection of a streamline at \( M_{\text{des}} \).

This condition is expressed in Equation (3.2.23).

\[
\theta \leq \sin^{-1} \sqrt{\frac{3 M_{\text{des}}^2 - 5 + \sqrt{3 (3 M_{\text{des}}^4 + 4 M_{\text{des}}^2 + 20)}}{7 M_{\text{des}}^2}} \tag{3.2.23}
\]
The third step is to determine whether or not \( \phi > \phi_{\text{trans}} \), which means \( \phi_{\text{trans}} \) must be found. Given \( M_{\text{des}}, \delta \) and \( \Theta \), \( \phi_{\text{trans}} \) is the value of \( \phi \) for which \( \Gamma_{\text{max}} - \Gamma_{\perp} \) goes to zero.

\( \Gamma_{\perp} (\delta, \Theta, \phi) \) is given by Equations (3.2.21) and (3.2.4-6).

\( \Gamma_{\text{max}} \) is a function of \( M_{\perp} (M_{\text{des}}, \Theta, \phi) \), which is given by Equations (3.2.12), (3.2.22), (3.2.4) and (3.2.5). The relation between \( \Gamma_{\text{max}} \) and \( M_{\perp} \) is

\[
\Gamma_{\text{max}} = \cot^{-1} \left[ \tan \left( \omega |_{\Gamma_{\text{max}}} \right) \left( \frac{6 M_{\perp}^2}{5(M_{\perp}^2 \sin^2(\omega |_{\Gamma_{\text{max}}}) - 1)} \right) \right]
\]

(3.3.24)

where \( \omega |_{\Gamma_{\text{max}}} \) is the shock angle that would occur if a streamline were deflected through the angle \( \Gamma_{\text{max}} \) and is given by

\[
\sin^2(\omega |_{\Gamma_{\text{max}}}) = \frac{3 M_{\perp}^2 - 5 + \sqrt{3(3M_{\perp}^4 + 4 M_{\perp}^2 + 20)}}{7 M_{\perp}^2}
\]

(3.2.25)

The equations are too cumbersome to set \( \Gamma_{\text{max}} - \Gamma_{\perp} \) equal to zero and solve for \( \phi_{\text{trans}} \). It is simpler, especially on the computer, to search for the value of \( \phi \) at which \( \Gamma_{\text{max}} - \Gamma_{\perp} \) goes to zero. Once \( \phi_{\text{trans}} \) is found, it can be
compared to $\phi$. If $\phi > \phi_{\text{trans}}$, the design point shock is
weak with respect to $M_\perp$ and calculation of $C_L$, $C_D$ and $L/D$
can begin.

3.3 Pressure Ratio Across Lower Surface Shock

An attached shock will not be possible if the leading
edge is subsonic or $\Gamma_{\max} \left\{ M_{\infty}, \theta, \phi \right\} < \Gamma_\perp(\delta, \theta, \phi)$.

$M_\perp (M_\infty, \theta, \phi)$ is given by Equations (3.2.12), (3.2.4) and
(3.2.5). If $M_\perp < 1$, the leading edge is subsonic and calcu-
lation of the aerodynamic coefficients for the current values
of the independent variables is aborted. Otherwise $\Gamma_{\max} (M_\perp)$
is calculated using Equations (3.2.24) and (3.2.25) and $\Gamma_\perp$ is
calculated from Equations (3.2.21) and (3.2.4-6). Again, if
$\Gamma_{\max} < \Gamma_\perp$ further calculation is terminated. However, if
$\Gamma_{\max} > \Gamma_\perp$, a weak shock is attached to the leading edge and
the pressure ratio can be found as follows.

No simple expression for the pressure ratio in terms of
$M_\perp$ and $\Gamma_\perp$ exists so it is necessary to calculate the shock
angle, $\omega$, as an intermediate step. There is a cubic equation
for $\sin^2 \omega$ with coefficients that depend on $M_\perp$ and $\Gamma_\perp$; however,
it was found to be easier to search for the value of $\omega$ be-
tween $\sin^{-1} (1/M_\infty)$ and $\omega|_{\Gamma_{\max}}$, which gives the correct value
of $\Gamma_\perp$ using the formula
\[ \Gamma_\perp = \cot^{-1} \left[ \tan \omega \left( \frac{6 M^2}{5 (M^2 \sin^2 \omega - 1)} - 1 \right) \right]. \quad (3.3.1) \]

Once \( \omega \) is known, the pressure ratio across the shock, \( \xi_\perp \), is given by

\[ \xi_\perp = \frac{\mathcal{P}_\perp}{\mathcal{P}_\infty} = \frac{7 M^2 \sin^2 \omega - 1}{6} \quad (3.3.2) \]

where \( \mathcal{P}_\infty \) and \( \mathcal{P}_\perp \) are the static pressures upstream and downstream of the shock.

### 3.4 Pressure Ratio Across Upper Surface Expansion

The expansion angle normal to the leading edge, \( \Gamma'_\perp \), through which the upper surface flow turns is calculated in the same manner as \( \Gamma_\perp \) except that \( \delta' \), \( C' \) and \( c'_2 \) replace \( \delta \), \( C \) and \( c_2 \) in Equations (3.2.3), (3.2.6) and (3.2.21).

These equations become

\[ C' = (1, c'_2', 0) \quad (3.4.1) \]
\[ c'_2 = -\tan \delta' \quad (3.4.2) \]

\[ \Gamma'_\perp = \sin^{-1} \left[ \frac{-c'_2 (1 + b_2^2 + b_3^2)}{\sqrt{c'_2^2 + 1 + (\frac{c_2 - b_2}{b_3})^2} \sqrt{b_2^4 + 2 b_2^2 b_3^2 + b_3^4 + b_2^2 + b_3^2}} \right]. \quad (3.4.3) \]
In order to calculate the pressure ratio across the upper surface expansion, \( \xi_u \), the Mach number normal to the leading edge and downstream of the expansion, \( \mu_u \), must be found. To find \( \mu_u \) the Prandtl-Meyer angle, \( \nu \), through which a stream would turn in expanding from \( M=1 \) to \( M=\mu_u \) is needed and is given by

\[
\nu = 2.4495 \tan^{-1}(0.40825 \sqrt{\mu^2 - 1}) - \tan^{-1}\sqrt{\mu^2 - 1} + \Gamma'.
\] (3.4.4)

\( \mu_u \) is found using the following equation by searching for the value which gives the correct Prandtl-Meyer angle, \( \nu \).

\[
\nu = 2.4495 \tan^{-1}(0.40825 \sqrt{\mu_u^2 - 1}) - \tan^{-1}\sqrt{\mu_u^2 - 1}
\] (3.4.5)

Once \( \mu_u \) is known, the pressure ratio can be determined with the formula

\[
\xi_u = \frac{p_u}{p_\infty} = \left[\frac{5 + \mu^2}{5 + \mu_u^2}\right]^{-3.5}
\] (3.4.6)

where \( p_\infty \) and \( p_u \) are the static pressures upstream and downstream of the expansion.
3.5 Average Skin Friction Coefficient

The calculation of four quantities will be described in this section. They are the average laminar and turbulent skin friction coefficients on the caret wing's lower surface, $C_{fL}$ and $C_{ftL}$, and the average laminar and turbulent skin friction coefficients on the upper surface, $C_{fU}$ and $C_{ftU}$.

