ABSTRACT

The purpose of this study is to compare two noise canceling system algorithms when the number of inputs to the system is small. The expected value algorithm is an estimate of the optimum solution for minimum mean square error analysis. The LMS (least mean square) algorithm was developed by Widrow (Widrow et al., 1975) to avoid the matrix inversion inherent in the optimum solution given by the Wiener-Hopf equation. The comparison between the two algorithms is measured by the rate of convergence of the mean square error and the minimum error after five hundred iterations.

A two input noise canceling system is investigated in the first part of the study and a three input system is studied in the second part. A two input noise canceling system has one input that contains a mixture of the signal and noise and a second input which is noise alone. The noise only input is multiplied by a weight, W, and subtracted from the first input to produce an estimate of the signal. The three input system adds another noise only input and a corresponding weight.

The expected value and LMS algorithms attempt to determine the Wiener-Hopf weight vector through different methods. The expected value algorithm estimates the necessary expected values, substitutes them into the Wiener-Hopf equation, and performs the necessary matrix inversion. The LMS algorithm uses gradient techniques and the method of steepest descent to avoid the complexity of the matrix inversion.
A computer simulation of a dc signal in Gaussian noise provided the comparison between the two algorithms. The tradeoff in terms of performance for simplicity in the LMS algorithm was discovered to be great. The expected value algorithm consistently produced better results in terms of faster rates of convergence and smaller minimum errors after five hundred iterations.

The LMS algorithm presented problems in implementation because of two parameter values that had to be chosen. A value for the initial weights had to be chosen since the weights were determined using only previous data. This value was not as important when considering such a large number of iterations as was the value of \( \mu \), the term that controls the rate of convergence. This term must be within a specific range in order to guarantee convergence of the algorithm. This range is small when only considering five hundred iterations. Large errors produced by the algorithm were also a problem.

In conclusion, the expected value algorithm was judged to be the better of the two. The differences in performance were great especially when the signal-to-noise ratio or the correlation between the noises was small. If a "correct" value of \( \mu \) is chosen, the results may be similar, but if not, the results can be extremely different from those of the expected value algorithm. Thus for a small number of inputs, where the matrix to be inverted is of small dimension, it is better in terms of performance to use the approximation to the optimum solution given by the expected value algorithm.
ACKNOWLEDGEMENTS

I would like to thank my advisor, Dr. L. W. Nolte, for his encouragement, guidance, and support of this research. I would like to thank also Dr. Jean Bullier and Dr. Sang C. Lee for their suggestions and guidance. The support of the Office of Naval Research is also acknowledged.

I wish to thank Mrs. Linda Hayes of Duke University for typing the final manuscript. Special thanks are also due to my fellow graduate students for their friendship, encouragement, and moral support.

A COMPARISON OF TWO NOISE CANCELING SYSTEM ALGORITHMS
CHAPTER I
INTRODUCTION

An important concept in signal detection theory is the noise canceling system which is used to eliminate noise from a contaminated signal. The noise canceling system consists of one input containing the contaminated signal and a varying number of noise alone inputs. Several algorithms have been developed in order to decrease the number of computations and thus increase the speed of convergence to the minimum error.

Early work in least squares estimation was done by Wiener in 1942 when he recognized that the solution of the Wiener-Hopf equation determined the optimum estimate for stochastic processes (Kailath, 1974). This was later extended to stationary and nonstationary processes. Kalman also contributed to the work by developing a filter which modeled the covariance of the signal process (Kailath, 1974). The LMS (least mean square) adaptive algorithm was developed in 1959 by Widrow and Hoff at Stanford University (Widrow et al., 1975). Work on adaptive systems continued in the 1960's with major contributions by Lucky at Bell Laboratories (Widrow, et al., 1975). This research compares the LMS algorithm with an estimate to the optimum solution for two and three input noise canceling systems.

A general n-input noise canceling system consists of one input with both signal and noise and (n-1) noise only inputs. Each noise only input is
multiplied by a weight and subtracted from the first input in order to obtain an estimate of the signal. The system is shown in Figure 1.1.

\[ x_1 = s + n_1 \]
\[ x_2 = n_2 \]
\[ \vdots \]
\[ x_n = n_n \]

\[ \tilde{s} \]

Figure 1.1. An n-input Noise Canceling System.

The weights are chosen so that the signal estimate, \( \tilde{s} \), is a linear least mean square estimate. That is, it is desirable to minimize

\[
E[e^2] = E[(\tilde{s} - s)^2]
\] (1.1)

through a linear combination of the inputs. The optimum solution is given by the Wiener-Hopf equation:

\[
W^* = R^{-1}P
\] (1.2)

where \( W^* \) is the optimum weight vector:

\[
W^* = \begin{bmatrix}
W_1^* \\
W_2^* \\
W_3^* \\
\vdots \\
W_n^*
\end{bmatrix}
\] (1.3)

\( \mathbf{X} \) is the input vector:
\begin{align*}
\mathbf{X} &= \begin{bmatrix} x_2 \\ x_3 \\ \vdots \\ x_n \end{bmatrix} \\
R &= \mathbb{E}[\mathbf{X} \mathbf{X}^T] = \begin{bmatrix} \mathbb{E}[x_2 x_2] & \ldots & \mathbb{E}[x_2 x_n] \\ \mathbb{E}[x_3 x_2] & \ddots & \\ \vdots & & \ddots \\ \mathbb{E}[x_n x_2] & \ldots & \mathbb{E}[x_n x_n] \end{bmatrix} \\
P &= \mathbb{E}[\mathbf{dX}] = \begin{bmatrix} \mathbb{E}[dx_2] \\ \mathbb{E}[dx_3] \\ \vdots \\ \mathbb{E}[dx_n] \end{bmatrix}
\end{align*}

R is the input correlation matrix:

The minimum error can be found by substituting this value of \( \mathbf{W} \) into
the equation for the error:

\[ \hat{s} = \mathbf{x}_1 - \mathbf{W}^T \mathbf{x} \]

and thus

\[ \min \mathbb{E}[(\hat{s} - s)^2] = \mathbb{E}[(x_1 - \mathbf{W}^T \mathbf{x} - s)^2] \]

The expected value and LMS (least mean square) algorithms attempt to
determine the Wiener-Hopf weight vector through different methods. The ex-
pected value algorithm estimates the expected values of the \( R \) and \( P \) matrices
and substitutes these into the Wiener-Hopf equation. Thus the weight vector
is determined by actually taking the matrix inverse. The LMS algorithm
discussed by Widrow et al., in "Adaptive Noise Cancelling: Principles and Applications" (Proceedings of the IEEE, December, 1975) uses gradient techniques and the method of steepest descent in order to avoid the complexity of the matrix inverse inherent in the optimum weight vector. The two algorithms are simulated on a PDP-11/45 computer at Duke University. A plot of the mean square error as a function of the number of iterations provides the main basis for the comparison.

Chapter II derives the algorithms for the two input noise canceling system. In this case, the $R$ matrix is a 1x1 matrix. The optimum weight vector and the theoretical minimum mean square error are also derived. Chapter III presents the computer simulation and the results.

Chapter IV extends both algorithms to the three input system. The expected value algorithm is again the estimate to the optimum weight vector formed by estimating the necessary expected values. The LMS algorithm is Widrow's algorithm where the one element weight vector of the two input system has been replaced by a two element weight vector. Chapter V presents the results of the three input noise canceling system computer simulation.

The final chapter, Chapter VI, summarizes the results. Directions for possible future research are discussed.
CHAPTER II
DERIVATION OF THE ALGORITHMS

This research explores the problem of minimizing the mean square error of a noise canceling system. A two input noise canceling system is shown in Figure 2.1.

\[ x_1 = s + n_1 \]

\[ x_2 = n_2 \]

Figure 2.1. Two Input Noise Canceling System.

The signal, \( s \), is uncorrelated with the noises, \( n_1 \) and \( n_2 \), which are correlated with each other. The weight, \( W \), attempts to transform the noise \( n_2 \) so that it can be subtracted from the \( x_1 \) input to give an estimate of the signal. This estimate is defined as

\[ \hat{s} = x_1 - Wx_2 \]  \hspace{1cm} (2.1)

Thus the error is given

\[ \epsilon = \hat{s} - s \]  \hspace{1cm} (2.2)
The mean square error is defined as the expected value of the squared error:

$$e_{MS} = E[e^2] = E[(\hat{s} - s)^2]$$  \hspace{1cm} (2.3)

It is desired to derive the weight, $W$, in such a way that the estimate of the signal, $\hat{s}$, produced is a linear least mean square estimate. Thus the estimate attempts to minimize the mean square error $E[e^2]$ through a linear combination of the inputs. The optimum solution is given by the Wiener-Hopf equation. This problem was studied by Widrow and the LMS (least mean square) algorithm was developed. This algorithm is used in many noise canceling systems and was one of the two studied in this research.

1. **LMS Algorithm**

   The LMS algorithm starts with the basic noise canceling structure shown in Figure 2.2.

   ![Figure 2.2. Noise Canceling Structure for LMS Algorithm](image)

   Figure 2.2. Noise Canceling Structure for LMS Algorithm

   The LMS algorithm as described in Widrow's "Adaptive Noise Cancelling: Principles and Applications," attempts to adjust the weight vector, $W$, to minimize the mean square error. The method of steepest descent is used as a practical way to find close approximate solutions to the Wiener-Hopf equation:
where \( \mathbf{W}^* \) is the optimum weight vector, \( \mathbf{R} \) is the input correlation matrix
\[
\mathbf{R} = \mathbf{E}[\mathbf{X}_j\mathbf{X}_j^T]
\]
and \( \mathbf{P} \) is the cross correlation vector between the desired response and the input, or \( \mathbf{X}_j \), vector
\[
\mathbf{P} = \mathbf{E}[\mathbf{d}_j\mathbf{X}_j]
\]
as defined in Chapter I for the \( j \)th inputs.

In order to avoid the matrix inversion required to find the optimum weight vector, the LMS algorithm sets the next weight vector, \( \mathbf{W}_{j+1} \), equal to the present weight vector \( \mathbf{W}_j \) plus another term proportional to the negative gradient, \( \nabla_j \), of the weight vector. Thus
\[
\mathbf{W}_{j+1} = \mathbf{W}_j - \mu \nabla_j
\]
where \( \mu \) is a parameter that controls stability and the rate of convergence.
(For a study of convergence to the optimum solution see Appendix A). The instantaneous gradient \( \nabla_j \) is also estimated by assuming that the squared error \( \epsilon_j^2 \) is an approximation of the mean square error \( \mathbf{E}[\epsilon_j^2] \). Thus the LMS algorithm uses an estimate \( \hat{\nabla}_j \) of the true gradient.

From Figure 2.2, the estimated signal, \( \hat{s} \), for an \( n \) input system is given by
\[
\hat{s} = \mathbf{x}_1 - \mathbf{W}^T\mathbf{x}
\]
Substituting (2.8) into the value of the error, \( \epsilon \), given by (2.2) yields
\[
\epsilon = \mathbf{n}_1 - \mathbf{W}^T\mathbf{x}
\]
Taking the partial derivative of the error with respect to \( \mathbf{W} \) produces
\[
\frac{\partial \epsilon}{\partial \mathbf{W}} = -\mathbf{x}
\]
The partial derivative of the squared error with respect to \( W \) is given by

\[
\frac{3\varepsilon^2}{3W} = 2\varepsilon \frac{3\varepsilon}{3W} = -2\varepsilon \chi \tag{2.11}
\]

The estimated gradient at the \( j \)th iteration, \( \hat{\theta}_j \), is set equal to the partial derivative of the squared error with respect to \( W \). Thus

\[
\hat{\theta}_j = \frac{3\varepsilon_j^2}{3W} = -2\varepsilon_j \chi_j \tag{2.12}
\]

Finally from the method of steepest descent, the weight vector can be determined:

\[
W_{j+1} = W_j - \mu \hat{\theta}_j \tag{2.13}
\]

\[
W_{j+1} = W_j + 2\mu \varepsilon_j \chi_j
\]

When the noise canceling system has only two inputs as shown in Figure 2.3, the expression for the weight vector reduces to a scalar quantity:

\[
W_{2j+1} = W_{2j} + 2\mu \varepsilon_j \chi_{2j} \tag{2.14}
\]

\[x_1 = s + n_1\]

\[x_2 = n_2\]

\[W_2\]

Figure 2.3. Two Input Noise Canceling System.

