ON THE IONOSPHERIC PARAMETERS WHICH GOVERN HIGH LATITUDE ELF PROPAGATION IN THE EARTHI
IONOSPHERE WAVEGUIDE

Carl Greifinger
Phyllis Greifinger

A simple approximate expression for the complex propagation constant emerges from the solution. The propagation constant depends on four parameters, two altitudes and a scale height associated with each altitude. The lower altitude is the height at which the conduction current parallel to the magnetic field becomes equal to the displacement current. The associated scale height is the local scale height of
the parallel conductivity. Under daytime ionospheric conditions, the upper altitude is the height at which the local wave number becomes equal to the reciprocal of the local scale height of the refractive index. The associated scale height is the local scale height of the refractive index. Under the simplest nighttime conditions, the second set of parameters is replaced by the altitude of the E-region bottom and the local wave number just inside the E-region. The relative phase velocity depends, in first approximation, only on the ratio of the two altitudes. The attenuation rate depends on the other two parameters, as well. The two principal attenuation mechanisms are Joule heating by longitudinal currents in the vicinity of the lower altitude and energy leakage of the whistler component of the ELF wave at the upper altitude.
PREFACE

The authors are indebted to Dr. William F. Moler of Naval Ocean Systems Center for providing full-wave calculations for comparison with our approximate results.

SECTION 1. INTRODUCTION

In a recent paper (Greifinger and Greifinger [1978], hereinafter referred to as I), the authors derived an approximate expression for the complex propagation constant for ELF propagation in the Earth-ionosphere waveguide. The theory was developed for an ionosphere that was sufficiently disturbed that there was no significant penetration of the electromagnetic field to altitudes where anisotropy due to the Earth's magnetic field had to be taken into account. It was shown that the propagation constant is determined by four parameters, two frequency-dependent altitudes and the local conductivity scale heights at those altitudes. The lower altitude, denoted by $h_0$, is where the conduction current becomes equal to the displacement current, and the higher altitude, denoted by $h_1$, is where the local reciprocal wave number becomes equal to the local scale height of the refractive index. There is a Joule heating maximum at $h_0$ arising from predominantly vertical currents, and a secondary maximum in the vicinity of $h_1$ arising from predominantly horizontal currents. At altitudes in the vicinity of and below $h_0$, the electric field is predominantly vertical, and energy flow in the waveguide is in the horizontal direction. Within a few scale heights above $h_0$, the electric field becomes horizontally polarized, and energy flow is vertical.

In this paper, the theory developed in I is extended to include the effects of anisotropy. For the sake of mathematical simplicity, it is assumed that the Earth's field is vertical, which limits the validity of the theory, strictly speaking, to high magnetic latitudes. The generalization to arbitrary dip angle is straightforward, though somewhat tedious. It turns out, however, that there is no significant dependence of the propagation constant on magnetic latitude except very
close to the magnetic equator, so the results have a rather large geographic range of applicability.

When anisotropy is included, the parameters which determine the propagation constant differ for daytime and nighttime ionospheric conditions. In both cases, two parameters which enter are the frequency-dependent altitude $h_0$ at which the conduction current parallel to the magnetic field becomes equal to the displacement current, and the local scale height of the parallel conductivity $\sigma_0$. Under daytime conditions, two additional pairs of altitudes (frequency-dependent) and scale heights appear as parameters. One pair is the altitude at which the local reciprocal wave number for vertically propagating $O$ waves becomes equal to the local scale height of the refractive index, and the scale height of this refractive index. The other pair are the corresponding quantities for vertically propagating $X$ (whistler) waves. It is assumed in this paper that these altitudes are attained in a region of the ionosphere where $|\sigma_H| >> |\sigma_P|$, $\sigma_H$ being the Hall conductivity and $\sigma_P$ the Pedersen conductivity. Under these conditions, which apply over a substantial altitude range, the two pairs of parameters become identical and the analysis is somewhat simpler. The vicinity of the single altitude $h_1$ is in this case a region of reflection, rather than of significant heating, as was the case for the isotropic ionosphere. The $O$ wave undergoes nearly total reflection at this altitude, but some of the $X$ wave energy leaks out of the waveguide, thereby contributing to the attenuation.