Reynolds numbers based on length downstream of the lower surface shock and upper surface expansion are required for the calculation of the skin friction coefficients. A power law for the variation of viscosity with temperature of the form

$$\frac{\mu}{\mu_r} = \left(\frac{T}{T_r}\right)^{0.76}, \quad 300^\circ R < T < 900^\circ R$$  \hspace{1cm} (3.5.1)

will be used in their determination. The Reynolds number ratio across the lower surface shock is given by

$$\frac{\text{Re}_{L_2}}{\text{Re}_\infty} = \frac{l_2}{S} \frac{\rho_L}{\rho_\infty} \frac{V_L}{V_\infty} \frac{\mu}{\mu_L}$$  \hspace{1cm} (3.5.2)

where $l_2$ is the length of the internal rib and the subscript $L$ refers to a property of the lower surface flow downstream of the shock. Expressions for the ratios in Equation (3.5.2) are
\[
\frac{L_2}{\sqrt{s}} = \frac{1}{\cos \delta \sqrt{\tan \theta \tan \frac{\phi}{2}}} \quad (3.5.3)
\]

\[
\frac{\rho_L}{\rho_\infty} = \frac{6 \xi_L + 1}{\xi_L + 6} \quad (3.5.4)
\]

\[
\frac{V_L}{V_\infty} = \left[ 1 - \frac{5(\xi_L^2 - 1)}{M_\infty^2(6 \xi_L + 1)} \right]^{1/2} \quad (3.5.5)
\]

\[
\frac{\mu_\infty}{\mu_L} = \left( \frac{T_\infty}{T_L} \right)^{0.76} = \left[ \frac{6 \xi_L + 1}{\xi_L (\xi_L + 6)} \right]^{0.76} \quad (3.5.6)
\]

Substituting Equations (3.5.3-6) into Equation (3.5.2) gives

\[
\frac{\text{Re}_{L_2}}{\text{Re}_\infty} = \frac{6 \xi_L + 1}{\xi_L + 6} \left[ 1 - \frac{5(\xi_L^2 - 1)}{M_\infty^2(6 \xi_L + 1)} \right]^{1/2} \left[ \frac{6 \xi_L + 1}{\xi_L (\xi_L + 6)} \right]^{0.76} \cos \delta \sqrt{\tan \theta \tan \frac{\phi}{2}} \quad (3.5.7)
\]
The Reynolds number ratio across the upper surface expansion is given by

$$\frac{Re_{l_3}}{Re_{\infty}} = \frac{l_3 \rho_u M_u a_u \mu_{\infty}}{\sqrt{5} \rho_{\infty} M_{\infty} a_\infty \mu_u}$$

(3.5.8)

where $l_3$ is the length of the upper surface rib and the subscript $u$ refers to a property of the upper surface flow downstream of the expansion. Expressions for the ratios in Equation (3.5.8) are

$$\frac{l_3}{\sqrt{5}} = \frac{1}{\cos \delta' \sqrt{\tan \Theta \tan \frac{\phi}{2}}}$$

(3.5.9)

$$\frac{\rho_u}{\rho_{\infty}} = \left[\frac{5 + M_u^2}{5 + M_{\infty}^2}\right]^{-\frac{5}{2}}$$

(3.5.10)

$$\frac{a_u}{a_{\infty}} = \left[\frac{5 + M_u^2}{5 + M_{\infty}^2}\right]^{-\frac{1}{2}}$$

(3.5.11)

$$\frac{\mu_{\infty}}{\mu_u} = \left(\frac{T_{\infty}}{T_u}\right)^{0.76} \left[\frac{5 + M_u^2}{5 + M_{\infty}^2}\right]^{0.76}$$

(3.5.12)
where

\[ M_u^2 = (5 + M_\infty^2)^{-2/7} \left( \xi_u \right)^{-5} \quad (3.5.13) \]

Substituting Equations (3.5.9–13) into Equation (3.5.8) gives

\[
\frac{Re_\lambda}{Re_\infty} = \frac{\left(5 + M_\infty^2\right)^{-2/7} \xi_u^{-5}}{M_\infty \cos \delta \tan \theta \tan \frac{\phi}{2}} \left( \xi_u \right)^{4.48} \frac{7}{\xi_u^2} \quad (3.5.14)
\]

The Mach number of the lower surface flow downstream of the shock is given by

\[
M_\lambda^2 = \frac{M_\infty^2(6\xi_h^2 + 1) - 5(\xi_h^2 - 1)}{\xi_h(\xi_h^2 + 6)} \quad (3.5.15)
\]

The four average skin friction coefficients can now be calculated. The local, laminar, incompressible skin friction coefficient is

\[
C_{f\lambda}(x) = \frac{0.664}{\sqrt{Re_x}} \quad (3.5.16)
\]
where \( x \) is the distance from the leading edge in the streamwise direction. The average over the lower wetted surface is given by

\[
(C_{f,l})_{i} = \frac{1}{h} \int_{0}^{H(z)} \frac{1}{l(z)} \int_{0}^{x} C_{f,l}(x) \frac{2.656}{Re_{l,2}}
\]

(3.5.17)

where \( h \) is the semi-span, \( l(z) = \frac{h}{z} \) (Figure 10) and the subscript \( i \) indicates incompressible flow. For the upper surface

\[
(C_{f,u})_{i} = \frac{2.656}{\sqrt{Re_{l,3}}}
\]

(3.5.18)

Multiplying Equations (3.5.17) and (3.5.18) by the ratio of compressible-to-incompressible laminar skin friction coefficients gives

\[
C_{f,l} = \frac{2.656 - 0.0718M_{l}}{\sqrt{Re_{l,2}}}, \quad 0 < M_{l} < 10
\]

(3.5.19)

\[
C_{f,u} = \frac{2.656 - 0.0718M_{u}}{\sqrt{Re_{l,3}}}, \quad 0 < M_{u} < 10.
\]

(3.5.20)
The average turbulent, incompressible skin friction coefficient between the leading edge and a point a distance \( \ell \) from it is

\[
C_{f_t}(\ell) = \frac{0.455}{(\log_{10} Re_{\ell})^{-2.58}}, \quad 5 \times 10^5 < Re_{\ell} < 10^9. \tag{3.5.21}
\]

The average over the lower wetted surface is

\[
(C_{f_t\ell})_i = \frac{1}{h} \int_0^h C_{f_t}(\ell(z)) \, dz
\]

\[
= \frac{0.455}{h} \int_0^h \left[ \log Re_{\ell/2} + \log \frac{z}{h} \right]^{-2.58} \, dz \tag{3.5.22}
\]

where \( \ell(z) = \frac{h}{2} z \) and \( h \) is the semi-span (Figure 10).