This noise canceling system can also be written in terms of a feedback system. A general two input feedback noise canceling system is shown in Figure 2.4. The input \( d_j \) is the desired response and \( \varepsilon_j \) is the error.
Figure 2.4. General Two Input Feedback Noise Canceling System.

Since the desired input is actually the unknown signal, $d_j$ is often set equal to $x_1$ (Widrow et al., 1975). When this is done, the system is not a feedback system in the true sense because the error term is now given by

$$
\varepsilon_j = d_j - \hat{s}_{LMS_j}
$$

$$
\varepsilon_j = x_{1j} - \hat{s}_{LMS_j}
$$

$$
\varepsilon_j = x_{2j}
$$

Thus the weight, $W_{j+1}$, is given in terms of inputs only when (2.14) is used to define the weight.

Since the noise canceling system employing the LMS algorithm as defined by (2.14), is not an actual feedback system, another algorithm was developed. This algorithm, the expected value algorithm, also attempts to minimize the mean square error. However, a feedback approach was not taken. Instead two weights and a brute force method of solving the matrix inverse avoided by the LMS algorithm were used. For a two input system this matrix is one dimensional so the inverse is quite simple.
2. Expected Value Algorithm

The expected value algorithm uses a ratio of estimates to the expected values of the inputs in order to minimize the mean square error. The weight, $W$, is derived for the expected value algorithm using the two input noise canceling structure shown in Figure 2.5.

For this system, the estimated signal, $\hat{s}$, is given by

$$\hat{s} = ax_1 + bx_2 \quad (2.16)$$

The orthogonality principle gives

$$E[(\hat{s} - s)x_1] = 0 \quad (2.17)$$

and

$$E[(\hat{s} - s)x_2] = 0 \quad (2.18)$$

Substituting the value of $\hat{s}$ given by (2.16) into (2.17) and (2.18) produces

$$aE[x_1x_1] + bE[x_2x_1] - E[sx_1] = 0 \quad (2.19)$$

and

$$aE[x_1x_2] + bE[x_2x_2] - E[sx_2] = 0 \quad (2.20)$$

Writing (2.19) and (2.20) in matrix form gives

$$\begin{bmatrix} E[x_1x_1] & E[x_2x_1] \\ E[x_1x_2] & E[x_2x_2] \end{bmatrix} \begin{bmatrix} a \\ b \end{bmatrix} = \begin{bmatrix} E[sx_1] \\ E[sx_2] \end{bmatrix} \quad (2.21)$$
Taking the matrix inverse, equation (2.21) can be solved for $a$ and $b$. Thus

$$a = \frac{E[sx_1]E[x_2^2] - E[x_1x_2]E[sx_2]}{E[x_1^2]E[x_2^2] - [E[x_1x_2]]^2} \quad (2.22)$$

and

$$b = \frac{E[x_1^2]E[sx_2] - E[x_1x_2]E[x_1]}{E[x_1^2]E[x_2^2] - [E[x_1x_2]]^2} \quad (2.23)$$

By hypothesis, $E[sn_1] = 0$ and $E[sn_2] = 0$. Thus $E[sx_2] = 0$ and

$$E[sx_1] = E[s(s + n_1)] = E[s^2] + E[sn_1] = E[s^2] \quad (2.24)$$

Substituting these values into (2.22) and (2.23) gives

$$a = \frac{E[s^2]E[x_2^2]}{E[x_1^2]E[x_2^2] - [E[x_1x_2]]^2} \quad (2.25)$$

and

$$b = -\frac{E[s^2]E[x_1x_2]}{E[x_1^2]E[x_2^2] - [E[x_1x_2]]^2} \quad (2.26)$$

Let

$$\alpha = \frac{E[s^2]}{E[x_1^2]E[x_2^2] - [E[x_1x_2]]^2} \quad (2.27)$$

Substituting the value of $\alpha$ into (2.25) and (2.26) gives

$$a = \alpha E[x_2^2] \quad (2.28)$$

and

$$b = -\alpha E[x_1x_2] \quad (2.29)$$

Looking again at the noise canceling system diagram and replacing the values of $a$ and $b$ as determined in (2.28) and (2.29) yields
The term $\alpha$ can be simplified by recognizing several relationships. One input to the noise canceling system is $x_1$ where

$$x_1 = s + n_1 \tag{2.30}$$

Squaring both sides of (2.30) gives

$$x_1^2 = s^2 + n_1^2 + 2sn_1 \tag{2.31}$$

Since $E(sn_1) = 0$, taking the expected value of both sides of (2.31) gives

$$E(x_1^2) = E(s^2) + E(n_1^2)$$

The term $\alpha$ can be simplified by recognizing several relationships. One input to the noise canceling system is $x_1$ where

$$x_1 = s + n_1 \tag{2.30}$$

Squaring both sides of (2.30) gives

$$x_1^2 = s^2 + n_1^2 + 2sn_1 \tag{2.31}$$

Since $E(sn_1) = 0$, taking the expected value of both sides of (2.31) gives
\[ E[x_1^2] = E[s^2] + E[n_1^2] \]  
(2.32)

The second input to the noise canceling system is \( x_2 \) where

\[ x_2 = n_2 \]  
(2.33)

Since \( x_2^2 = n_2^2 \), taking the expected value of both sides gives \( E[x_2^2] = E[n_2^2] \).

Also since \( x_1 x_2 = s n_2 + n_1 n_2 \), taking the expected value yields \( E[x_1 x_2] = E[n_1 n_2] \).

The correlation between \( n_1 \) and \( n_2 \) is defined as \( \rho_{12} \) where

\[ \rho_{12} = \frac{E[n_1 n_2]}{\sqrt{E[n_1^2] E[n_2^2]}} \]  
(2.34)

Squaring and rearranging (2.34) produces

\[ [E[n_1 n_2]]^2 = \rho_{12}^2 E[n_1^2] E[n_2^2] \]  
(2.35)

Substituting (2.35) into (2.27) gives

\[ \alpha = \frac{E[s^2]}{E[n_2^2]} \left( \frac{1}{[E[s^2] + E[n_1^2]] - \rho_{12}^2 E[n_1^2]} \right) \]  
(2.36)

Since \( E[x_2^2] = E[n_2^2] \), let

\[ \beta = \alpha E[x_2^2] = \alpha E[n_2^2] \]

Thus

\[ \beta = \frac{E[s^2]}{E[s^2] + E[n_1^2](1 - \rho_{12}^2)} \]  
(2.37)

The system of Figure 2.7 can be reduced again to produce a multiplier of one in the top branch as shown in Figure 2.8.

The term \( \beta \) is found to depend on the apriori knowledge in terms of the signal-to-noise ratio and the correlation between the two noise terms.

Dividing the numerator and denominator of (2.37) by \( E[n_1^2] \) and recognizing...
that the signal-to-noise ratio (S/N) is the term $E[s^2]/E[n_1^2]$ yields

$$\beta = \frac{S}{N + 1 - \rho_{12}^2}$$  \hspace{1cm} (2.38)

Thus the weight, $W$, for the expected value algorithm is given by

$$W = \frac{E[x_1 x_2]}{E[x_2^2]}$$  \hspace{1cm} (2.39)

where the term $\beta$ must also be a multiplier of the output of the system.

In summary, the expected value algorithm uses a ratio of the expected values of the inputs in order to determine the weight, $W$. However, since expected values are mathematical concepts, they are estimated for the computer simulation in terms of the jth sequence of inputs. The two input noise canceling system with the expected value algorithm is shown in Figure 2.9.

Both the LMS and expected value algorithms have only one weight which is multiplied by the noise only input. Therefore an interesting problem is to find the optimum weight for a linear least mean square estimate.
3. Optimum Weight Vector

The noise canceling structure is shown in Figure 2.10.

\[ x_1 = s + n_1 \]
\[ x_2 = n_2 \]

![Diagram](image)

Figure 2.10. Two Input Noise Canceling System.

The error, \( \varepsilon \), for a linear least mean square estimate is given by

\[ \varepsilon = E[(\hat{s} - s)^2] \] (2.40)

where \( \hat{s} \) is defined in (2.1). Substituting the value of \( \hat{s} \) given by (2.1) into (2.40) yields

\[ \varepsilon = E[(x_1 - Wx_2 - s)^2] \] (2.41)

Taking the derivative of the error with respect to the weight and setting the
result equal to zero produces the optimum weight. Thus taking the partial derivative of (2.41) with respect to $W$ produces

$$\frac{\partial e}{\partial W} = E[(x_1 - Wx_2 - s)^2] = 0$$

and thus

$$E[x_1 x_2] - WE[x_2^2] - E[sx_2] = 0 \quad (2.42)$$

By hypothesis

$$E[sn_1] = E[sn_2] = E[sx_2] = 0$$

Solving for $W$ in (2.42) yields

$$W_{opt} = \frac{E[x_1 x_2]}{E[x_2^2]} \quad (2.43)$$

Thus the optimum weight for a linear least mean square estimate is given by (2.43) and the noise canceling system is shown in Figure 2.11. This weight is the same as that given by the Wiener-Hopf equation for a two input noise canceling system.

Figure 2.11. Optimum Weight Vector for the Two Input Noise Canceling System.
Notice that the optimum weight and the theoretical weight for the expected value algorithm are the same. The expected value algorithm, however, has a multiplier of $\beta$ which is not present in the noise canceling structure of Figure 2.11. When $\beta = 1$, the expected value algorithm would be the same as the optimum if the expected values could be computed directly. The weight for the LMS algorithm will converge to the optimum weight as the number of iterations increase (see Appendix A).

Since both the LMS and expected value algorithms have weights which converge to the same value, the theoretical minimum mean square error can be found.