For typical nighttime conditions, a sharp reflecting $E$-region bottom may be encountered before the local reciprocal wave number becomes equal to the local scale height. Under such circumstances, the altitude of the $E$-region bottom replaces
As in I, the approximate propagation constants are given by simple algebraic expressions involving the various parameters. Numerical results have been obtained for a hypothetical daytime ionospheric profile in which the electron density is assumed to increase exponentially with altitude and the electron collision frequency to decrease exponentially with altitude. The results are in excellent agreement with full-wave calculations for the same profile which were carried out by Dr. William Moler of Naval Ocean Systems Center. The agreement lends support to the physical assumptions on which the theory is based.

Booker and Lefeuvre (1977) have also proposed a method for the calculation of approximate ELF propagation constants in the anisotropic Earth-ionosphere waveguide. The method is based on a simplified model of the waveguide in which the ionosphere is cut off discontinuously at a frequency-dependent level and abolished below this level. The altitude at which the ionosphere is truncated corresponds very closely to the altitude $h_1$, and their treatment of the fields above this level is quite similar to ours. In their formulation, the region around $h_0$, which plays a unique and important role in our theory, is treated as part of the vacuum. This results in a predicted phase velocity which is in general significantly higher than that obtained from our theory. They attempt to account for the attenuation due to Joule heating at levels below their truncated ionosphere, but do so in a manner which may seriously overestimate the size of the effect, especially at the low end of the ELF band.
SECTION 2. BASIC EQUATIONS

It will be assumed that the Earth-ionosphere waveguide is horizontally stratified and, as discussed in the Introduction, that the geomagnetic field is in the vertical (z) direction. The equations governing electromagnetic propagation in the anisotropic waveguide are, of course, Maxwell's equations

\[ \nabla \times \mathbf{E} = \imath \omega \mathbf{B} \]

\[ \nabla \times \mathbf{B} = \mu_0 \mathbf{j} - \frac{\imath \omega}{c^2} \mathbf{E}, \]

where we have assumed a time dependence \( e^{-\imath \omega t} \), and the generalized Ohm's law

\[ \mathbf{j} = \sigma_o (\mathbf{E} \cdot \mathbf{\hat{z}}) \mathbf{\hat{z}} + \sigma_p [\mathbf{E} - (\mathbf{E} \cdot \mathbf{\hat{z}}) \mathbf{\hat{z}}] + \sigma_h (\mathbf{E} \times \mathbf{\hat{z}}), \]

where \( \mathbf{\hat{z}} \) is a unit vector in the z direction and \( \sigma_o, \sigma_p, \) and \( \sigma_h \) are the parallel, Pedersen, and Hall conductivities, respectively. The fields can be written in terms of the customary potentials as

\[ \mathbf{B} = \nabla \times \mathbf{A} \]

\[ \mathbf{E} = \nabla \psi + \imath \omega \mathbf{A}. \]

Combining Eq. (4) with the time derivative of Eq. (2), we obtain

\[ \imath \omega [\nabla (\nabla \cdot \mathbf{A}) - \nabla^2 \mathbf{A}] - \imath \mu \omega \mathbf{j} - k^2 \mathbf{E} = 0. \]
The modal solutions of this equation are obtained by a separation of variables. The rectangular components of \( \mathbf{A} \) and the potential \( \psi \) satisfy a two-dimensional wave equation

\[
(\nabla_1^2 + k^2 S^2) F = 0 ,
\]

where \( \nabla_1^2 \) is the Laplacian operator in the horizontal plane and \( kS \) is the (complex) horizontal propagation constant for the mode.

At ELF, only the lowest mode is non-evanescent in the Earth-ionosphere waveguide. In the absence of anisotropy, this is a TM mode which is derivable from a vector potential with only a vertical component \( A_z \). When anisotropy is included, the lowest mode acquires a TE component, which requires a horizontal component of the vector potential. It will be shown that all the boundary conditions can be satisfied by a vector potential of the form

\[
\mathbf{A} = A_z \mathbf{\hat{e}}_z - \frac{1}{(i\omega)} \nabla \times (u \mathbf{\hat{e}}_z) ,
\]

where \( u \) is a scalar function.