Using the binomial expansion

\[
(C_{f_t\ell})_i = \frac{0.455}{h} \int_0^h \left[ (\log Re_{\ell/2})^{-2.58} - 2.58 (\log Re_{\ell/2})^{-3.58} \log \frac{z}{h} \right] \, dz
\]

\[
= 0.455 \left[ (\log Re_{\ell/2})^{-2.58} + \frac{2.58}{\ln 10} (\log Re_{\ell/2})^{-3.58} \right]. \tag{3.5.23}
\]
For the upper surface

\[ (C_{ftu})_i \approx 0.455 \left[ \left( \log \text{Re}_{\lambda} \right)^{-2.58} + \frac{2.58}{\ln 10} \left( \log \text{Re}_{\lambda} \right)^{-3.58} \right] \]

(3.5.24)

Multiplying Equations (3.5.23) and (3.5.24) by the ratio of compressible-to-incompressible turbulent skin friction coefficients gives

\[ C_{ftu} = \begin{cases} 
(1.0 - 0.1186 M^2) (C_{ftu})_i, & 0 \leq M \leq 5.36 \\
(0.5962 - 0.0430 M^2) (C_{ftu})_i, & 5.36 < M \leq 10
\end{cases} \]  

(3.5.25)

\[ C_{ftu} = \begin{cases} 
(1.0 - 0.1186 M_u) (C_{ftu})_i, & 0 \leq M_u \leq 5.36 \\
(0.5962 - 0.0430 M_u) (C_{ftu})_i, & 5.36 < M_u \leq 10
\end{cases} \]  

(3.5.26)

3.6 Base Pressure Ratio

The ratio of base pressure to free stream static pressure is calculated for two cases. \( \xi_{bt} \) is the pressure ratio for a turbulent boundary layer approaching the trailing edge and \( \xi_{bl} \) is the pressure ratio for a laminar boundary layer.
Base pressure ratio is correlated to the ratio of boundary layer thickness at the trailing edge to trailing edge thickness. This parameter depends on the thickness ratio and Reynolds number based on chord length. The thickness ratio, \( \tau \), is given by

\[
\tau = (\tan \delta - \tan \delta') \cos \left( \frac{\delta' + \delta}{2} \right)
\]  

(3.6.1)

The average Reynolds number based on chord length over the span is

\[
Re_{ave} = \frac{Re_\infty}{2 \cos \left( \frac{\delta' + \delta}{2} \right) \sqrt{\tan \theta \tan \frac{\phi}{2}}}
\]  

(3.6.2)

For a turbulent boundary layer the correlation parameter, \( \eta_t \), is given over the range \( 0 < \eta_t < 5 \) by

\[
\eta_t = \frac{1}{\tau (Re_{ave})^{1/5}}
\]  

(3.6.3)

and the lines fit to Chapman's (11) and Goecke's (12) data are
At intermediate Mach numbers linear interpolation between the lines is used.

For a laminar boundary layer the correlation parameter, \( \eta_L \), is given over the range \( 0 \leq \eta_L \leq 0.2 \) by

\[
\eta_L = \frac{1}{\tau (Re_{she})^{1/2}}. \tag{3.6.5}
\]

Data taken from Chapman's (11) curves at \( M_\infty = 1.5, 2.0 \) and \( 3.1 \) is presented in Table 1. The base pressure ratio at these three Mach numbers is found by parabolic interpolation. At intermediate Mach numbers linear interpolation between the curves is used.

### 3.7 Lift Coefficient, Drag Coefficient and Lift-to-Drag Ratio

Formulas for the aerodynamic coefficients are developed in this section. These expressions depend on the pressure ratios and skin friction coefficients determined in the preceding sections, the ratio of free stream static pressure to
dynamic pressure, $p_\infty/q_\infty$, and several area ratios described in this section.

Let $L_1$ be the caret wing length measured from the apex to the plane containing the base (Figure 4). Then the plan area, $S$, is given by

$$S = \frac{L_1^2}{2} \tan \theta \tan \frac{\phi}{2}.$$  \hspace{1cm} (3.7.1)

The area of the projection of the lower surface onto a plane perpendicular to the free stream $E_L$, is used to calculate the contribution of the lower surface pressure to the drag. It is given by

$$E_L = \frac{L_1^2}{2} \tan \theta \tan \frac{\phi}{2} \tan \delta.$$  \hspace{1cm} (3.7.2)

Similarly, the area of the projection of the upper surface onto a plane perpendicular to the free stream, $E_U$, is used to calculate the contribution of the upper surface pressure to the drag. Changing $\delta$ to $\delta'$ in Equation (3.7.2) gives the following expression for $E_U$.

$$E_U = \frac{L_1^2}{2} \tan \theta \tan \frac{\phi}{2} \tan \delta'.$$  \hspace{1cm} (3.7.3)
The base area, $B$, is just the difference of these two and is given by

$$B = E_u - E_l = \frac{\ell_1}{2} \tan \theta \tan \Phi (\tan \delta - \tan \delta') . \quad (3.7.4)$$

The area of a triangle with sides of length $a$, $b$ and $c$ is given by

$$\text{Area} = \sqrt{s(s-a)(s-b)(s-c)} \quad (3.7.5)$$

where the semi-perimeter, $s$, is

$$s = \frac{1}{2} (a + b + c) . \quad (3.7.6)$$

The wetted areas of the lower and upper surfaces, $A_l$ and $A_u$, are each composed of two triangles. For the lower surface, the two triangles have sides whose lengths are given by

$$a = \frac{\ell_1}{\cos \delta} \quad (3.7.7)$$

$$b = \ell_1 \sqrt{\tan^2 \theta \tan^2 \Phi + (\tan \theta - \tan \delta)^2} \quad (3.7.8)$$

$$c = \ell_1 \sqrt{\tan^2 \theta \tan^2 \Phi + \tan^2 \theta + 1} . \quad (3.7.9)$$
The wetted area of the lower surface is

\[ A_L = 2 \sqrt{s(a-b)(a-c)} \]  \hspace{1cm} (3.7.10)

Changing \( \delta \) to \( \delta' \) in Equations (3.7.6-10) gives the wetted area of the upper surface.

Only ratios of areas appear in the formulas for \( C_L, C_D \) and \( L/D \), so \( l_1 \) drops out.

These ratios are

\[ \frac{E_L}{S} = \tan \delta \]  \hspace{1cm} (3.7.11)

\[ \frac{E_U}{S} = \tan \delta' \]  \hspace{1cm} (3.7.12)

\[ \frac{B}{S} = \tan \delta - \tan \delta' \]  \hspace{1cm} (3.7.13)

\[ \frac{A_L}{S} = 2 \sqrt{s'(a'-b')(a'-c')} \frac{\tan \theta \tan \frac{\phi}{2}}{\tan \delta} \]  \hspace{1cm} (3.7.14)

where

\[ a' = \frac{1}{\cos \delta} \]  \hspace{1cm} (3.7.15)

\[ b' = \sqrt{\tan^2 \theta \tan^2 \frac{\phi}{2} + (\tan \theta - \tan \delta)^2} \]  \hspace{1cm} (3.7.16)

\[ c' = \sqrt{\tan^2 \theta \tan^2 \frac{\phi}{2} + \tan^2 \theta + 1} \]  \hspace{1cm} (3.7.17)

\[ S' = \frac{1}{2} (a'+b'+c') \]  \hspace{1cm} (3.7.18)
Changing $\delta$ to $\delta'$ in Equations (3.7.14-18) gives the ratio $A_u/S$.

The final quantity needed in the formulas for the aero-
dynamic coefficients is the ratio of free stream static
pressure to dynamic pressure. It is given by

$$\frac{P_\infty}{q_\infty} = \frac{1}{0.7 M_\infty^2} \quad (3.7.19)$$

Expressions for $C_L$, $C_D$ and $L/D$ can now be derived. The
lift, $L$, is given by

$$L = (p_\infty - p_u)S - \tau_A \frac{A_u}{S} \sin \delta - \tau_u \frac{A_u}{S} \sin \delta' \quad (3.7.20)$$

where $\tau_A$ and $\tau_u$ are the boundary layer shear stresses on
the lower and upper surfaces. The lift coefficient is given
by

$$C_L = \frac{L}{q_\infty S} = \frac{(p_\infty - p_u)}{P_\infty} \frac{P_\infty}{q_\infty} - \frac{\tau_A}{q_\infty} \frac{A_u}{S} \sin \delta - \frac{\tau_u}{q_\infty} \frac{A_u}{S} \sin \delta'$$

$$= (\xi_u - \xi_u) \frac{P_\infty}{q_\infty} - \frac{(C_f)}{q_\infty} \frac{A_u}{S} \sin \delta - \frac{(C_{f_u})}{q_\infty} \frac{A_u}{S} \sin \delta'. \quad (3.7.21)$$

The drag, $D$, is given by
where $p_b$ is the base pressure.