4. Theoretical Minimum Mean Square Error

The theoretical minimum mean square error for both algorithms is the same (since the weights converge to the value given by the optimum weight) and can be determined from the optimum weight vector. Using the noise canceling structure of Figure 2.10 and the optimum weight vector given by (2.43), the minimum mean square error, $\varepsilon_{\text{MMS}}$, can be computed:

\[ \varepsilon_{\text{MMS}} = E[(\hat{s} - s)^2] \]

\[ \varepsilon_{\text{MMS}} = E[(x_1 - \frac{E[x_1 x_2]}{E[x_2]} x_2 - s)^2] \]

and

\[ \varepsilon_{\text{MMS}} = E[(n_1 - \frac{E[n_1 n_2]}{E[n_2]} n_2)^2] \]  

(2.44)

If

\[ \gamma = \frac{E[n_1 n_2]}{E[n_2]} \]  

(2.45)

then substituting (2.45) into (2.44) produces
\[ \varepsilon_{\text{MMS}} = E[(n_1 - \gamma_2)^2] \]  
(2.46)

Expanding (2.46) yields
\[ \varepsilon_{\text{MMS}} = E[n_1^2] - 2\gamma E[n_1 n_2] + \gamma^2 E[n_2^2] \]  
(2.47)

The correlation coefficient, \( \rho_{12} \), is defined in (2.34) and can be re-written in terms of \( E[n_1 n_2] \). That is:
\[ E[n_1 n_2] = \rho_{12} \sqrt{E[n_1^2]E[n_2^2]} \]  
(2.48)

Substituting (2.48) into (2.45) yields
\[ \gamma = \rho_{12} \sqrt{\frac{E[n_1^2]}{E[n_2^2]}} \]  
(2.49)

Using (2.48) and (2.49) the minimum error can be simplified:
\[ \varepsilon_{\text{MMS}} = E[n_1^2] - 2 \left[ \rho_{12} \frac{E[n_1^2]}{E[n_2^2]} \right] \rho_{12} \sqrt{E[n_1^2]E[n_2^2]} + \left[ \rho_{12}^2 \frac{E[n_1^2]}{E[n_2^2]} \right] E[n_2^2] \]

and thus
\[ \varepsilon_{\text{MMS}} = E[n_1^2] (1 - \rho_{12}^2) \]  
(2.50)

The theoretical minimum mean square error for the noise canceling system of Figure 2.10 is given by (2.50). The minimum error depends only on the power of the noise mixed with the signal and the correlation between the two noises. As the correlation decreases to zero, the error approaches its largest value. When the correlation actually equals zero, this is the worst case in terms of error. Thus the error would be the same if no noise canceling system had been used. When the correlation equals one, the error equals zero and the best case is realized. Thus as the correlation increases and the noise power decreases (implying increasing signal-to-noise ratio), the theoretical minimum mean square error also decreases.
For the expected value algorithm, Figure 2.10 assumes that $\beta = 1$. This is a reasonable assumption because $\beta$ depends on apriori knowledge of the signal-to-noise ratio and the correlation coefficient $\rho_{12}$. If this knowledge is known, a better estimate can be obtained.

Using the noise canceling structure of Figure 2.9 and the value of $\beta$ from (2.38), the theoretical minimum mean square error for $\beta \neq 1$ can be computed. From Figure 2.9, the estimated signal, $\hat{s}$, is given by:

$$\hat{s} = \beta [x_1 - \frac{E[x_1 x_2]}{E[x_2^2]} x_2] \quad (2.51)$$

Substituting (2.51) into (2.40) gives

$$\varepsilon_{\text{MMS}} = E[(\beta x_1 - \frac{E[x_1 x_2]}{E[x_2^2]} \beta x_2 - s)^2] \quad (2.52)$$

Using (2.43) and (2.48), equation (2.52) can be simplified:

$$\varepsilon_{\text{MMS}} = E[n_1^2](1 - \rho_{12}^2)\beta^2 + E[s^2](\beta - 1)^2 \quad (2.53)$$

If $\beta = 1$, then (2.53) reduces to (2.50).

5. Summary of the Algorithms

The algorithms were derived in a theoretical manner, but are summarized here in the forms which were implemented for the computer simulation. The inputs, weights, and estimates are given in terms of the $j$th iteration.

A. LMS Algorithm

The weight vector for the LMS algorithm was defined in (2.13) in terms of the error:

$$w_{j+1} = w_{j} + 2\mu e_{j} x_{j} \quad (2.13)$$

However, since the signal, $s$, is not generally known, it is desirable to replace the error $e_{j}$ in (2.13) by $\hat{s}_{j}$. Then the weight vectors can be shown to
converge to the same value. Thus for the jth iteration
\[ \epsilon_j = \hat{s}_j - s_j \quad (2.54) \]

Replacing \( \epsilon_j \) by \( \hat{s}_j \) in (2.13) gives
\[ W_{s_j+1} = W_{s_j} + 2\mu \epsilon_j x_j + 2\mu s_j x_j \quad (2.55) \]

and in general
\[ W_{s_j} = W_0 + 2\mu \sum_{i=0}^{j-1} \epsilon_j x_i + 2\mu \sum_{i=0}^{j-1} x_i s_i \quad (2.56) \]

Taking the expected value of both sides of (2.56) produces
\[ E[W_{s_j}] = W_0 + 2\mu \sum_{i=0}^{j-1} E[\epsilon_i x_i] + 2\mu \sum_{i=0}^{j-1} E[x_i s_i] \quad (2.57) \]

By hypothesis \( E[x_i s_i] = 0 \). Therefore
\[ E[W_{s_j}] = W_0 + 2\mu \sum_{i=0}^{j-1} E[\epsilon_i x_i] \quad (2.58) \]

Therefore replacing \( \epsilon_j \) by either \( \hat{s}_j \) or \( \epsilon_j = \hat{s}_j - s_j \) produces the same weight solution.

The weight vector used throughout the remainder of this paper replaces \( \epsilon_j \) by \( \hat{s}_j \) and for the two input system is given by
\[ W_{j+1} = W_j + 2\mu \hat{s}_j x_{2_j} \quad (2.59) \]

The weight vector can also be written in terms of the data inputs alone by substituting for the value of \( \hat{s}_j \) from (2.1). Thus
\[ W_{j+1} = W_j (1 - 2\mu x_{2_j}^2) + 2\mu x_{1_j} x_{2_j} \quad (2.60) \]

The weight vector, \( W_{j+1} \), is computed during the computer simulation after determining \( \hat{s}_{LMS} \). This value is stored in a vector so that it can be
used to compute $\hat{s}_{LMS}$ for the next iteration. Figure 2.12 shows the LMS algorithm for the $j$th iteration of the computer simulation.

\[
x_{1j} = s_j + n_{1j} + x_{2j}
\]

\[
x_{2j} = n_{2j}
\]

\[
W_{j+1} = W_j(1 - 2x_{2j}^2) + 2\mu x_{1j} x_{2j}
\]

Figure 2.12. LMS Algorithm as Computer Simulated.

B. Expected Value Algorithm

When the expected value algorithm was implemented on the PDP-11/45 computer, the expected values were estimated using an iterative approximation. For example:

\[
E[x_1 x_2] = \frac{\sum_{i=1}^{j} x_{1i} x_{2i}}{j}
\]  

(2.61)

The term $\mu$ was set equal to one for reasons explained later. Thus for the $j$th iteration, the expected value algorithm is implemented as shown in Figure 2.13.

The expected value algorithm can be written in a form which reveals the way in which the weight is updated:

\[
W_{EVj} = \frac{\sum_{i=1}^{j} x_{1i} x_{2i}}{\sum_{i=1}^{j} x_{2i}^2} = \frac{W_{j-1} + x_{1j} x_{2j}}{W_{j-1} + x_{2j}^2} = \frac{W_{j}}{W_{j}}
\]  

(2.62)
This form also indicates the estimation of the expected values needed for the optimum weight vector defined in (2.43).

C. Comparison of the Algorithms

The optimum weight vector as given in Figure 2.11 will produce the best results in terms of mean square error estimation for the two input system. However, since the expected values are not known quantities, they must be estimated. The difference in performance between the expected value and LMS algorithms can be traced to the weights. The expected value algorithm makes two estimates (one for the numerator and another for the denominator) before dividing the two to obtain an estimate of the weight:

$$W_{EV_j} = \frac{\sum_{i=1}^{j} x_{1_i} x_{2_i}}{\sum_{i=1}^{j} x_{2_i}^2} \cdot \frac{W'_{j-1} + x_{1_j} x_{2_j}}{W''_{j-1} + x_{2_j}^2}$$

(2.63)

The jth inputs are used to update the (j-1)st estimates before the division
is made.

The LMS algorithm however, makes one estimate for the weight:

$$W_{lMS_j} = W_{lMS_{j-1}} + 2u_s j^{-1} x_{2j-1}$$ (2.64)

or in terms of the inputs:

$$W_{lMS_j} = W_{lMS_{j-1}} (1 - 2u x_{j-1} x_{2j-1}) + 2u x_{1j-1} x_{2j-1}$$ (2.65)

Although the same terms, $x_1 x_2$ and $x_2^2$, are being calculated, the two estimate approach of the expected value algorithm generally will produce a better estimate in fewer iterations. The expected value algorithm also uses the jth inputs to compute the jth weight, but the LMS algorithm only uses the data through the (j-1)st inputs. This is the reason the LMS algorithm can be written as a feedback system and the expected value algorithm can not.
CHAPTER III

COMPUTER SIMULATION OF TWO INPUT NOISE CANCELING SYSTEM

The two algorithms described and developed in Chapter II were simulated on a PDP-11/45 computer at Duke University. In order to make the algorithms more comparable, the noise canceling structure of Figure 2.10 was used for the simulation. The multiplier of $B$ for the expected value algorithm, as shown in Figure 2.8, was set equal to one. If $B$ is actually calculated, a better estimate could be obtained. However, for purposes of comparison it was desirable to use the same amount of apriori knowledge for both algorithms. The comparison was based on a graph with the mean square error plotted as a function of the number of iterations.

1. Problem Description

Values for the inputs to the noise canceling system of Figure 2.10 had to be chosen before beginning the computer simulation. A dc signal was used as the signal component of the system. The value of the signal was constant and arbitrarily chosen to be 10.0. The choice of a dc signal enabled a more comprehensive study since a frequency dependent signal, such as a sine wave, would have had the effects of changes in phase or frequency embedded in the results.

The noise was generated using the computer's random number generator. Uniformly distributed random numbers were obtained and then transformed to

\[ 25 \]
zero mean Gaussian random numbers by employing the Box-Muller equations. Each pair of Gaussian random numbers had a given variance and correlation and served as the noise components needed for the inputs to the noise canceling system.

The algorithms were implemented on the computer using several iterative estimates. The expected values needed for the expected value algorithm were computed using the approximation

\[
E[x_1 x_2] = \frac{\sum_{i=1}^{j} x_{1i} x_{2i}}{j}
\]  

(3.1)

The mean square error was also approximated:

\[
E[(\hat{s}_j - s_j)^2] = \frac{\sum_{i=1}^{j} (\hat{s}_i - s_i)^2}{j}
\]  

(3.2)

The initial weight vector, \( \mathbf{w}(1) \), for the LMS algorithm was set to a constant value of 5.0. This value was an arbitrary choice. Since the mean square error was computed for five hundred iterations, the effect of the initial weight vector washed out. If it was necessary to use a smaller number of iterations, the effect of the initial weight vector would be more important and thus it should be carefully chosen.

The LMS algorithm also required values for the parameter \( \mu \) which controls the rate of convergence of the algorithm. In order for the two input system LMS algorithm to converge, the value of \( \mu \) must be within a given range (see Appendix A) defined as

\[
1 - 2\mu E[x_2^2] < 1
\]  

(3.3)

As the value of \( \mu \) decreases, the rate of convergence also decreases since
\[ |1 - 2\mu E[x_2^2]| \text{ approaches } 1. \text{ Three values of } \mu \text{ were chosen for the computer simulation. These were values of } .01, .001, \text{ and } .0001 \text{ which correspond to graphs } b, c, \text{ and } d, \text{ respectively on each page of figures. For convenience in the computer simulation}

\[ E[n_1^2] = E[n_2^2] \quad (3.4) \]

Therefore when the signal-to-noise ratio is 10.0, all three \( \mu \) values are within the range for convergence of the algorithm. When the signal-to-noise ratio is 1.0, \( \mu \) values of .001 and .0001 are within the range, but a \( \mu \) value of .01 results in equality in equation (3.3). When the signal-to-noise ratio is .1, only the \( \mu \) value of .0001 is within the range of convergence. Equality in equation (3.3) results for a \( \mu \) value of .001 and a \( \mu \) value of .01 is outside the range for convergence of the algorithm.