The various relations above may now be incorporated into Eq. (6) to obtain a set of coupled equations for the system. The vertical component of Eq. (6) becomes

\[
\frac{\partial \psi}{\partial z} = -i \omega A_z \left[ 1 - \frac{\varepsilon_0 \sigma}{\varepsilon_0 \omega} \right] ,
\]

while the horizontal component becomes
(\mathbf{\hat{e}_z} \times \mathbf{\hat{v}}) [v^2 u + (i\mu_0 \omega_p + k^2)u - i\mu_0 \omega_H \psi]$

\begin{equation}
- \hat{\mathbf{v}} \cdot \mathbf{A} - (i\mu_0 \omega_p + k^2)\psi - i\mu_0 \omega_H u = 0 .
\end{equation}

(10)

A gauge condition remains to be specified. A convenient choice is clearly

\begin{equation}
i\omega \hat{\mathbf{v}} \cdot \mathbf{A} = (i\mu_0 \omega_p + k^2)\psi + i\mu_0 \omega_H u ,
\end{equation}

(11)

which removes the terms involving \( \hat{\mathbf{v}} \) from Eq. (10). The contents of the first brackets must then also vanish, which gives

\begin{equation}
\frac{\partial^2 u}{\partial z^2} = -[i\mu_0 \omega_p k^2 (1 - S^2)]u + i\mu_0 \omega_H \psi .
\end{equation}

(12)

The basic equations are (9), (11), and (12), in which \( S \) appears as an eigenvalue parameter. The eigenvalue is determined by solving these coupled equations with appropriate boundary conditions at the ground and at large altitudes. An approximate method for determining the eigenvalue, similar to that developed in I, will be presented below. The method consists of constructing two approximate analytic solutions of the equations. One solution obeys the proper boundary conditions at the ground and is valid up to an altitude a few scale heights above \( h_o \). The other obeys the proper boundary conditions at large altitudes and is valid down to an altitude a few scale heights below \( h_1 \). There is a common altitude region where both solutions are valid. The eigenvalue is determined by requiring that the leading terms of the two solutions agree in the overlap region.
SECTION 3. APPROXIMATE SOLUTIONS AND EIGENVALUES

3.1 VACUUM AND LOWER IONOSPHERE

The conductivities of the medium are increasing functions of altitude. As in I, we define a frequency-dependent altitude \( h_0 \) at which the parallel conduction current becomes equal to the displacement current. Between the ground and a few conductivity scale heights above \( h_0 \), the right-hand sides of Eq. (11) and (12) are very small, and these equations become approximately

\[
\frac{\partial A_z}{\partial z} = 0 \quad (13)
\]

\[
\frac{\partial^2 u}{\partial z^2} = 0 \quad . \quad (14)
\]

At ELF, the ground may be considered as perfectly conducting, and the appropriate boundary condition is therefore \( E_{x,y}(0) = 0 \). This in turn requires \( \psi(0) = u(0) = 0 \). The solution of Eqs. (9), (13), and (14) satisfying these boundary conditions is

\[
A_z = A_0 \ \text{(constant)} \quad (15)
\]

\[
u = \beta z \quad (16)
\]

\[
\psi = -i \omega A_0 \left[ z - \frac{1}{2} \int_0^z \frac{dz}{\varepsilon_o(1 + \sigma_0 \varepsilon_o \omega)} \right] \quad (17)
\]
The integrand in Eq. (17) is essentially unity up to a conductivity scale height or so below $h_0$ and becomes very small a few scale heights above this altitude. It is therefore necessary to represent $\sigma_0$ accurately only in the neighborhood of $h_0$, where a simple exponential provides a very good approximation. Thus, we write

$$\sigma_0 = \varepsilon_0 \omega e^{(z-h_0)/\zeta_0},$$

where $\zeta_0$ is the local scale height at $h_0$. The integral in Eq. (17) can now be evaluated, giving

$$\psi = -i\omega A_o \left( z - S^2 \left[ h_0 - \frac{i\pi}{2} \zeta_0 - \zeta_0 \ln \left( 1 - i e^{(h_0-z)/\zeta_0} \right) \right] \right)$$

(19)

The constant $\beta$ and the eigenvalue $S$ remain to be determined.

3.2 MIDDLE AND UPPER IONOSPHERE

A few scale heights above $h_0$, the parallel current becomes much larger than the displacement current, and Eq. (9) becomes approximately

$$\frac{\partial \psi}{\partial z} + i\omega A_z = 0$$

(20)

The left-hand side of Eq. (20) is exactly the vertical component of the electric field, which thus becomes very small somewhat above $h_0$. The electric field thus undergoes an important transition from vertical to horizontal polarization in the region around $h_0$. 
At the altitudes in question, the Pedersen and Hall currents are also much larger than the displacement current, so that the terms proportional to $k^2$ in Eqs. (11) and (12) may be neglected (a QL approximation). These equations therefore become

$$\frac{\partial^2 \psi}{\partial z^2} + i\mu_0 \omega \sigma_p \psi + i\mu_0 \omega \sigma_H u = 0$$  \hspace{1cm} (21)

$$\frac{\partial^2 u}{\partial z^2} + i\mu_0 \omega \sigma_p u - i\mu_0 \omega \sigma_H \psi = 0$$  \hspace{1cm} (22)

where $A_z$ has been eliminated by use of Eq. (20).