The drag coefficient is given by

$$ C_D = \frac{D}{q_\infty S} = (\xi_l \frac{E_q}{S} - \xi_u \frac{E_u}{S} - \xi_b \frac{B}{S}) \frac{p_\infty}{q_\infty} + (C_f) \frac{A_q}{S} \cos \delta $$

$$ + (C_f)_u \frac{A_u}{S} \cos \delta' $$

The lift-to-drag ratio is given by

$$ \frac{L}{D} = \frac{C_L}{C_D} $$

In the case of a laminar boundary layer, $(C_f)_{\ell \ell}$, $(C_f)_{tu}$ and $\xi_{b\ell}$ are used for $(C_f)_{\ell}$, $(C_f)_{u}$ and $\xi_b$ in Equations (3.7.21), (3.7.23) and (3.7.24). For a turbulent boundary layer case, $(C_f)_{t\ell}$, $(C_f)_{tu}$ and $\xi_{bt}$ are used for $(C_f)_{\ell}$, $(C_f)_{u}$ and $\xi_b$. For the case of zero skin friction, $(C_f)_{\ell}$ and $(C_f)_{u}$ are set to zero. For zero base drag $\xi_b$ is set equal to 1.0.

3.8 Computer Program

The calculations described in this chapter are straightforward but quite lengthy. Therefore, a computer program was
written for the calculation of the aerodynamic coefficients using the FORTRAN IV language. Execution of this program was carried out at M.I.T.'s Information Processing Center on their IBM System 370/168 computer. Graphical output was produced on a CalComp 563 Drum Plotter using a CalComp 905 Controller.

The computer program is broken up into subroutines along the lines of the sectional division of this chapter. Subroutine CARET coordinates the basic process of calculating $C_L$, $C_D$ and $L/D$ as functions of $\delta, \delta', \theta, \phi, M_{\infty}$ and $Re_{\infty}$. Depending on the test matrix desired, a main program is written to feed subroutine CARET with a sequence of values for the independent variables. The form in which the results are recorded, either tabular or graphical, is also controlled by the main program. A flow chart of the interaction between the main program and subroutines appears in Figure 11. Appendix I contains listings of the main programs and subroutines and a short description of each.
CHAPTER IV

RESULTS

4.1 Test Matrix

Testing all possible combinations of the six independent variables throughout their entire ranges would yield an enormous and unmanageable amount of data. Therefore, a test matrix was devised which would elucidate most of the relationships with a reasonable amount of computation. One of the independent variables, $\delta'$, was eliminated entirely by setting it equal to $\delta - 3^\circ$. Essentially, this restricts the study to wings which are approximately five per cent thick. The remaining independent variables can be broken into two groups, those which specify the caret wing's geometry and incidence and those which specify the flight conditions. The test matrix was divided along these lines into two parts, the variable geometry test and the fixed geometry test.

In the variable geometry test the flight conditions, $M_\infty$ and $Re_\infty$, were held fixed while the geometric parameters, $\delta$, $\theta$ and $\phi$, were allowed to vary. This test is composed of three parts according to which of the geometric parameters is being examined. When the dependence of the aerodynamic coefficients on $\delta$ is being considered, $\delta$ is varied from $3^\circ$
to 13° in steps of two tenths of a degree. When θ is being considered, it is varied from 4° to 80° in steps of two degrees. When φ is being considered, it is varied from 24° to 178° in steps of two degrees. In each of the three parts of the variable geometry test, the other two geometric parameters are allowed to take on all combinations of the following values: δ=4°, 6°, 8° and 10°; θ = 30°, 50° and 70°; and φ = 60°, 90°, 120° and 150°.

The entire variable geometry test was carried out at two different flight conditions. First at low Mach number and high Reynolds number with a turbulent boundary layer: $M_\infty = 2.0$ and $Re_\infty = 10^7$. Second at high Mach number and low Reynolds number with a laminar boundary layer: $M_\infty = 3.1$ and $Re_\infty = 10^5$.

In the fixed geometry test the geometric parameters, δ, θ and φ, were held fixed and the effects of Mach number and Reynolds number on the aerodynamic coefficients were examined. This test is composed of two parts according to whether the skin friction and base drag calculations are based on a laminar or turbulent boundary layer. For the laminar boundary layer case the Mach number is varied from 1.5 to 3.1 by tenths. For the turbulent boundary layer case the Mach number is varied from 1.5 to 5.0 by tenths. Each part of the fixed geometry test is repeated for Reynolds numbers of $10^5$, $10^6$, $10^7$ and $10^8$. 
The particular caret wings selected for the fixed geometry test were chosen for their high L/D based on the results of the variable geometry test. For the laminar boundary layer case the caret wing $\delta = 8.3^\circ$, $\theta = 30.0^\circ$ and $\phi = 120.0^\circ$ was used. For the turbulent boundary layer case the caret wing $\delta = 6.5^\circ$, $\theta = 30.0^\circ$ and $\phi = 120.0^\circ$ was used.

Many of the combinations of the independent variables which occur in the above test matrix do not correspond to caret wings that belong to the restricted class considered in this study. They may be disqualified for any of the following reasons. No design Mach number exists, the design point shock is strong with respect to the free stream, $\phi$ is less than $\phi_{\text{trans}}$, the leading edge is subsonic or $\Gamma_{\text{max}}$ is less than $\Gamma_1$. Such cases are dropped from the test matrix by the computer program when they are found.

The test matrix is summarized in Table 2.

4.2 Variable Geometry Test

4.2.1 Dependence on $\delta$

The dependence of the aerodynamic coefficients on $\delta$ is illustrated in three types of graphs. Graphs of the first type indicate the effect of a second geometric parameter. This is done with a family of curves for four different values of $\phi$ ($60^\circ$, $90^\circ$, $120^\circ$ and $150^\circ$). The curves, like those on
all graphs described in this chapter, are distinguished from each other by symbols plotted at every tenth data point. There are eighteen graphs of this type, one for each combination of the three aerodynamic coefficients, two flight conditions and three values of $\theta$ ($30^\circ$, $50^\circ$ and $70^\circ$). Graphs of $C_L$ vs. $\delta$, $C_D$ vs. $\delta$ and $L/D$ vs. $\delta$ appear in Figures 12-17, 24-29 and 36-41 respectively.

Graphs of the second type illustrate the contribution of skin friction and base drag to the overall lift, drag and $L/D$. The three curves on each graph correspond to inclusion of all the forces, no base drag and no base drag or skin friction. There are twelve graphs of this type, one for each combination of the three aerodynamic coefficients, two flight conditions and two values of $\theta$ ($30^\circ$ and $50^\circ$). The value of $\phi$ is $120^\circ$ in all of them. Graphs of $C_L$ vs. $\delta$, $C_D$ vs. $\delta$ and $L/D$ vs. $\delta$ appear in Figures 18-21, 30-33 and 42-45.