The theoretical minimum mean square error is defined in (2.50) and depends only on the values of \( E[n_1^2] \) and \( \rho_{12} \). Thus when \( \rho_{12} = 0 \), the worst error is produced. Figure 3.1 shows the worst case for the signal-to-noise ratio of 10.0. When \( \rho_{12} = 1 \), the best case is realized and the noise is completely canceled. Therefore when \( \rho_{12} \) is between 0 and 1 in value, some noise canceling is achieved, but some error also exists.

With the noise canceling system described, the method of comparison was a graph of the mean square error as a function of the number of iterations. Each curve consisted of five hundred iterations. Twenty-five curves were averaged point by point before this ensemble average was plotted. In this way, the effect of a single ensemble (or particular sequence of random numbers) was less and the averaged curve was a smoother curve. The curves can be compared directly or the difference from the theoretical minimum mean square error after five hundred iterations can be used as a basis of comparison.
2. **Performance Comparison**

The graphs of the mean square error as a function of the number of iterations follow. They are arranged by pages with the same signal-to-noise ratio (S/N) and noise correlation ($\rho_{12}$) on each page. Each page contains a graph using the expected value algorithm and three graphs of the LMS algorithm, each of which employs a different $\mu$ value. The pages are arranged in order of decreasing signal-to-noise ratio and decreasing correlation coefficients. All of the graphs were plotted using the same scale in order to compare them directly. When the mean square error was too large to be within the bounds set by the scale, the curve was plotted as a straight line until the iteration when the value came within bounds. This does not mean that the mean square error was a constant value through this iteration, only that it was too large for the desired scale (see Appendix C). Table 3.1 gives representative values of the curves.

The difference between the minimum mean square errors of the curves is explained by the different rates of convergence. The theoretical minimum error is the same for each set of values of signal-to-noise ratio and noise correlation. Changes in the amount of noise correlation have little effect on the rate of convergence itself, but do change the value of the theoretical minimum error.

Figure 3.1 demonstrates the worst case ($\rho_{12} = 0.0$) for a signal-to-noise ratio of 10.0. The expected value algorithm shows rapid convergence to the theoretical minimum error of 10.0. After five hundred iterations, the actual error (with a value of 11.22) is very close to the theoretical. This is the worst case for this signal-to-noise ratio. Any larger value of noise correlation will improve the ability of the system to eliminate the noise. The LMS algorithm does not perform as well as the expected value.
algorithm because the rate of convergence is slower and the minimum error after five hundred iterations is larger. As the value of $\mu$ is decreased, the rate of convergence becomes less. However, the $\mu$ value of .001 produces a smaller error than does the $\mu$ value of .01. Although the rate of convergence is less, the minimum error is smaller due to fewer fluctuations in the weight vector.

Figures 3.2 through 3.4 all have the signal-to-noise ratio of 10.0. Each figure has a different value of noise correlation. For each figure, the expected value algorithm exhibits the best performance in terms of a lower minimum value and a faster rate of convergence. In each case the LMS algorithm with $\mu$ equal to .01 compares more favorably with the expected value algorithm in terms of rate of convergence. However, with $\mu$ equal to .001, the LMS algorithm compares better in terms of minimum error. The $\mu$ equal to .0001 case of the LMS algorithm has a slow rate of convergence and large initial and final errors. Thus this case is not as important in the comparison between the two algorithms.

When the signal-to-noise ratio is 10.0, small changes in correlation produce only small changes in the curves. As the correlation is reduced, the rate of convergence of all of the curves decreases. The minimum error after five hundred iterations becomes larger. The maximum error for the expected value algorithm never exceeded 100, but the LMS algorithm often produced large errors. As the correlation decreased, these maximum errors increased.

When the signal-to-noise ratio was lowered to 1.0, the comparison is more dramatic. Figures 3.5 through 3.7 display these results. Again the expected value algorithm produces the best results. The change in signal-to-noise ratio has scarcely affected the performance of this algorithm. However,
the LMS algorithm has been affected by the change to a great degree. The μ equal to .01 case of the LMS algorithm produces a curve that is entirely off of the scale. This is due to the fact that the value of μ is outside of the range of convergence. The μ equal to .0001 curve has a very slow rate of convergence and the initial values are so large that the straight line effect is observed. Thus the μ equal to .001 curve is the only curve for the LMS algorithm that can be effectively compared with expected value algorithm. The rate of convergence is much slower than for the expected value algorithm and the minimum error is much larger. The LMS algorithm again produces large initial errors.

With a smaller signal-to-noise ratio, changes in noise correlations are more important. Small differences in correlation have a greater effect on the rate of convergence and the maximum and minimum errors than when the signal-to-noise ratio is larger. If the correlation is constant and the signal-to-noise ratio is lowered or if the signal-to-noise ratio is constant and the correlation decreases, the rate of convergence is slower and the maximum and minimum errors for five hundred iterations increase. This was true for all of the cases tested except that the maximum error for the expected value algorithm was never greater than 100.

When the signal-to-noise ratio was lowered to .10, the expected value algorithm alone produced curves with values small enough to be within the desired scale. The μ values of .01 and .001 are too large for the algorithm to converge. However, as the μ value gets smaller, the rate of convergence becomes too slow for convergence within five hundred iterations. Thus the μ value of .0001 also produces a curve with values too large for the scale. Small changes in correlation produce noticeable changes in the expected value algorithm curves. When the signal-to-noise ratio was 10.0, a change in
correlation from .99 to .98 produced barely distinguishable changes in the
curves. Nevertheless, the expected value algorithm produces good results in
terms of a fast rate of convergence and a minimum error that approaches the
theoretical minimum.

3. Summary of Two Input Results

In all of the cases tested, the expected value algorithm produced the
superior results. The expected value algorithm consistently had a faster
rate of convergence and a smaller minimum value. It also had two fewer in-
puts than the LMS algorithm since an initial weight vector, \( W(1) \), and a \( \mu \)
value did not have to be chosen. The expected value algorithm never produced
error values greater than 100, but the LMS algorithm produced many values that
were too large to be graphed on the desired scale.

The complexity of the two algorithms is approximately the same. In
order to calculate the weight vector, each algorithm requires two multipli-
cations. The expected value algorithm also required an additional division.
However, in terms of performance, the extra division time is well worth the
small trade off in speed. Each algorithm computes the same terms, \( x_1x_2 \) and
\( x_2^2 \), but the expected value algorithm updates two estimates at each iteration
before dividing the two to obtain an estimate of the weight, \( W \). The LMS al-
gorithm, however, only computes one estimate of the weight. Although the one
estimate takes less time, the two estimate approach produces better perform-
ance.

The problem in choosing a \( \mu \) value proved to be great. In general, as
the \( \mu \) value decreased, the rate of convergence also decreased, but the minimum
values of the curves approached more closely the theoretical minimum error due
to fewer fluctuations in the weight vector. Since only the first 500 iter-
tions were used, the range of $\mu$ was even smaller than equation (3.3) would indicate. This small range proved to be an important drawback to the LMS algorithm. The large error values produced by some values of $\mu$ created storage and graphing problems that were not present in the expected value algorithm. For signal-to-noise ratios of 1.0 and .10, the reason that the larger values of $\mu$ generated curves off the scale was due to the fact that the $\mu$ value was not in the range for convergence. However, for small values of $\hat{\mu}$, the large errors were probably due to the slow rate of convergence of the weights.

Although the choice of the initial weight vector was not important in this study because of such a large number of iterations, it could have an effect when considering a smaller number. In any case, the effect of the choice is not as important as that of the $\mu$ value because it tends to wash out after several iterations. This is another value, however, which must be chosen for the LMS algorithm and which is not necessary for the expected value algorithm.

The comparison between the two algorithms is dramatic when the signal-to-noise ratio is high, but becomes even more so as the signal-to-noise ratio decreases. When the signal-to-noise ratio is 10.0, the results are closer if a correct $\mu$ value is chosen than when the signal-to-noise ratio is .10 and only the expected value algorithm can be said to converge within five hundred iterations. The performance for all signal-to-noise ratios and correlation values tested reveal that the expected value algorithm works better for a two input noise canceling system with a dc signal and Gaussian noise than does the LMS algorithm.
Table 3.1. Representative Values of the Curves Obtained:
Two Input Noise Canceling System

Each page contains four graphs labeled a, b, c, and d. These have characteristic values given by several parameters:

- \( S/N \) - the signal-to-noise ratio
- \( P_{12} \) - the correlation between the noises \( n_1 \) and \( n_2 \)
- \( T_{MIN} \) - the theoretical minimum mean square error
- Algorithm - the algorithm employed—either expected value or LMS
- \( \mu \) - the value of the parameter \( \mu \) for the LMS algorithm
- \( MAX \) - the maximum value of the curve
- \( MIN \) - the minimum value of the curve

minimum error too large for scale
CHAPTER IV
EXTENSION TO THREE INPUT NOISE CANCELING SYSTEM:
DERIVATION OF THE ALGORITHMS

The algorithms derived and simulated in Chapters II and III are extended in this chapter to a three input noise canceling system. The goal of the algorithms is to minimize the mean square error. Again the performance of the algorithms is determined from a computer simulation.

A three input noise canceling system has one input containing a mixture of signal and noise and two inputs of noise only. The weight vector contains two weights. The three input system is shown in Figure 4.1.

Figure 4.1. Three Input Noise Canceling System.

\[ x_1 = s + n_1 \]
\[ x_2 = n_2 \]
\[ x_3 = n_3 \]
The signal, $s$, is uncorrelated with the noises, $n_1$, $n_2$, and $n_3$, but the noises are correlated with each other. The estimated signal, $\hat{s}$, is given by

$$\hat{s} = x_1 - W_2 x_2 - W_3 x_3$$  \hspace{1cm} (4.1)

and the error is defined by (2.2) as

$$e = \hat{s} - s$$  \hspace{1cm} (2.2)

The weights, $W_2$ and $W_3$, are determined such that the signal estimate, $\hat{s}$, is a linear least mean square estimate.

1. LMS Algorithm

The LMS algorithm is easily extended to the three input noise canceling system of Figure 4.1 because several scalar quantities of the two input system are simply replaced with vectors. The weight, $W$, of the two input system is replaced with the vector $\bar{W}$ where

$$W = \begin{bmatrix} W_2 \\ W_3 \end{bmatrix}$$  \hspace{1cm} (4.2)

The input $x_2$ is replaced with a vector of noise only inputs:

$$x = \begin{bmatrix} x_2 \\ x_3 \end{bmatrix}$$  \hspace{1cm} (4.3)

The next weight vector, $W_{j+1}$, is calculated utilizing (2.13) and (2.59) with (4.2) substituted for $W$ and (4.3) substituted for $x_2$. Thus,

$$W_{j+1} = W_j + 2\mu \hat{s}_j x_j$$  \hspace{1cm} (4.4)

or in matrix form:

$$\begin{bmatrix} W_2 \\ W_3 \end{bmatrix}_{j+1} = \begin{bmatrix} W_2 \\ W_3 \end{bmatrix}_j + 2\mu \hat{s}_j \begin{bmatrix} x_2 \\ x_3 \end{bmatrix}_j$$  \hspace{1cm} (4.5)
where
\[ \hat{s}_j = x_{1j} - W_j^T x_j \] (4.6)

or
\[ \hat{s}_j = x_{1j} - W_{2j} x_{2j} - W_{3j} x_{3j} \] (4.7)

In terms of the inputs, the weights of the three input system are given in Figure 4.2.

![Diagram of the LMS algorithm](image)

Figure 4.2. LMS Algorithm.