If we introduce as variables

$$\psi_\pm = \psi \pm iu$$  \hspace{1cm} (23)

we obtain the two uncoupled wave equations

$$\frac{\partial^2 \psi_\pm}{\partial z^2} + n_\pm^2 k^2 \psi_\pm = 0$$  \hspace{1cm} (24)

where

$$n_\pm^2 = \frac{1}{\varepsilon_0 \omega} (i\sigma_p \pm \sigma_H)$$  \hspace{1cm} (25)

The upper sign corresponds to vertical $\phi$ wave propagation and the lower sign to vertical $X$ wave (whistler) propagation. These equations must be solved subject to the radiation boundary condition at large altitudes.
3.2.1 Daytime Ionospheric Conditions

Following the procedure of I, we will construct an approximate solution of the upper ionosphere equations which satisfies the boundary condition at large altitudes and which has a common region of validity with the lower ionosphere solution. This involves the introduction of the altitude $h_1$, at which the local wave number $|n|k$ is equal to the reciprocal of the refractive index scale height. Under highly disturbed daytime conditions, this occurs at an altitude where the ionosphere is nearly isotropic, i.e., where

$$n_+^2 \approx n_-^2 = \frac{i\sigma}{\varepsilon_0 \omega} \quad (26)$$

This was the case treated in I, for which the eigenvalue was shown to be

$$s^2 = \frac{(h_1 + i\pi \zeta_1)}{(h_0 - i\pi \zeta_0)} \quad (27)$$

where $\zeta_1$ is the conductivity scale height at the altitude $h_1$. The altitudes $h_0$ and $h_1$ were shown to be locations of maximum Joule heating, the lower altitude maximum being associated with vertical currents and the higher altitude maximum with horizontal currents. There was no significant field penetration much above the altitude $h_1$.

Under normal daytime conditions, and over most of the ELF band, the altitude $h_1$ occurs where $|\sigma_H| >> |\sigma_p|$, i.e., where

$$n_+^2 \approx -n_-^2 = \frac{\sigma_H}{\varepsilon_0 \omega} = -n^2 \quad (28)$$
In the vicinity of $h_1$, we may approximate the index of refraction by an exponential with a scale height appropriate to that altitude. Thus we write

$$n^2 = n_1^2 \frac{(z-h_1)/\zeta_1}{\tanh (z-h_1)/\zeta_1}$$  \hspace{1cm} (29)$$

where $h_1$ is defined as the frequency-dependent altitude at which

$$2|n_1|k\zeta_1 = 1 .$$  \hspace{1cm} (30)$$

(The scale height for the refractive index has been taken as $2\zeta_1$ for consistency with the theory for the isotropic ionosphere.)

Since the imaginary part of $\sigma_H$ is very small, the quantity $n_1$ is nearly real. The outgoing wave solutions of Eq. (24) are then

$$\psi_+ = a \gamma H_o^{(1)} (iy)$$  \hspace{1cm} (31)$$

$$\psi_- = \gamma a H_o^{(1)} (y)$$  \hspace{1cm} (32)$$

$$y = e^{(z-h_1)/2\zeta_1}$$  \hspace{1cm} (33)$$

where $a$ and $\gamma$ are constants to be determined. The potential functions $\psi$ and $u$, as determined from Eq. (23), are

$$\psi = \frac{a}{\pi} \left[ H_o^{(1)} (iy) + \gamma H_o^{(1)} (y) \right]$$  \hspace{1cm} (34)$$

$$u = \frac{a}{2i} \left[ H_o^{(1)} (iy) - \gamma H_o^{(1)} (y) \right].$$  \hspace{1cm} (35)$$
The potentials given by Eqs. (34) and (35) must agree with Eqs. (16) and (19), respectively, in the altitude range $h_0 << z << h_1$, where both approximations are valid. In this altitude range, $|y| << 1$ and the Hankel functions may be approximated by their small argument expansions. The leading terms give

\[ U = \frac{a}{2\pi i \zeta_1} [(1 + \gamma)(z - h_1) + i\pi \gamma \zeta_1] \quad (36a) \]

\[ \psi = \frac{ia}{2\pi i \zeta_1} [(1 - \gamma)(z - h_1) - i\pi \gamma \zeta_1] \]

\[(h_0 << z << h_1) . \quad (36b)\]