Graphs of the third type illustrate the effect of boundary layer type. The two curves on each graph correspond to laminar and turbulent boundary layers. There is a graph for each combination of the three aerodynamic coefficients and two values of $\theta$ ($30^\circ$ and $50^\circ$). All six of these graphs are for the low Mach number, high Reynolds number flight condition and $\phi$ equal to $120^\circ$. The high Mach number, low
Reynolds number flight condition is excluded because the Reynolds number is outside the range of validity of the formula for the turbulent skin friction coefficient. Graphs of $C_L$ vs. $\delta$, $C_D$ vs. $\delta$ and $L/D$ vs. $\delta$ appear in Figures 22-23, 34-35 and 46-47.

The graphs of $C_L$ vs. $\delta$ appear in Figures 12-23. As one would certainly expect, all these graphs show that $C_L$ increases with $\delta$. The greater the value of $\delta$, the greater will be the deflection of the free stream. Consequently, the pressure ratio across the lower surface shock will increase with $\delta$ while the pressure ratio across the upper surface expansion decreases. As a result the lift coefficient increases with $\delta$.

Since the base of the caret wing was constructed perpendicular to the free stream, the base pressure ratio should have absolutely no effect on the lift coefficient. This is confirmed by Figures 18-21 in which the curves for all forces and no base drag lie directly on top of each other.

Because the skin friction shear stress acts tangent to the caret wing's surface and the wing is at fairly low angle of attack, skin friction should have only a small effect, which increases slightly with $\delta$, on the lift coefficient. Exactly this behavior is observed in Figures 18-21. Since the skin friction has only a small effect on $C_L$, the boundary
layer type (laminar or turbulent) should not make a significant difference in the lift coefficient. This, too, is confirmed by Figures 22 and 23.

Since base pressure and skin friction do not play an important role in the behavior of $C_L$, the only forces which make a significant contribution are those due to the upper and lower surface pressures. In Figure 7 the pressure ratio across the lower surface shock of the caret wing family $\delta = 5.0^\circ$, $\theta = 34.0^\circ$ is plotted for several off design Mach numbers as a function of $\phi$. When $M_{des} < M_\infty$, the pressure ratio increases with $\phi$ and when $M_{des} > M_\infty$, the pressure ratio decreases with increasing $\phi$. On this basis one might predict that $C_L$ will increase with $\phi$ when $M_{des} < M_\infty$ and decrease with increasing $\phi$ when $M_{des} > M_\infty$. This trend is precisely confirmed by Figures 12-17. In Figure 12, $M_{des}$ ranges from 2.158 at $\delta = 3.0^\circ$ to 3.031 at $\delta = 13.0^\circ$, always greater than the free stream Mach number of 2.0. The family of curves in this graph shows that $C_L$ decreases with increasing $\phi$. In Figures 13-17 $M_{des}$ is always less than $M_\infty$ and $C_L$ increases with $\phi$. 
For the first flight condition, $M_\infty = 2.0$ and $Re_\infty = 10^7$, the lift coefficient ranges from a minimum of 0.036 to a maximum of 0.535. For the second flight condition, $M_\infty = 3.1$ and $Re_\infty = 10^5$, $C_L$ ranges from a minimum of 0.019 to a maximum of 0.313.

The graphs of $C_D$ vs. $\delta$ appear in Figures 24-35. Many of the comments made about the dependence of $C_L$ on $\delta$ also apply to $C_D$. Again, as expected, all the graphs show that $C_D$ increases with $\delta$.

Unlike the situation for $C_L$, the base pressure and skin friction do have an important effect on $C_D$. For the flight condition $M_\infty = 2.0$, $Re_\infty = 10^7$ and a turbulent boundary layer, Figures 30 and 31 show that the base drag is about twice the skin friction drag. For the flight condition $M_\infty = 3.1$, $Re_\infty = 10^5$ and a laminar boundary layer, Figures 32 and 33 show that the skin friction drag is about ten times the base drag. This change in relative importance makes sense because base drag is lower for a laminar boundary layer than for a turbulent boundary layer and skin friction drag is higher for a lower Reynolds number. For both flight conditions, Figures 30-33 show that base drag and skin friction drag are
the principle sources of drag at low values of $\delta$ but that pressure drag takes over at higher $\delta$. Figures 34 and 35 show that $C_D$ is higher for a turbulent boundary layer than for a laminar boundary layer but that the difference is small.

At the larger values of $\delta$, where pressure drag is more significant than base drag or skin friction drag, $C_D$ displays the same dependence on $\phi$ as discussed for $C_L$ (see Figures 24-29). At lower values of $\delta$, the pressure drag becomes insignificant compared to the other sources of drag and the arguments which explain the dependence of $C_L$ on $\phi$ can no longer be applied to $C_D$. As $\phi$ increases, there is less wetted area for a given plan area and therefore, the skin friction drag goes down with increasing $\phi$. This effect is observed in Figures 25, 27 and 28 where the dependence of $C_D$ on $\phi$ reverses as $\delta$ decreases and skin friction drag becomes more important than pressure drag.

For the first flight condition, $M_\infty = 2.0$ and $Re_\infty = 10^7$, the drag coefficient ranges from a minimum of 0.021 to a maximum of 0.133. For the second flight condition, $M_\infty = 3.1$ and $Re_\infty = 10^5$, $C_D$ ranges from a minimum of 0.022 to a maximum of 0.093.
The graphs of $L/D$ vs. $\delta$ appear in Figures 36-47. Since the angle $\delta$ is closely related to the angle of attack, these curves would be expected to exhibit a maximum. Those curves which cover a large enough range of $\delta$ have the expected maximum.

Figures 42-45 show the contribution of skin friction and base drag to $L/D$. The relative importance of skin friction and base drag is the same here as described for the drag coefficient. For $M_\infty = 2.0$ and $Re_\infty = 10^7$, base drag is significant compared to skin friction. For $M_\infty = 3.1$ and $Re_\infty = 10^5$, base drag is insignificant compared to skin friction. Figures 46 and 47 show that the higher drag associated with a turbulent boundary layer leads to a lower $L/D$ than for a laminar boundary layer.

Figures 37-41, in which $M_{des} < M_\infty$, show a predominant tendency for $L/D$ to increase with $\phi$. However, there are some exceptions in Figures 39 and 40. Figure 36, in which $M_{des} > M_\infty$, shows the opposite trend. In this figure $L/D$ decreases with increasing $\phi$.

For the first flight condition, $M_\infty = 2.0$ and $Re_\infty = 10^7$, the maximum $L/D$ occurs at $\delta = 6.4^0$ on the curve $\phi = 120^0$ and is equal to 5.679. For the second flight condition, $M_\infty = 3.1$ and $Re_\infty = 10^5$, the maximum $L/D$ occurs at $\delta = 8.4^0$ on the curve $\phi = 120^0$ and is equal to 4.057.
4.2.2 Dependence on $\theta$

The dependence of the aerodynamic coefficients on $\theta$ is illustrated in Figures 48-65. These figures also indicate the dependence on $\delta$ with a family of curves corresponding to four values of that parameter ($4^\circ$, $6^\circ$, $8^\circ$ and $10^\circ$). There is a graph for every combination of the three aerodynamic coefficients, two flight conditions and three values of $\phi$ ($90^\circ$, $120^\circ$ and $150^\circ$). The design point has been marked on the four curves of Figure 48 and occurs at the same values of $\theta$ in Figures 49-65.

In Section 4.2.1 it was established that the lift coefficient is primarily influenced by upper and lower surface pressure rather than skin friction or base pressure. Examining the expression for $C_L$, Equation (3.7.21), these pressures enter in terms of the pressure ratios across the lower surface shock and upper surface expansion in such a way that $C_L$ increases with increasing $\xi_l$ and/or decreasing $\xi_u$. The pressure ratios are functions of $M_\perp$, $\Gamma_\perp$ and $\Gamma_\parallel'$, which in turn depend on $\theta$.