The LMS algorithm can be easily extended to any number of inputs necessary to solve a noise canceling problem. The expected value algorithm involves a matrix inversion, but is an estimation of the theoretical optimum solution. The tradeoff between the two algorithms is in terms of the complexity and performance.
2. Expected Value Algorithm

The expected value algorithm attempts to minimize the mean square error by estimating the optimum weight vector for Figure 4.1. The optimum weight vector can be determined by solving for the weights that make the partial derivative of the mean square error with respect to the weights equal to zero. This is equivalent to solving the Wiener-Hopf equation for a three input system.

Equation (4.1) can be written in matrix form:

\[ \hat{s} = x_1 - \mathbf{W}^T \mathbf{X} \]  

where \( \mathbf{W} \) and \( \mathbf{X} \) were defined in (4.2) and (4.3). Substituting (4.2) and (4.3) into the definition of the error given by (2.2) yields

\[ \varepsilon = x_1 - \mathbf{W}^T \mathbf{X} - s \]  

Squaring and taking the expected value of both sides of equation (4.9) produces the mean square error:

\[ \mathbb{E}[\varepsilon^2] = \mathbb{E}[(x_1 - s)^2] - 2\mathbf{W}^T \mathbb{E}[(x_1 - s)\mathbf{X}] + \mathbf{W}^T \mathbb{E}[\mathbf{XX}^T] \mathbf{W} \]  

In order to find the value of \( \mathbf{W} \) that minimizes (4.10), it is necessary to take the partial derivative with respect to \( \mathbf{W} \). Thus

\[ \frac{3}{\mathbf{W}} \mathbb{E}[\varepsilon^2] = -2\mathbb{E}[(x_1 - s)\mathbf{X}] + 2\mathbb{E}[\mathbf{XX}^T] \mathbf{W} \]  

Expanding (4.11) and recalling the hypotheses that \( \mathbb{E}[sx_2] = 0 \) and \( \mathbb{E}[sx_3] = 0 \) gives

\[ \frac{3}{\mathbf{W}} \mathbb{E}[\varepsilon^2] = -2\mathbb{E}[x_1\mathbf{X}] + 2\mathbb{E}[\mathbf{XX}^T] \mathbf{W} \]  

Define the two expected value terms in (4.12) as follows:

\[ \mathbf{g}_{xx} = \mathbb{E}[^{\mathbf{X}}_{XX}] \]
or
\[
\Phi_{xx} = \begin{bmatrix}
E[x_2 x_2] & E[x_2 x_3] \\
E[x_2 x_3] & E[x_3 x_3]
\end{bmatrix}
\]

and
\[
\Phi_{x1} = E[x_1 x_1]
\]
or
\[
\Phi_{x1} = \begin{bmatrix}
E[x_1 x_2] \\
E[x_1 x_3]
\end{bmatrix}
\]

Thus, substituting (4.13) and (4.14) into (4.12) gives
\[
\frac{\partial}{\partial W} E[\epsilon^2] = -2\Phi_{x1} x + 2\Phi_{xx} W
\]

In order to find the minimum error, the partial derivative in (4.15) is set equal to zero. Solving for \( W \) gives
\[
\Phi_{xx} W = \Phi_{x1} x
\]

Equation (4.16) can also be written in matrix form utilizing (4.13) and (4.14):
\[
\begin{bmatrix}
E[x_2 x_2] & E[x_2 x_3] \\
E[x_2 x_3] & E[x_3 x_3]
\end{bmatrix}
\begin{bmatrix}
w_2 \\
w_3
\end{bmatrix}
= \begin{bmatrix}
E[x_1 x_2] \\
E[x_1 x_3]
\end{bmatrix}
\]

Taking the matrix inverse, (4.17) can be solved for \( w_2 \) and \( w_3 \):
\[
w_2 = \frac{E[x_1 x_2]E[x_3 x_3] - E[x_2 x_3]E[x_1 x_3]}{E[x_2 x_2]E[x_3 x_3] - E[x_2 x_3]E[x_2 x_3]}
\]

and
\[
w_3 = \frac{E[x_2 x_2]E[x_1 x_3] - E[x_2 x_3]E[x_1 x_2]}{E[x_2 x_2]E[x_3 x_3] - E[x_2 x_3]E[x_2 x_3]}
\]

Thus the values of \( w_2 \) and \( w_3 \) as determined in (4.18) and (4.19) are the optimum values necessary to minimize the mean square error. They are...
in fact the solutions to the Wiener-Hopf equation, (1.2), for a three input system where \( R = \Phi_{XX} \) and \( P = \Phi_{X_1X_2} \). The expected value algorithm utilizes these optimum weights in order to estimate the signal. The expected values are mathematical terms and are estimated (see (2.61)) for the computer simulation of the three input system. Figure 4.3 shows the three input noise canceling system with the weights determined from the theoretical derivation of the expected value algorithm.

\[
\begin{align*}
  x_1 &= s + n_1 \\
  x_2 &= n_2 \\
  x_3 &= n_3
\end{align*}
\]

\[
W_2 = \frac{E[x_1x_2]E[x_3^2] - E[x_2x_3]E[x_1x_3]}{E[x_2^2]E[x_3^2] - [E[x_2x_3]]^2}
\]

\[
W_3 = \frac{E[x_2^2]E[x_1x_3] - E[x_2x_3]E[x_1x_2]}{E[x_2^2]E[x_3^2] - [E[x_2x_3]]^2}
\]

Figure 4.3. Expected Value Algorithm.

Since the expected value and LMS algorithms both converge to the same error (see Appendix A), it is useful to determine the theoretical minimum mean square error.

3. **Theoretical Minimum Mean Square Error**

In order to effectively compare the two algorithms, it is desirable to determine the theoretical minimum mean square error. The optimum weight vector for a linear least mean square estimate was determined by the expected...
value algorithm. Thus using (4.18) and (4.19) for the weight vector, (4.1) for the estimated signal, and (2.40) for the minimum error, the theoretical minimum error can be calculated:

\[ \epsilon_{\text{min}} = E[(\hat{s} - s)^2] \] (2.40)

and

\[ \epsilon_{\text{MMS}} = E[(n_1 - W_2 x_2 - W_3 x_3)^2] \] (4.20)

Equation (4.20) can be simplified using Figure 4.1 and replacing \( x_1, x_2, \) and \( x_3 \) with their equivalent values in terms of \( s, n_1, n_2, \) and \( n_3. \) The definition of correlation given by (2.34) is also used:

\[ \epsilon_{\text{MMS}} = E[n_1^2] - 2W_2E[n_1n_2] - 2W_3E[n_1n_3] + 2W_2W_3E[n_2n_3] \]

\[ + W_2^2E[n_2^2] + W_3^2E[n_3^2] \]

and thus

\[ \epsilon_{\text{MMS}} = E[n_1^2] - 2W_2\rho_{12}\sqrt{E[n_1^2]E[n_2^2]} - 2W_3\rho_{13}\sqrt{E[n_1^2]E[n_3^2]} \]

\[ + 2W_2W_3\rho_{23}\sqrt{E[n_2^2]E[n_3^2]} + W_2^2E[n_2^2] + W_3^2E[n_3^2] \] (4.21)

The optimum weight vector given by (4.18) and (4.19) can be rewritten in terms of \( s, n_1, n_2, \) and \( n_3. \) The definition of correlation in (2.34) also helps to simplify the vector. Thus,

\[ W_2 = c_1 \sqrt{\frac{E[n_1^2]}{E[n_2^2]}} \] (4.22)

where

\[ c_1 = \frac{\rho_{12} - \rho_{23}\rho_{13}}{1 - \rho_{23}^2} \] (4.23)
and
\[ w_3 = c_2 \sqrt{\frac{E[n_1^2]}{E[n_3^2]}} \] (4.24)

where
\[ c_2 = \frac{\rho_{13} - \rho_{12} \rho_{23}}{1 - \rho_{23}^2} \] (4.25)

Substituting (4.22) and (4.24) into (4.21), the theoretical minimum error can be simplified further:
\[ e_{\text{MMS}} = E[n_1^2] \left[ 1 - 2\rho_{12} c_1 - 2\rho_{13} c_2 + 2c_1 c_2 \rho_{23} + c_1^2 + c_2^2 \right] \] (4.26)

where \( c_1 \) and \( c_2 \) are defined by (4.23) and (4.25).

Since the weight vectors of both algorithms converge to the optimum weight vector (see Appendix A), the theoretical minimum mean square error of both algorithms is given by (4.26).

4. Summary of the Algorithms

The algorithms are summarized here in the forms that are used for the computer simulation. The inputs, weights, and estimates are presented in terms of the jth iteration.

A. LMS Algorithm

The LMS algorithm utilized the computed value of \( \hat{s}_{\text{LMS}} \) for the computer simulation. The values of the weights at each iteration are stored so that they can be used to compute the weights for the next iteration. Therefore the LMS algorithm is simulated for the jth iteration as shown in Figure 4.4.
B. Expected Value Algorithm

The expected value algorithm is derived in terms of the expected values of the inputs which will minimize the mean square error. Since the expected values are mathematical quantities which are not known exactly, the expected value algorithms must estimate them and is therefore only an approximation to the optimum solution.

The expected values were estimated using the iterative procedure described in Chapter II. The expected value algorithm for the jth iteration of the computer simulation is implemented as seen in Figure 4.5.

C. Comparison of the Algorithms

The optimum weight vector will produce the best results for the three input system. However, since it can't be calculated directly the expected value algorithm approximates it by estimating the expected values. As in the two input case, the LMS algorithm attempts to estimate the optimum weight vector as one term while the expected value algorithm estimates each expected value before combining them to form the weight vector. Although this method
Figure 4.5. Expected Value Algorithm as Computer Simulated.

is more complex and more time consuming due to the increased number of multiplications and divisions, the improved performance justifies it. The LMS algorithm could also be written in terms of a feedback system as in the two input case, but this is not necessary. The expected value algorithm can't be a feedback system because it needs the jth inputs to compute the jth estimate. The LMS algorithm instead computes the jth weights with the data through the (j-1)st inputs. This method is not as effective as that of the expected value algorithm.
CHAPTER V
COMPUTER SIMULATION OF THE THREE INPUT NOISE CANCELING SYSTEM

The three input algorithms developed in Chapter IV were simulated on a PDP-11/45 computer at Duke University. Figures 4.4 and 4.5 give the algorithms in terms of their computer implementation.

1. Problem Description

Parameter values had to be chosen before starting the simulation. The signal was a dc signal with value 10.0 as in the two input case. The values of the initial weight vector for the LMS algorithm were again constant. The first weight, $W_2$, was set equal to 5.0 as in the two input case, and the second, $W_3$, was arbitrarily set to 3.0. These values were not important due to the large number of iterations.

The choice of the parameter $\mu$ for the LMS algorithm was again a problem as it was for the two input system. In order for the algorithm to converge, the value of $\mu$ must be in the range (see Appendix A) defined as:

$$1 - 2\mu E[x^T x] < 1$$

where $x$ is defined by (4.3). The three $\mu$ values of .01, .001, and .0001, corresponding to graphs b, c, and d, respectively on each page of figures, are the same as those used in the two input system simulation. Also for convenience in the simulation,
\[ E[n_1^2] = E[n_2^2] = E[n_3^2] \] (5.2)

When the signal-to-noise ratio is 10.0, all three values of \( \mu \) are within the range for convergence of the algorithm. When the signal-to-noise ratio is lowered to 1.0, the \( \mu \) value of .01 is outside the range of convergence. Both \( \mu \) values of .01 and .001 are outside the range of convergence when the signal-to-noise ratio is .1. For a given signal-to-noise ratio, a decrease in the parameter \( \mu \) results in a decrease in the rate of convergence since the quantity \( |1-2 \mu E[\mathbf{x}^T \mathbf{x}]| \) approaches one.