Matching these functions to the leading terms of the lower ionosphere solutions in the same altitude range, we obtain

\[ \gamma = \frac{h_1}{h_1 + i\pi \zeta_1} \quad (37) \]

\[ S^2 = \frac{h_1(h_1 + i\pi \zeta_1)}{(h_0 - i\pi \zeta_0)(h_1 + i\pi \zeta_1)} . \quad (38) \]

Although this completes the derivation of the approximate eigenvalue, there are two additional relationships which exist among the three remaining undetermined constants. These are

\[ \frac{a}{\Lambda_0} = -2\pi \omega \frac{\zeta_1(h_1 + i\pi \zeta_1)}{(2h_1 + i\pi \zeta_1)} \quad (39) \]
\[
\frac{\beta}{A_0} = -i\pi\omega \frac{\zeta_1}{(2h_1 + i\pi\zeta_1)} ,
\]

with \(A_0\) remaining as an arbitrary normalization factor. An approximate analytic solution has thus been obtained not only for the eigenvalue, but for the height dependence of the various field components as well.

The approximate eigenvalue given by Eq. (38) is slightly different from its counterpart for the isotropic ionosphere given by Eq. (27). However, since \(\zeta_0/h_0 \ll 1\) and \(\zeta_1/h_1 \ll 1\), both eigenvalues are to first approximation

\[
S \approx \left(\frac{h_1}{h_0}\right)^{1/2} \left[1 + \frac{i\pi}{4} \left(\frac{\zeta_0}{h_0} + \frac{\zeta_1}{h_1}\right)\right] .
\]

The relative phase velocity is thus approximately

\[
\frac{\nu}{c} \approx \left(\frac{h_0}{h_1}\right)^{1/2} ,
\]

and the horizontal attenuation rate in decibels per megameter is approximately

\[
\alpha \approx .143 f \left(\frac{h_1}{h_0}\right)^{1/2} \left(\frac{\zeta_0}{h_0} + \frac{\zeta_1}{h_1}\right) ,
\]

where \(f\) is the frequency in Hertz. Thus, in first approximation, the relative phase velocity depends only on the ratio of the two altitudes, and is independent of the scale heights. This is quite different from the theory of Booker and Lefeuvre.
(1977), in which the relative phase velocity differs from unity by an amount proportional to \( \zeta_1/h_1 \).

The horizontal attenuation in the waveguide arises from two sources. The part proportional to \( \zeta_0/h_0 \) is due to Joule heating by vertical currents, which has a maximum at \( h_0 \) as in the isotropic case. However, the part proportional to \( \zeta_1/h_1 \) is no longer associated with Joule heating by horizontal currents. The horizontal currents are now Hall currents, which are non-dissipative. The field at this altitude has been decomposed by the anisotropic medium into two vertically propagating waves, an \( 0 \) wave component whose index of refraction is almost purely imaginary and an \( X \) wave component whose index is almost purely real. Thus, the \( 0 \) wave undergoes total reflection in this region, whereas some of the \( X \) wave energy leaks out of the waveguide. The part of the attenuation rate proportional to \( \zeta_1/h_1 \) is associated with this leakage, as pointed out by Booker and Lefeuvre (1977), who obtained a very similar result for this quantity. The reflected part of the \( X \) wave results in a small TE component in the field at the ground. From Eqs. (4), (8), (16), and (40), the ratio of the TE and TM components at the ground is

\[
\frac{B_{TE}}{B_{TM}} = \left( \frac{1}{1 \omega A_z} \frac{\partial u}{\partial z} \right)_{z=0} = -\frac{\beta}{1 \omega A_0} = \frac{\pi \zeta_1}{2h_1 + i\pi \zeta_1}.
\]

The magnetic field at the ground thus has slight elliptical polarization, with the major axis nearly perpendicular to the plane of propagation.

The theory has been developed under the assumption that \( h_1 \) is reached at an altitude where \( |\sigma_H| >> |\sigma_p| \). If the criterion is met where the Pedersen conductivity is not negligible, there
is a separate pair of values of \( h_1 \) and \( \zeta_1 \) for the O and the X components, which in general differ only slightly. It is not difficult to generalize the theory to this situation. This results, however, in only a small correction to the eigenvalue obtained by replacing the two pairs of parameters by their average.