Sample calculations within the ranges of $\delta, \delta'$ and $\phi$ of interest show that $\Gamma_\perp$ and $\Gamma_\parallel'$ increase with decreasing $\theta$. Since $\xi_l$ increases with $\Gamma_\perp$ and $\xi_u$ decreases with
increasing $\Gamma'$, it follows that $C_L$ will tend to increase with decreasing $\Theta$ due to changes in the stream deflection angles.

Combining Equations (3.2.4), (3.2.5) and (3.2.12) gives an expression for $M_\perp$ as a function of $\Theta$. The derivative of $M_\perp$ with respect to $\Theta$ is always positive, so $M_\perp$ increases with $\Theta$. However, the pressure ratios across the shock and expansion may increase or decrease with increasing $M_\perp$ depending on the values of $M$, $\Gamma_\perp$ and $\Gamma'_\perp$. Thus the dependence of $C_L$ on $\Theta$ due to changes in the normal component of the Mach number will vary with the situation.

In light of these results, the overall dependence of $C_L$ on $\Theta$ has not been anticipated. Looking at the graphs of $C_L$ vs. $\Theta$ which appear in Figures 48-53, it can be seen that $C_L$ increases with decreasing $\Theta$ throughout the range of the present test matrix. The graphs are also consistent with the previous finding that $C_L$ increases with $\delta$. For the flight condition $M_\infty = 2.0$, $Re_\infty = 10^7$, the lift coefficient ranges from a minimum of 0.077 to a maximum of 0.484. For the flight condition $M_\infty = 3.1$, $Re_\infty = 10^5$, the lift coefficient ranges from 0.045 to 0.263.
The remarks made about the dependence of $C_L$ on $\theta$ due to upper and lower surface pressure also apply to the drag coefficient. The changes in $\xi_L$ and $\xi_u$ which cause $C_L$ to decrease with increasing $\theta$ will also cause the pressure drag to decrease with increasing $\theta$.

Besides pressure drag, skin friction and base drag also influence the drag coefficient. The ratio of base area to plan area given by Equation (3.7.13) does not depend on $\theta$. However, the Reynolds number based on length decreases with increasing $\theta$ leading to a higher base pressure ratio and lower base drag. Thus base drag reinforces the effect of pressure drag, driving the drag coefficient down when $\theta$ increases.

Equations (3.7.14-18) show that the ratio of wetted area to plan area increases with $\theta$. This means that skin friction drag and its importance relative to the other sources of drag increase with $\theta$. At large enough values of $\theta$ skin friction drag might predominate and reverse the dependence of $C_D$ on $\theta$.

This reversal is observed clearly at the high Mach number, low Reynolds number flight condition in Figures 57-59. The curves of $C_D$ vs. $\theta$ have a negative slope at low values of $\theta$ and positive slope at high values of $\theta$. It was shown in Section 4.2.1 that the magnitude of the pressure
drag relative to skin friction drag increases with $\delta$. This accounts for the shift of the minimum in these curves to the right with increasing $\delta$.

It was also shown in Section 4.2.1 that base drag is greater than skin friction drag at the low Mach number, high Reynolds number flight condition. Most of the curves corresponding to this flight condition, Figures 54-56, do not have a minimum. Except for a few cases at low $\delta$ and high $\theta$, the drag coefficient decreases with increasing $\theta$.

The graphs for both flight conditions are consistent with the previous finding that $C_D$ increases with $\delta$. For $M_\infty = 2.0$ and $Re_\infty = 10^7$ the drag coefficient ranges from a minimum of 0.024 to a maximum of 0.097. For $M_\infty = 3.1$ and $Re_\infty = 10^5$ the drag coefficient ranges from 0.021 to 0.066.

The dependence of the lift-to-drag ratio on $\theta$ is shown in Figures 60-65. Due to the effect of skin friction, $C_D$ does not fall off as rapidly as $C_L$ when $\theta$ is increased. As a result, the lift-to-drag ratio decreases with increasing $\theta$. For the $M_\infty = 2.0$, $Re_\infty = 10^7$ flight condition, the maximum $L/D$ occurs at $\delta = 6^\circ$, $\theta = 14^\circ$ and $\phi = 150^\circ$ and has the value 5.483. For the $M_\infty = 3.1$, $Re_\infty = 10^5$ flight condition, the maximum $L/D$ occurs at
\( \delta = 6^\circ, \theta = 16^\circ \) and \( \phi = 120^\circ \) and has the value 4.973.

Figures 60-65 are consistent with the previous finding that the lift-to-drag ratio goes through a maximum as \( \delta \) increases.

### 4.2.3 Dependence on \( \phi \)

The dependence of the aerodynamic coefficients on \( \phi \) is illustrated in Figures 66-83. These figures also indicate the dependence on \( \delta \) with a family of curves corresponding to four values of that parameter \((4^\circ, 6^\circ, 8^\circ \) and \(10^\circ\)). There is a graph for every combination of the three aerodynamic coefficients, two flight conditions and three values of \( \theta \) \((30^\circ, 50^\circ \) and \(70^\circ\)).

Figures 12-17, 24-29 and 36-41 discussed in Section 4.2.1 have already indicated the dependence of \( C_L, C_D \) and \( L/D \) on \( \phi \). Essentially the same dependence is observed in Figures 66-83. It was established in Section 4.2.1 that the lift coefficient increases with \( \phi \) when \( M_{des} < M_\infty \) and decreases with increasing \( \phi \) when \( M_{des} > M_\infty \). In Figures 67-71 \( M_{des} \) is less than \( M_\infty \) and \( C_L \) is observed to increase with \( \phi \) in most cases. A few exceptions are present in which \( C_L \) begins to decrease as \( \phi \) approaches \( 180^\circ \). In Figure 66 \( M_{des} \) is greater than \( M_\infty \) and \( C_L \) decreases with increasing \( \phi \).
At \( M_\infty = 2.0 \) and \( Re_\infty = 10^7 \) the lift coefficient ranges from 0.051 to 0.484. At \( M_\infty = 3.1 \) and \( Re_\infty = 10^5 \) \( C_L \) ranges from 0.026 to 0.225.

The drag coefficient shows the same dependence on \( \phi \) as \( C_L \) except at low enough values of \( \delta \) and \( \phi \) where the effect of skin friction can reverse the behavior (Figures 72-77). \( C_D \) ranges from 0.024 to 0.097 for the first flight condition and from 0.023 to 0.091 for the second flight condition.

The increase in lift-to-drag ratio with \( \phi \) when \( M_{des} < M_\infty \) observed in Section 4.2.1 is confirmed by Figures 79-83. Exceptions to this trend which were noted in that section are seen here as a sharp decrease in \( L/D \) as \( \phi \) approaches 180\(^\circ\). Figure 78 is consistent with the previously observed decrease in \( L/D \) with increasing \( \phi \) when \( M_{des} > M_\infty \). The maximum \( L/D \) for the first flight condition occurs at \( \delta = 6^\circ \), \( \Theta = 30^\circ \) and \( \phi = 100^\circ \) and has the value 6.006. The maximum \( L/D \) for the second flight condition occurs at \( \delta = 8^\circ \), \( \Theta = 30^\circ \) and \( \phi = 124^\circ \) and has the value 4.050.