The noise was generated using the method described in Appendix B. Independent zero mean Gaussian random numbers were generated and then transformed using this method to correlated Gaussian random numbers. The correlations, \( \rho_{12}, \rho_{13}, \) and \( \rho_{23} \), were parameter values of the program. The input matrix \( E[\mathbf{x}_j \mathbf{x}_j^T] \) has to be a positive semi-definite matrix. Thus the transformation matrix, made up of correlation values and given by (5.3)

\[
\begin{bmatrix}
1 & \rho_{12} & \rho_{13} \\
\rho_{12} & 1 & \rho_{23} \\
\rho_{13} & \rho_{23} & 1
\end{bmatrix}
\] (5.3)

has to positive semi-definite. This restricts the choices of the correlation values. Once two correlation values have been chosen, the third must be selected in such a manner that the matrix is positive semi-definite.

The mean square error was approximated using (3.2) as in the two input case. Iterative estimates were used for the expected values as shown in Figure 4.5.

The theoretical minimum mean square error was defined in (4.26). Its value depends only upon the values of \( E[n_1^2], \rho_{12}, \rho_{13}, \) and \( \rho_{23} \). When the three correlations all have values of zero, the worst case is realized and
no noise can be effectively canceled. As the correlations increase in value, noise canceling occurs.

The method of comparison of the two algorithms was the same as for the two input case. Graphs of the mean square error as a function of the number of iterations were used. Twenty-five, five hundred iteration ensembles were averaged to obtain the curve that was plotted. As in the two input system, the three input system simulation curves are compared for differences in rates of convergence and minimum error after 500 iterations.

2. Performance Comparison

Following are the graphs of the mean square error as a function of the number of iterations. Each page contains graphs with the same signal-to-noise ratio and correlation values. One graph using the expected value algorithm and graphs of three values of $\mu$ for the LMS algorithm are on each page. Again all of the graphs are plotted on the same scale. The straight line effect (see Appendix C) is still observed when the value of the mean square error is too large for the boundaries of the scale. Table 5.1 gives representative values for the curves.

Figures 5.1 through 5.3 set the signal-to-noise ratio to 10.0. Each figure has a different set of correlation values. The expected value algorithm exhibits the fastest rate of convergence and the smallest error after five hundred iterations. However, graphs 5.1b and 5.2b, which are the $\mu$ values of .01 for the LMS algorithm, are very similar to those of the expected value algorithm. Thus if a "correct" $\mu$ value is chosen, the results can be close to the optimum results as estimated by the expected value algorithm. As the $\mu$ value decreases, a slower rate of convergence is evidenced and the minimum error after five hundred iterations is further from
the theoretical minimum. If two of the correlation values are small (Figure 5.3), the difference between the expected value and LMS algorithm becomes much greater.

Figures 5.4 through 5.6 lower the signal-to-noise ratio to 1.0. The same correlation values are used again. The smaller signal-to-noise ratio produces dramatic results. The expected value algorithm generates the best curves in terms of the rate of convergence and the minimum error. The \( \mu \) value of .001 for the LMS algorithm produces the only curve that can truly be compared with the expected value algorithm. Nevertheless, its rate of convergence is much slower and its minimum error is much greater. The \( \mu \) value of .01 generally produces values that are too large for the desired scale or curves that appear to converge to a large error. For this signal-to-noise ratio, the \( \mu \) value of .01 is outside the range necessary for convergence. The \( \mu \) value of .0001 has such a slow rate of convergence that the straight line effect is again observed. As the correlation decreases, this case of the LMS algorithm has an even slower rate of convergence and eventually the value of the mean square error for five hundred iterations is too large for the desired scale.

Figures 5.7 through 5.9 lower the signal-to-noise ratio to .10. Only the expected value algorithm generates curves with values small enough for the desired scale. The \( \mu \) values of .01 and .001 are outside the range for convergence of the algorithm. When \( \mu \) equals .0001, the rate of convergence is too slow for convergence within five hundred iterations and the minimum values of the curves are still too large for the scale. Although the \( \mu \) value of .00001 is not shown, the minimum value was found to be larger (for only five hundred iterations) than the case where \( \mu \) equaled .0001. Again there is a storage and graphing problem created due to the large numbers generated
by the LMS algorithm that is not present with the expected value algorithm.

3. **Summary of the Three Input System Results**

   The expected value algorithm proved to be the superior algorithm for the three input case as it was for the two input system. The rate of convergence is consistently faster and the minimum error is smaller than for any of the \( \mu \) values of the LMS algorithm that were tested. For a signal-to-noise ratio of 10.0, the LMS algorithm produces curves similar to those of the expected value algorithm. However, this occurs for only one particular \( \mu \) value since other \( \mu \) values do not produce results that are as similar. As the signal-to-noise ratio decreases, the expected value algorithm clearly produces the best results. Several \( \mu \) values also generate curves which have values too large to be plotted.

   In several cases, the expected value algorithm generated curves whose minimum values were less than the theoretical minimum values. This is probably a peculiarity of the computer simulation and the computer used. Since all of the noise was generated with the same variance, this probably contributed to the small minimum errors. This would be especially noticeable with small signal-to-noise ratios because of a higher possibility of arithmetic roundoff errors.

   The expected value algorithm is more complex in terms of the number of multiplications and divisions required to implement it. Again, the several estimate approach of the weight vector used by the expected value algorithm enables a better estimate in fewer iterations. For a three input noise canceling system, a two dimensional matrix inverse is required. Although an inverse of this size matrix is more complex than the LMS algorithm, the tradeoff in terms of performance appears to justify this added complexity.
The effect of changes in correlation is hard to ascertain because of the large number of values per curve. Generally as the correlations were lowered, the difference between performance of the two algorithms became greater. With three inputs, the signal-to-noise ratio appeared to have more of an effect on the results.

The problem with the LMS algorithm is the same as in the two input system. Values for the initial weight vectors and for $\mu$ must be chosen. It is almost impossible to determine beforehand the best values for these parameters (in terms of minimum mean square error and convergence rate). Unfortunately, unless the $\mu$ value is chosen correctly, the LMS algorithm may not converge or may have a slow rate of convergence and large errors even after five hundred iterations.
Table 5.1. Representative Values of the Curves Obtained: Three Input Noise Canceling System

Each page contains four graphs labeled a, b, c, and d. These have characteristic values given by several parameters:

- **S/N** - the signal-to-noise ratio
- **ρ_{12}** - the correlation between the noises n_1 and n_2
- **ρ_{13}** - the correlation between the noises n_1 and n_3
- **ρ_{23}** - the correlation between the noises n_2 and n_3
- **TMIN** - the theoretical minimum mean square error
- **Algorithm** - the algorithm employed—either expected value or LMS
- **μ** - the value of the parameter μ for the LMS algorithm
- **MAX** - the maximum value of the curve
- **MIN** - the minimum value of the curve

CHAPTER VI
SUMMARY AND FUTURE WORK

1. Summary

This research compares two algorithms used in noise canceling systems. The first part studies a two input noise canceling system. The expected value and LMS (least mean square) algorithms are compared in terms of their mean square error performance. The second section extends both algorithms to a three input noise canceling system. These results are then compared.

Chapter II derives the algorithms for the two input noise canceling system. The optimum weight vector is given by the Wiener-Hopf equation as explained in Chapter I. The expected value algorithm as implemented for the computer simulation is an estimate to the optimum algorithm in that the mathematical expected values are replaced with estimates. The LMS algorithm attempts to lessen the complexity involved in the matrix inversion by using gradient techniques and the method of steepest descent.

Chapter III reveals the results of the two input system computer simulation. The expected value algorithm proved superior in that it had a faster rate of convergence and lower minimum errors after five hundred iterations. The difference was especially apparent at lower signal-to-noise ratios and lower values of noise correlation. The LMS algorithm also presented problems in that values for the initial weight vector and for $\mu$ had to be chosen. Although the choice of the initial weight vector was not as
important when considering five hundred iterations, the value of \( \mu \) was extremely important. In order for the algorithm to converge, the value of the term had to be within a specified range which proved small when only five hundred iterations were considered.

The algorithms are extended to a three input noise canceling system in Chapter IV. Again the expected value algorithm is an estimate to the optimum for a minimum linear least mean square estimate. The LMS algorithm is much simpler because it does not involve a matrix inversion.

Chapter V reveals the results of the computer simulation of the three input system. The results are similar to those for the two input system. The expected value algorithm has a faster rate of convergence and smaller minimum errors. However, for several cases of correlation values, the LMS algorithm produced results that were extremely similar to those produced by the expected value algorithm. Nevertheless, this only happened for one value of \( \mu \) while the other two \( \mu \) values tested produced results that were much worse. The additional complexity of the expected value algorithm due to the matrix inverse is still justified. Unless the "correct" \( \mu \) value is chosen, the results will be much worse than the optimum.

In general, the expected value algorithm performs better than the LMS algorithm. For a noise canceling system with only two or three inputs, an estimate to the optimum method is better. With a small number of inputs, the added complexity involved in inverting the input matrix is justified in terms of performance. This added complexity in forming the weight vector is probably the reason for the better performance. Although both algorithms compute the same terms (in terms of the data), the expected value algorithm updates several estimates before combining these to form one estimate for the weight vector. The LMS algorithm, however, only forms one estimate. The several
estimate approach of the expected value algorithm produces a better estimate of the weight vector in a fewer number of iterations.

The additional problems encountered when implementing the LMS algorithm (that is, choosing values for \( \mu \) and the initial weight vector) also discourage its use. The expected value algorithm does not have these problems and its performance is better in terms of rate of convergence and minimum errors.

2. **Future Research**

This research should encourage efforts to study the tradeoffs between complexity and performance that exist in many algorithms. Often algorithms are developed for the more intricate cases of a problem. Thus while the algorithm may be the only practical way to solve the more complex problem, this is not always true when the problem is in a simpler form.

The two input noise canceling system was studied thoroughly and the expected value algorithm produced better results. The three input system needs to be studied more carefully. The relationship between changes in correlation values should be established. With variations for three correlation values, only a few were selected to study here. The importance of one correlation value with respect to the others should be ascertained. Changes in the variance between the noise inputs should also be studied.

In general, the importance of the initial weight vector of the LMS algorithm should be studied. For this research, the value was arbitrarily chosen. If less than five hundred iterations are essential, the initial weight value will be more important.

This study should also be extended to systems with more inputs to determine how large a system can be handled practically with the expected
value algorithm. Many programs today are available to invert a matrix quickly. This would enable larger systems to employ this estimate to the optimum weight vector.

This research is only a beginning, but it should encourage further research in this area. The major contribution should be the questioning of algorithms to solve simpler problems when the optimum method would produce much better results.
APPENDIX A

CONVERGENCE OF THE WEIGHT VECTOR FOR
THE LMS ALGORITHM

In order to make the comparison between the expected value and LMS algorithms valid, it is necessary that their weight vectors converge to the same value. The weight vector for the expected value algorithm is shown to be an estimate to the optimum weight vector in Section 3 of Chapter II. Therefore, it is only necessary to prove that the weight vector for the LMS algorithm converges to the optimum weight vector.