The dependence of \( C_L \), \( C_D \) and \( L/D \) on \( \delta \) in Figures 66-83 is the same as described in Sections 4.2.1 and 4.4.4.
4.3 Fixed Geometry Test

The dependence of the aerodynamic coefficients on Mach number and Reynolds number is illustrated in Figures 84-89. Mach number is the abscissa and Reynolds number a parameter in these figures. There is a graph for every combination of the three aerodynamic coefficients and two boundary layer types. The caret wing used in the turbulent boundary layer case is on design at $M_\infty = 2.38$ and the one used in the laminar boundary layer case is on design at $M_\infty = 2.53$.

In linearized thin airfoil theory (18) the dependence of the pressure coefficient on free stream Mach number is proportional to $(M_\infty^2 - 1)^{-1/2}$. Since the deflection of the streamlines in the caret wing flow field is small, the dependence of the lift and drag coefficients on Mach number should be fairly similar to this. As a further indication of the influence of Mach number, consider the terms in the expressions for $C_L$ and $C_D$, Equations (3.7.21) and (3.7.23). The difference between the pressure ratios across the shock and expansion, multiplied by the ratio of free stream static-to-dynamic pressure is proportional to the difference in pressure coefficient between the upper and lower surfaces. For small stream deflection
angles this term is proportional to \((M_\infty^2 - 1)^{-1/2}\), corresponding to thin airfoil theory. As described in Sections 2.4 and 3.5, a linear approximation to the decrease in skin friction coefficient with increasing Mach number is used. The contribution of base drag to \(C_D\) is proportional to \((1 - \xi_b)p_\infty/q_\infty\). The factor \((1 - \xi_b)\) increases slowly with \(M_\infty\) but the ratio of static-to-dynamic pressure falls off with \(M_\infty^2\). Overall, this term decreases as \(M_\infty\) increases.

These remarks are consistent with the dependence of \(C_L\) and \(C_D\) on \(M_\infty\) shown in Figures 84-87. The curves of \(L/D\) vs. \(M_\infty\) for the turbulent boundary layer case, Figure 88, have a minimum near \(M_\infty = 3.2\). The highest \(L/D\) on each curve occurs at the low end of the Mach number range. For the laminar boundary layer case, Figure 89, the maximum \(L/D\) on each curve also occurs at the low end of the Mach number range. Two of the curves decrease throughout the range and two have a minimum.

Reynolds number influences the aerodynamic coefficients through the skin friction coefficients and base pressure ratio. The skin friction drag decreases and the base drag increases as \(Re_\infty\) increases. In most cases the skin friction effect is the primary one.
Changes in skin friction have little effect on the lift coefficient and changes in base drag have no effect so $C_L$ should be nearly independent of $Re_\infty$. The curves for different Reynolds numbers in Figures 84 and 85 confirm this by lying virtually on top of each other.

For a turbulent boundary layer, Figure 86 shows that the drag coefficient decreases as $Re_\infty$ increases. This is also true in the laminar boundary layer case for Mach numbers above 2.3 (Figure 87). For lower Mach numbers there is a narrow range of Reynolds numbers, between $10^6$ and $10^7$, in which the effect of base drag dominates and the dependence of $C_D$ on $Re_\infty$ reverses. This coincides with the steepest portion of the laminar base pressure curves in Figure 9.

The dependence of the lift-to-drag ratio on $Re_\infty$ is just the inverse of the drag coefficient's behavior. For a turbulent boundary layer $L/D$ increases with $Re_\infty$ (Figure 88). This is also true in the laminar boundary layer case above $M_\infty = 2.3$ (Figure 89). At lower Mach numbers, the lift-to-drag ratio decreases over some range of Reynolds numbers between $10^6$ and $10^7$. 
CHAPTER V

CONCLUSIONS and RECOMMENDATIONS

A clear picture of the way the lift coefficient, drag coefficient and lift-to-drag ratio vary with caret wing geometry and flight condition has emerged. The influence of $\delta$, $\Theta$, $\phi$, $M_\infty$ and $Re_\infty$ on each of the aerodynamic coefficients is summarized below.

The lift coefficient increases with $\delta$ under all conditions and with $\phi$ when $M_{des} < M_\infty$. It decreases as $\Theta$ or $M_\infty$ increase and, when $M_{des} > M_\infty$, as $\phi$ increases. Reynolds number has no appreciable effect on $C_L$.

The drag coefficient also increases with $\delta$ under all conditions. Drag due to upper and lower surface pressure decreases as $\Theta$ increases. However, skin friction drag increases with $\Theta$ and can be the dominant factor at some flight conditions. Depending on whether $M_{des}$ is greater than or less than $M_\infty$, the drag coefficient will decrease or increase, respectively, as $\phi$ increases. This dependence on $\phi$ arises through the influence of upper and lower surface pressure. At low values of $\delta$ and $\phi$ the effects of skin friction may override this dependence and, in such cases, $C_D$ will decrease as $\phi$ increases regardless of the relative magnitudes of $M_{des}$ and $M_\infty$. Finally, the
drag coefficient decreases as $M_\infty$ or $Re_\infty$ increase. The exception to this dependence on $Re_\infty$ noted in Section 4.3 is a consequence of the rapid rise in laminar base drag over a narrow Reynolds number range. This result must be viewed with suspicion because the two-dimensional base pressure data gives, at best, only a rough indication of the base drag.

The lift-to-drag ratio goes through a maximum as $\delta$ is varied and, when $M_{\text{des}} < M_\infty$, there is a maximum in its dependence on $\phi$. When $M_{\text{des}} > M_\infty$, L/D decreases as $\phi$ increases. The lift-to-drag ratio also decreases with increasing $\theta$. For cases where the Mach number range extended up to 5.0, a minimum was found in the dependence of L/D on $M_\infty$. Finally, the lift-to-drag ratio increases with $Re_\infty$. The remarks made about the exception to the dependence of $C_D$ on $Re_\infty$ also apply here.

The best lift-to-drag ratio found in the variable geometry test was 6.483 for the caret wing $\delta = 6^\circ$, $\theta = 14^\circ$ and $\phi = 150^\circ$ and the flight condition $M_\infty = 2.0$, $Re_\infty = 10^7$. The corresponding lift coefficient and design Mach number are 0.285 and 5.989. Taking the best L/D from each of the graphs of L/D vs. $\delta$, $\theta$ and $\phi$, two other cases were found in which the lift-to-drag ratio exceeded 6.0 and many were found between 5.0 and 6.0.
The best L/D found in the fixed geometry test was 6.391 for the caret wing $\delta = 6.5^\circ$, $\Theta = 30^\circ$ and $\Phi = 120^\circ$ and flight condition $M_\infty = 1.8$, $Re_\infty = 10^8$. The corresponding lift coefficient and design Mach number are 0.324 and 2.384.

These examples of high L/D are only the best cases from the test matrix considered in this study. Some improvement can be expected by searching in the neighborhood of these cases, using the behavior of L/D described above as a guide. Additional improvement in L/D could be achieved by adding some type of afterbody and thereby reducing the base drag. The curves for zero base drag in Figures 42-45 give an indication of the room for improvement. In Figure 42, for example, the L/D goes from 5.679 to 8.945 when base drag is eliminated.