Looking first at the two input noise canceling system, the weight vector for the LMS algorithm is defined to be

\[ \mathbf{w}_{\text{LMS},j+1} = \mathbf{w}_{\text{LMS},j} + 2\mu s_j x_{2j} \quad (A.1) \]

The optimum and theoretical expected value algorithms have a weight vector given by

\[ \mathbf{w}_{\text{opt},j} = \mathbf{w}_{\text{EV},j} = \frac{E[x_1 x_{2j}]}{E[x_{2j}^2]} \quad (A.2) \]

To prove that the LMS weight vector converges to the optimum weight vector, it is essential to show that

\[ \lim_{j \to \infty} E[\mathbf{w}_{\text{LMS},j+1}] = \mathbf{w}_{\text{opt}} \quad (A.3) \]

(77)
For the two input noise canceling system,

\[ \hat{s}_j = x_{1j} - W_j x_{2j} \]  

(A.4)

Substituting (A.1) and (A.4) into (A.3) produces

\[ E[W_{\text{LMS}_{j+1}}] = E[(1 - 2\mu x_{2j}^2)W_{\text{LMS}_j} + 2\mu x_1 x_{2j}] \]  

(A.5)

Reducing the index by one, \( W_{\text{LMS}_j} \) can be written in terms of \( W_{\text{LMS}_{j-1}} \). Thus (A.5) becomes

\[ E[W_{\text{LMS}_{j+1}}] = E[(1-2\mu x_{2j}^2)(1-2\mu x_{2j-1}^2)W_{\text{LMS}_{j-1}} + (1-2\mu x_{2j}^2)(2\mu x_{1j-1} x_{2j-1}) + 2\mu x_1 x_{2j}] \]  

(A.6)

Equation (A.6) can be rewritten in terms of \( W_{\text{LMS}_0} \). Both inputs \( x_1 \) and \( x_2 \) are uncorrelated over time. Therefore, the expected value can be taken of each product in (A.6):

\[ E[W_{\text{LMS}_{j+1}}] = (1-2\mu E[x_2^2])^{j+1}W_{\text{LMS}_0} + 2\mu E[x_1 x_2][1 + (1-2\mu E[x_2^2]) + (1-2\mu E[x_2^2])^2 + \ldots + (1-2\mu E[x_2^2])^j] \]  

(A.7)

Recognizing that the second term in (A.7) is a geometric series, (A.7) can be simplified:

\[ E[W_{\text{LMS}_{j+1}}] = (1-2\mu E[x_2^2])^{j+1}W_{\text{LMS}_0} + \left[ \frac{1 - [1 - 2\mu E[x_2^2]]^{j+1}}{1 - [1 - 2\mu E[x_2^2]]} \right] 2\mu E[x_1 x_2] \]  

(A.8)

In order for (A.8) to converge, it is required that

\[ |1 - 2\mu E[x_2^2]| < 1 \]  

(A.9)

Assuming that (A.9) is true, taking the limit as \( j \) approaches infinity of both sides of (A.8) gives
This is the desired result. The weight vector for the LMS algorithm converges to the optimum weight vector when (A.9) is true.

A study of convergence was made in more detail with an arbitrary set of parameters for the two input noise canceling system. A signal-to-noise ratio of 10.0 and a correlation of .95 were used for the study. The values of \( \mu \) tested were .01, .001, .0001, and .00001. Figure A.1 shows the graphs of the mean square error versus the number of iterations for one ensemble and the above parameter values. One ensemble was graphed instead of the usual average of twenty-five ensembles to emphasize the fluctuations in the error. Looking at Figure A.1, the largest \( \mu \) value coincides with the fastest rate of convergence, but the mean square error does not steadily or smoothly decrease to a minimum value. Instead the value fluctuates considerably. The second graph with \( \mu = .001 \) exhibits the smoothest decline towards a minimum value, but the rate of convergence is slower than the curve in (a) and the mean square error still varies with a small number of iterations. Nevertheless, the mean square error in (b) has reached a smaller value after five hundred iterations than in (a). Graph (c) displays an even slower rate of convergence than (b) and graph (d) does not appear to begin to converge after five hundred iterations.

For the above parameters, the value of the optimum weight is approximately .95. Examining the value of the weight vector at each iteration reveals more about the rate of convergence towards the optimum weight vector. Although with \( \mu = .01 \), the rate of convergence is the fastest, there are large fluctuations in the value of the weight vector. Even after two thousand
iterations, the weight vector does not appear to converge, but instead fluctuates in value between -1 and +3. With $\mu = 0.001$, the rate of convergence is slower, but the weight vector exhibits fewer variations in value. The fluctuations are mainly between 0.7 and 1.7. The case with $\mu = 0.0001$ shows an even slower rate of convergence than the previous case, but the fluctuations in the values of the weight vector have almost disappeared. Inspecting the rate of convergence for two thousand iterations indicates that the weight should converge after approximately twenty-five hundred iterations. The last case studied was with $\mu = 0.00001$. The weight vector again showed almost no fluctuations in value, but instead, a steady decline towards the optimum value. Convergence based on this rate will not occur until approximately six thousand iterations.

The results of the convergence test can be extended to the three input case. Although the study is not as extensive as for the two input system, it is shown here that the weight vector for the LMS algorithm converges to the optimum weight vector. It was shown in Section 2 of Chapter IV that the weight vector for the expected value algorithm is an estimate to the optimum weight vector.

The weight vector for the LMS algorithm can be written in vector form:

$$W_{LMS_{j+1}} = W_{LMS_j} + 2\mu s_j x_j$$  \hspace{1cm} (A.11)

or

$$\begin{bmatrix} W_2_{LMS_{j+1}} \\ W_3_{LMS_{j+1}} \end{bmatrix} = \begin{bmatrix} W_2_{LMS_j} \\ W_3_{LMS_j} \end{bmatrix} + 2\mu s_j \begin{bmatrix} x_2_j \\ x_3_j \end{bmatrix}$$  \hspace{1cm} (A.12)

It is necessary that
The optimum weight vector is given by (4.17) and is

\[ \mathbf{W}_{\text{opt}} = \mathbf{X}_x^{-1} \mathbf{X}_1 \mathbf{X} \]  \hspace{1cm} (A.14)

or

\[ \mathbf{W}_{\text{opt}} = \begin{bmatrix} E[\mathbf{x}_2 \mathbf{x}_2] & E[\mathbf{x}_2 \mathbf{x}_3] \\ E[\mathbf{x}_2 \mathbf{x}_3] & E[\mathbf{x}_3 \mathbf{x}_3] \end{bmatrix} \begin{bmatrix} E[\mathbf{x}_1 \mathbf{x}_2] \\ E[\mathbf{x}_1 \mathbf{x}_3] \end{bmatrix} \]  \hspace{1cm} (A.15)

Taking the expected value of both sides of (A.11) gives

\[ E[\mathbf{W}_{\text{LMS}}_{j+1}] = E[\mathbf{W}_{\text{LMS}}_j + 2\mu \mathbf{x}_j] \]  \hspace{1cm} (A.16)

Substituting for \( \hat{x}_j \) in (A.16) yields

\[ E[\mathbf{W}_{\text{LMS}}_{j+1}] = E[2\mu \mathbf{x}_j \mathbf{x}_j + \mathbf{W}_{\text{LMS}}_j [1 - 2\mu \mathbf{x}_j^T \mathbf{x}_j]] \]  \hspace{1cm} (A.17)

Equation (A.17) can be rewritten in terms of the \( (j-1) \)st iteration:

\[ E[\mathbf{W}_{\text{LMS}}_{j+1}] = E[2\mu \mathbf{x}_j \mathbf{x}_j + 2\mu \mathbf{x}_j \mathbf{x}_{j-1} (1 - 2\mu \mathbf{x}_j^T \mathbf{x}_j) \]

\[ + \mathbf{W}_{\text{LMS}}_{j-1} (1 - 2\mu \mathbf{x}_{j-1}^T \mathbf{x}_{j-1})(1 - 2\mu \mathbf{x}_j^T \mathbf{x}_j)] \]  \hspace{1cm} (A.18)

Equation (A.18) can also be written in terms of \( \mathbf{W}_{\text{LMS}}_0 \) and the expected value can be taken of each term. Thus

\[ E[\mathbf{W}_{\text{LMS}}_{j+1}] = W_0 (1 - 2\mu E[\mathbf{x}_j^T \mathbf{x}_j])^j + 2\mu E[\mathbf{x}_1 \mathbf{x}_j] [1 + (1 - 2\mu E[\mathbf{x}_j^T \mathbf{x}_j]) + ... + (1 - 2\mu E[\mathbf{x}_j^T \mathbf{x}_j])^j] \]  \hspace{1cm} (A.19)

Recognizing that (A.19) contains a geometric series which will converge when

\[ |1 - 2\mu E[\mathbf{x}_j^T \mathbf{x}_j]| < 1 \]  \hspace{1cm} (A.20)

(A.19) can be written in a simpler form:
\[ E[W_{\text{LMS}_{j+1}}] = W_0(1-2\mu E[x^T x])^{j+1} + 2\mu E[x_1 x] \frac{1-(1-2\mu E[x^T x])^{j+1}}{1-(1-2\mu E[x^T x])} \]  \hspace{1cm} (A.21)

Thus when (A.20) holds, the series will converge. Taking the limit of both sides of (A.21) produces

\[ \lim_{j \to \infty} E[W_{\text{LMS}_{j+1}}] = (E[x^T x])^{-1} E[x_1 x] \]  \hspace{1cm} (A.22)

This is the desired result. Thus the weight vector of the LMS algorithm does in fact converge to the optimum weight vector for both the two and three input noise canceling systems.
Figure A.1. Convergence Test of the LMS Algorithm for the Two Input System.

$S/N = 10.0$ and $\rho_{12} = .95$.

(a) $\mu = .01$.
(b) $\mu = .001$.
(c) $\mu = .0001$.
(d) $\mu = .00001$. 
APPENDIX B
NOISE GENERATION FOR THE THREE INPUT NOISE CANCELING SYSTEM

The computer simulation requires three correlated Gaussian random numbers for the noise components to the three input noise canceling system. An unpublished paper by Charles S. Liu, University of Michigan-Dearborn, develops a technique to transform a n-dimensional vector of independent Gaussian random numbers to correlated Gaussian random numbers. The method will be summarized here.

Let \( \mathbf{Z}^T = [Z_1, Z_2, \ldots, Z_n] \) be an n-dimensional random vector whose elements are independent Gaussian random numbers with zero mean and unit variance. The vector \( \mathbf{Z} \) may be transformed such that it contains new random variables:

\[
\mathbf{Z'} = \mathbf{PZ}
\]  

(B.1)

where \( \mathbf{P} \) is an n \times n transformation matrix specified by the covariance matrix of \( \mathbf{Z'} \):

\[
\mathbf{Q} = \mathbb{E}[\mathbf{Z'Z'}^T]
\]

\[
\mathbf{Q} = \mathbf{PP}^T
\]  

(B.2)

The transformation \( \mathbf{Z'} = \mathbf{PZ} \) is not unique since there are an infinite number of matrices which satisfy (B.2). Since the covariance matrix is real

(84)
symmetric, the eigenvectors, \( \{Y_i\} \) of \( Q \) are orthogonal. Thus \( Q \) can be diagonalized as shown:

\[
\begin{bmatrix}
Y_1, Y_2, \ldots, Y_n
\end{bmatrix}^T Q \begin{bmatrix}
Y_1, Y_2, \ldots, Y_n
\end{bmatrix} = \begin{bmatrix}
\lambda_1 & 0 \\
0 & \lambda_2 \\
& \ddots \\
& & \lambda_n
\end{bmatrix}
\]

(B.3)

If (B.3) is premultiplied by \( \begin{bmatrix} Y_1, Y_2, \ldots, Y_n \end{bmatrix} \) and postmultiplied by \( \begin{bmatrix} Y_1, Y_2, \ldots, Y_n \end{bmatrix}^T \), then

\[
\begin{bmatrix}
Y_1, Y_2, \ldots, Y_n
\end{bmatrix} \begin{bmatrix}
\lambda_1 & 0 \\
0 & \lambda_2 \\
& \ddots \\
& & \lambda_n
\end{bmatrix} \begin{bmatrix}
Y_1, Y_2, \ldots, Y_n
\end{bmatrix}^T = Q
\]

(B.4)

Thus \( Q \) can be rewritten using (B.4) so that

\[
Q = \begin{bmatrix}
\sqrt{\lambda_1} & \sqrt{\lambda_2} & \cdots & \sqrt{\lambda_n}
\end{bmatrix} \begin{bmatrix}
\sqrt{\lambda_1} & 0 \\
0 & \sqrt{\lambda_2} \\
& \ddots \\
& & \sqrt{\lambda_n}
\end{bmatrix} \begin{bmatrix}
Y_1, Y_2, \ldots, Y_n
\end{bmatrix}^T
\]

(B.5)

Recognizing that (B.5) is of the same form as (B.2), the transformation matrix \( P \) can be defined as

\[
P = \begin{bmatrix}
\sqrt{\lambda_1} \\
\sqrt{\lambda_2} \\
& \ddots \\
& & \sqrt{\lambda_n}
\end{bmatrix}
\]

(B.6)

Therefore the eigenvalues and eigenvectors of the covariance matrix determine the transformation matrix necessary to obtain correlated Gaussian
random numbers from independent ones. That transformation is defined by (8.1) where $P$, the transformation matrix, is given by (8.6).
APPENDIX C
STRAIGHT LINE EFFECT OF GRAPHS

In order to make the comparison between the algorithms clearer and more apparent, it was desirable to plot all of the mean square error curves using the same graph scale. The graphs were produced on a computer screen of limited size. When the values were too large to be within the range of the scale, the curve was plotted as a straight line at the top of the screen. Although the straight line section of the curve tends to imply that the curve has a constant value over this range, this is not the case. Figure C.1 shows this effect by rescaling one graph so that the entire curve lies within the boundaries of the scale. This is done using the maximum and minimum values of the curve as the maximum and minimum points of the scale. If a graph is replaced by the statement that the minimum error is too large for the scale, this means that for five hundred iterations the error is always greater than 140.
Figure C.1. Straight Line Effect (Two Input System).
S/N = 1.0 and $\rho_{12} = .95$.
(a) LMS algorithm, $\mu = .0001$, normal scale
(b) LMS algorithm, $\mu = .0001$, rescaled.
APPENDIX D

COMPUTER SIMULATION PROGRAMS

A. Two Input Noise Canceling System

Purpose:

The computer simulation was the basis of comparison between the expected value and LMS algorithms. The equations given for the algorithms in Figures 2.12 and 2.13 were implemented on a PDP-11/45 at Duke University. The mean square error was computed and plotted as a function of the number of iterations.

Specifications:

The specifications of the problem were described in Section 1 of Chapter III and they are summarized here.

1. The signal is a dc signal with value 10.0.

2. The noise was generated using the computer's uniformly distributed random number generator and transforming to zero mean Gaussian random numbers with the Box-Muller equations.

3. The initial weight vector, W(1), for the LMS algorithm was set equal to 5.0.

4. The mean square error was computed using an iterative estimate:
The mean square error is computed for 500 iterations to produce one ensemble curve. Twenty-five ensembles are averaged point by point and this curve is plotted as a function of the number of iterations.

**Program Structure:**

A separate program is employed for each algorithm. The program ESTSIG implements the expected value algorithm and the program ANEST implements the LMS algorithm. Each program is divided into two main parts. One part generates the noise, computes the weight vector, and determines the mean square error. The other part averages the ensembles and plots the result. Figures 0.1 and 0.2 show the structure of the programs.

**Program Segment Descriptions**

1. **ESTSIG** -- Main program to implement the expected value algorithm and compute the mean square error; calls subroutines CGAUSS and PLOTIT.

   **INPUTS:**
   - RO -- correlation $\rho_{12}$ between the two noises
   - XVAR -- variance of the noise $n_1$; $E[n_1^2]$
   - YVAR -- variance of the noise $n_2$; $E[n_2^2]$

   **OUTPUTS:** plot of the mean square error as a function of the number of iterations.

2. **ANEST** -- Main program to implement the LMS algorithm and compute the mean square error; calls subroutines CGAUSS and PLOTIT.
INPUTS: C -- term which determines the rate of convergence.
RO -- correlation $\rho_{12}$ between the two noises.
XVAR -- variance of the noise $n_1$; $E[n_1^2]$.
YVAR -- variance of the noise $n_2$; $E[n_2^2]$.

OUTPUTS: plot of the mean square error as a function of the number of iterations.

3. CGAUSS (I1,I2,RO,X,Y) -- generates a pair of zero mean Gaussian random numbers using the Box-Muller equations to transform two uniformly distributed random numbers; calls library uniformly distributed random number generator RANDU.

INPUTS: I1 -- seed number
RO -- desired correlation $\rho_{12}$ between the pair of numbers.
XVAR -- desired variance $E[n_1^2]$ through COMMON statement.
YVAR -- desired variance $E[n_2^2]$ through COMMON statement.

OUTPUTS: X -- zero mean Gaussian random number
Y -- zero mean Gaussian random number
I2 -- seed number.

4. PLOTIT (X,NP,NV,NS) -- plots mean square error as a function of the number of iterations; calls library plotting subroutine TEKPLT.

INPUTS: X -- matrix where each row is a vector of points to be plotted so that up to five curves can be plotted on the same graph; can also be entered as a vector if only one curve is to be plotted.
NP -- number of points within each vector for plotting.
NV — number of variables or curves to be plotted on the same graph.

NS — scaling determinant; value of zero allows programmer to scale while value of one provides automatic scaling.

OUTPUTS: plot of vectors entered as a function of the number of points within the vector.

B. Three Input Noise Canceling System

Purpose:
This computer simulation extends the two input system in order to further compare the two algorithms. The equations for the two algorithms are given in Figures 4.4 and 4.5. These were implemented on the PDP-11/45 computer at Duke University. The mean square error was plotted as a function of the number of iterations.

Specifications:
The specifications for the problem were described in Section 1 of Chapter V and are summarized here.

1. The signal is a dc signal with value 10.0.
2. The noise was generated with a method developed by Charles Liu and described in Appendix B. Independent Gaussian random numbers are transformed to correlated ones using this method.
3. The initial weights for the LMS algorithm were set to arbitrary values: $W_2(1) = 5.0$ and $W_3(1) = 3.0$.
4. The mean square error was computed using an iterative estimate:
Figure D.1. Computer Program Structure Diagram for the Two Input Noise Canceling System with the Expected Value Algorithm.

Program Structure

A separate program is utilized for each algorithm. The programs ESTSI2 and ANEST2 implement the expected value and LMS algorithms, respectively. Each program is divided into three main parts. The first part finds the eigenvalues and eigenvectors of the input correlation matrix so that correlated Gaussian random variables can be generated. The second section generates the noise, computes the weight vector, and calculates the mean square error. The third section averages the ensemble curves and plots the resulting curve. Figures D.3 and D.4 show the structure of the programs.

Program Segment Descriptions

1. ESTSI2 -- Main program to implement the expected value algorithm and compute the mean square error; calls subroutines JACOBI, GAUSS3, and PLOTIT.
   
   INPUTS: VARNI -- variance of the noise $n_1$; $E[n_1^2]$.
   
   OUTPUTS: plot of the mean square error as a function of the number of iterations.

2. ANEST2 -- Main program to implement the LMS algorithm and compute the mean square error; calls subroutines JACOBI, GAUSS3, and PLOTIT.

\[ E[\sum_{j=1}^{J} (s_j - s_j)^2] = \frac{\sum_{i=1}^{J} (s_i - s_i)^2}{J} \]
INPUTS:  
VARNI -- variance of the noise \( n_1 \); \( \text{E}[n_1^2] \).
CMU -- rate of convergence term, \( \mu \).

OUTPUTS:  
plot of the mean square error as a function of the number of iterations.

3. JACOBI(T, EIGEN, R012, R013, R023)

-- subroutine to compute the eigenvalues and eigenvectors of a symmetric matrix. This program is a variation of the one listed in Applied Numerical Methods. It is used to transform independent Gaussian random numbers to correlated ones.

INPUTS:  
\( A(1,2) \) -- correlation, \( \rho_{12} \), between the noises \( n_1 \) and \( n_2 \).
\( A(1,3) \) -- correlation, \( \rho_{13} \), between the noises \( n_1 \) and \( n_3 \).
\( A(2,3) \) -- correlation, \( \rho_{23} \), between the noises \( n_2 \) and \( n_3 \).

OUTPUTS:  
\( T \) -- matrix where each column is an eigenvector.
EIGEN -- vector of eigenvalues
R012 -- correlation, \( \rho_{12} \), between the noises \( n_1 \) and \( n_2 \).
R013 -- correlation, \( \rho_{13} \), between the noises \( n_1 \) and \( n_3 \).
R023 -- correlation, \( \rho_{23} \), between the noises \( n_2 \) and \( n_3 \).
list of the elements of the input matrix, \( A \).

4. GAUSS3 (IX, S, AM, F) -- subroutine to generate three independent Gaussian random numbers; calls GAUSS.

INPUTS:  
IX -- seed number
S -- standard deviation of the variance of each random number; \( \sqrt{\text{E}[n_1^2]} \).
AM -- desired mean of the generated Gaussian random numbers.
5. **GAUSS (IX, S, AM, V)** -- scientific subroutine package program to generate one independent Gaussian random number; calls library subroutine RANDU.

**INPUTS:**
- **IX** -- seed number
- **S** -- standard deviation of the desired random number.
- **AM** -- desired mean of the random number.

**OUTPUTS:**
- **V** -- Gaussian random number generated.

6. **PLOTIT (X, NP, NV, NS)** -- plots mean squares error as a function of the number of iterations; calls library plotting subroutine TEKPLT.

**INPUTS:**
- **X** -- matrix where each row is a vector of points to be plotted so that up to five curves can be plotted on the same graph; can also be entered as a vector if only one curve is to be plotted.
- **NP** -- number of points within each vector to be plotted.
- **NV** -- number of variables or curves to be plotted on the same graph.
- **NS** -- scaling determinant; value of zero allows programmer to scale while value of one provides automatic scaling.

**OUTPUTS:** plot of vectors entered as function of the number of points within the vector.

Huffman, Steven D., 1976. Private communications.

The purpose of this study is to compare two noise canceling system algorithms when the system has a small number of inputs. The expected value and LMS (least mean square) algorithms attempt through different methods to determine the optimum solution given by the Wiener-Hopf weight vector. The expected value algorithm estimates the necessary expected values, substitutes them into the Wiener-Hopf equation, and performs the necessary matrix inversion. The LMS algorithm uses gradient techniques and the method of steepest descent to avoid the complexity of the matrix inversion. The algorithms are compared for two and three input systems in terms of the rate of convergence of the mean square error and the minimum error after five hundred iterations.

A computer simulation of a dc signal in Gaussian noise provided the comparison between the two algorithms. The LMS algorithm presented problems in implementation because of two parameter values that had to be chosen. Although a value for the initial weights had to be determined, this value was not as important as was the value of \( \mu \), the term that controls the rate of convergence. This term must be within a specific range in order to guarantee convergence of the algorithm.

In conclusion, the expected value algorithm was judged to be the better of the two. The tradeoff in terms of performance for simplicity in the LMS algorithm was great especially when the signal-to-noise ratio or the correlation between the noises was small. If a "correct" value of \( \mu \) is chosen, the results may be similar, but if not, the results can be extremely different from those of the expected value algorithm. Thus for a small number of inputs, where the matrix to be inverted is of small dimension, it is better in terms of performance to use the approximation to the optimum solution given by the expected value algorithm.