The performance of caret wings is compared to that of delta wings in Figure 90. Wind tunnel tests of 8 percent thick delta wings with double wedge profiles at $M_\infty = 1.92$ and Reynolds number based on two-thirds the root chord, $Re_\infty$, covering the range $0.57 \times 10^6$ to $1.25 \times 10^6$ were made by Love (19). A thinner series of delta wings, 1.3 to 1.8 percent thick, constructed from flat plate with sharpened leading and trailing edges are also included in his tests.
The boundary layer over most of the wetted surface was shown to be turbulent by a liquid-film method. Love measured the aerodynamic coefficients through an angle of attack range of ± 6°. The maximum L/D of these delta wings is plotted as a function of apex half-angle in Figure 90.

The free stream conditions in the first part of the variable geometry test, $M_\infty = 2.0$ and $Re_\infty = 10^7$, are nearly the same as the conditions in Love's experiment. Caret wings with high L/D from this part of the study are plotted alongside the delta wing data in Figure 90 using the apex half-angle of the planform for the abscissa. The Mach number and average Reynolds number of Love's experiment were duplicated exactly at one point of the test matrix in the fixed geometry test and this case is also included in the figure. The caret wing data does not represent the maximum L/D for any given planform, only the best to occur in the test matrix. Geometric properties, $M_\infty$ and $Re_\infty$ are listed in tabular form on the figure.

The thickness ratio of the caret wings is .052, about midway between the two groups of delta wings. As shown in Figure 90, the lift-to-drag ratios of the caret wings also lie between the two groups of delta wings, indicating that
caret and delta wings have comparable lifting efficiencies. However, the delta wings considered here have sharp trailing edges while the caret wings have blunt bases. If the addition of an afterbody to the caret wings could significantly reduce their base drag, the resulting lift-to-drag ratios would be superior to those for delta wings.

One objective of further research should be the determination of the accuracy and range of applicability of the method of calculation presented in this thesis. This could be accomplished through experimental measurements or calculations based on a more sophisticated model of the caret wing flow field.

The work of Ziph (7) mentioned in the Introduction could be used as a starting point in the latter approach. Ziph treated the case of a reentrant pyramid with surface curvature in the transverse plane. His numerical solution of the equations of conical flow is restricted to flow fields in which the shock is attached to the apex but detached from the leading edges. This restriction is the result of a transformation of the region of computation into a square. The computational region is bounded by the shock, the body and two symmetry lines extending radially from the leading edge and internal rib to the shock. If the shock were attached, the length of one side of the
computational region would go to zero and the transformation would have a singularity.

As shown in Chapter II, the leading edge shock can be calculated correctly by treating the caret wing as a swept wedge. One way of extending Ziph's method to the attached shock case would be to modify the computational region so that the part near the leading edge is no longer included. The leading edge shock of Chapter II would then be used in this region and would give the boundary conditions necessary for the new computational region. Neglecting boundary layer effects, this procedure would yield the correct shock shape and pressure distribution over the caret wing's lower surface. The error incurred by approximating the average pressure over the lower surface with the pressure downstream of the leading edge shock could then be assessed. If found to be unacceptably large, this approximation could be abandoned in favor of Ziph's lengthier, but more accurate method.

Another objective of further research would be the inclusion of caret wings whose design point shocks are strong with respect to flow normal to the leading edge ($\phi < \phi_{\text{trans}}$) in the search for high lift-to-drag ratios.
If these "strong" shocks actually occur, the high lower surface pressure that could be generated at low angle of attack would yield lift-to-drag ratios much higher than those found in this study. An experimental investigation of this possibility would be very interesting.
APPENDIX I

COMPUTER PROGRAM LISTING

A short description of the subroutines precedes the listing.

Subroutine \texttt{HEAD} prints a heading for data printed by subroutine \texttt{PRINT}. There are no arguments.

Subroutine \texttt{CARET} calculates $M_{\text{des}}$, design point shock type with respect to flow normal to the leading edge, $\xi_u$, $\xi^*, \xi^*, \xi^*_{bt}$, $C_L$, $C_D$ and $L/D$ given $\delta$, $\delta^*$, $\Theta$, $\Phi$, $M_\infty$ and $Re_\infty$.

Subroutine \texttt{PRINT} prints data under the heading produced by subroutine \texttt{HEAD}. Input arguments are $\delta$, $\delta^*$, $\Theta$, $\Phi$, $M_\infty$, $Re_\infty$, $M_{\text{des}}$, shock type, $\xi_u$, $\xi^*, \xi^*_{bt}$, $C_L$, $C_D$ and $L/D$.

Subroutine \texttt{LOWER} calculates $M_{\text{des}}$, $\xi_u$, shock type, $C_{f_{ll}}$ and $C_{f_{ll}}$ given $\delta$, $\Theta$, $\Phi$, $M_\infty$ and $Re_\infty$.

Subroutine \texttt{DESIGN} calculates $M_{\text{des}}$ and $\phi_{\text{trans}}$ given $\delta$ and $\Theta$.

Subroutine \texttt{DG} calculates $R_{\text{max}}$, $R_{\perp}$, $R_{\text{max}} - R_{\perp}$ and $M_{\perp}$ given $\delta$, $\Theta$, $\Phi$ and $M_\infty$. It also calculates $R_{\perp}'$ when given $\delta'$ instead of $\delta$.

Subroutine \texttt{SHOCKW} calculates the pressure ratio across a weak shock given the upstream Mach number and stream deflection angle.
Subroutine SHOCKS calculates the pressure ratio across a strong shock given the upstream Mach number and stream deflection angle.

Subroutine SFL calculates $C_{fl}$ and $C_{ft}$ given $\delta$, $\theta$, $\phi$, $M_\infty$, $Re_\infty$ and $\xi_l$.

Subroutine UPPER calculates $\xi_u$, $C_{flu}$ and $C_{ftu}$ given $\delta'$, $\theta$, $\phi$, $M_\infty$ and $Re_\infty$.

Subroutine PM calculates the pressure ratio across a Prandtl-Meyer expansion given the upstream Mach number and angle through which the stream turns.

Subroutine SFU calculates $C_{flu}$ and $C_{ftu}$ given $\delta'$, $\theta$, $\phi$, $M_\infty$, $Re_\infty$ and $\xi_u$.

Subroutine BASE calculates $\xi_{bt}$ and $\xi_{bu}$ given $\delta$, $\delta'$, $\theta$, $\phi$, $M_\infty$ and $Re_\infty$.

Subroutine COEFF calculates $C_L$, $C_D$ and $L/D$ given $\delta$, $\delta'$, $\theta$, $\phi$, $M_\infty$, $\xi_l$, $\xi_u$, $\xi_{bl}$, $\xi_{bt}$, $C_{fl}$, $C_{ft}$, $C_{flu}$ and $C_{ftu}$.

Subroutine PICTR draws labeled axes, title and subtitle and plots up to four curves identified by symbols.

Figure 90. Comparison of Caret Wing and Delta Wing L/D
REFERENCES

A simple model of the off design caret wing flow field which includes the effects of an upper expansion surface, skin friction and base drag is proposed. Based on this approximate model, calculations of the lift coefficient, drag coefficient and lift-to-drag ratio as functions of body geometry, incidence, Mach number and Reynolds number are made and the dependence of the aerodynamic coefficients on these variables is identified. A test matrix covering a wide range of caret wings and flight conditions is employed in a search for wings with high lift-to-drag ratio. Caret wing performance is then compared to that of delta wings. Lift-to-drag ratios as high as 6.5 for 5 percent thick wings at...
Free stream Mach number and Reynolds number of \(2.0 \text{ and } 10^7\) were found. This performance is similar to that of delta wings. However, significantly higher caret wing lift-to-drag ratios could be achieved by replacing the blunt base with an afterbody, thereby reducing the base drag.