3.2.2 **Nighttime Ionospheric Conditions**

Under nighttime conditions, a sharp E-region bottom is usually encountered before the altitude \( h_1 \) is established. The electron density undergoes a very sharp increase in passing through the bottom, above which it can be quite variable. We will consider only the simplest model where the density above this bottom varies slowly on the scale of the local wavelength. Under such conditions, the phase integral approximation is valid above the E-region bottom, and we may take as solutions of Eq. (24)

\[
\psi_+ = \Lambda_+ (n_+ k)^{-1/2} \exp \left\{ i k \int_{h_E}^z n_+(z) \, dz \right\} \tag{45}
\]

where \( h_E \) is the altitude of the E-region bottom and \( \Lambda_+ \) are constants. The associated potential functions \( \psi \) and \( u \) have the form

\[
\psi = \Lambda (\psi_+ + \delta \psi_-) \tag{46}
\]

\[
u = i \Lambda (\psi_- - \delta \psi_+) \tag{47}
\]

where \( \Lambda \) and \( \delta \) are constants to be determined. Under nighttime conditions, the solution up to the E-region bottom is well
approximated by Eqs. (16) and (19). The boundary conditions require that the tangential electric and magnetic fields be continuous at $z = h_E$. This, in turn, requires the continuity of $u$, $\frac{du}{dz}$, $\psi$, and $\frac{d\psi}{dz}$ at this interface. If we assume, as in Eq. (28), that

$$n^2_+(h_E) \equiv n^2_-(h_E) \equiv -n^2_E, \quad (48)$$

then application of the boundary conditions leads to

$$S^2 = \frac{h_E}{(h_0 - i\frac{\pi}{2}\zeta_0)} \left\{ 1 + \frac{\epsilon}{2} \left[ \frac{1 + i(1+2\epsilon)}{1 + \frac{1}{2} \epsilon(1+i)} \right] \right\} \quad (49)$$

where

$$\epsilon = \frac{1}{kn_E h_E}. \quad (50)$$

Assuming that $n_E$ is nearly real, the eigenvalue is in first approximation

$$S \approx \left( \frac{h_E}{h_0} \right)^\frac{1}{2} \left[ 1 + i \left( \frac{\pi}{4} \frac{\zeta_0}{h_0} + \frac{1}{4kn_E h_E} \right) \right] \quad (51)$$

Comparison with the daytime results shows that the altitude of the E-region bottom has replaced the frequency-dependent altitude $h_1$ as a parameter and the local wavelength just inside the E-region has replaced $\zeta_1$. The physical processes occurring at $h_E$ are the same as those associated with $h_1$, namely nearly total reflection of the O wave and partial leakage of the X wave. Although we have considered only the simplest case of a
single reflecting boundary, the method can obviously be
generalized to include any number of such discontinuities.
SECTION 4. NUMERICAL RESULTS AND CONCLUSIONS

The validity of the theory has been examined by comparing approximate eigenvalues with a full-wave calculation for a hypothetical daytime conductivity profile. For simplicity, it was assumed that only electrons contributed to the conductivity at all altitudes. Although this assumption may be unrealistic, it does not invalidate a comparison of an approximate solution with a full-wave solution for the same profile. The electron density and collision frequency profiles were assumed to be simple exponentials

\[ N_e = N_0 e^{z/\zeta_e} \]  
\[ \nu = \nu_0 e^{-z/\zeta_\nu} \]  
with \( N_0 = 3.73 \times 10^3 \, \text{m}^{-3} \), \( \nu_0 = 1.63 \times 10^{12} \, \text{sec}^{-1} \), and \( \zeta_e = \zeta_\nu = 6 \, \text{km} \). With these profiles, the conductivities

\[ \sigma_O = \frac{\omega_p^2}{\varepsilon_0 (\nu_e - i\omega)} \]  
\[ \sigma_P = \frac{\omega_p^2 (\nu_e - i\omega)}{(\nu_e - i\omega)^2 + \omega_e^2} \]  
\[ \sigma_H = -\frac{\omega_p^2 \omega_e}{(\nu_e - i\omega)^2 + \omega_e^2} \]  
were calculated, taking \( \omega_e = 10^7 \, \text{rad/sec} \) as the electron gyro-frequency. From the calculated conductivity profiles, the parameters \( h_c, \zeta_0, h_1, \) and \( \zeta_1 \) were determined for
frequencies of 50 Hertz and 100 Hertz, and the approximate eigenvalues were calculated from Eq. (38). A full-wave calculation for the profiles given by Eqs. (52) and (53) was carried out by Dr. William Moler of Naval Ocean Systems Center for comparison with the approximate eigenvalues. The two sets of results are shown in Table 1. The phase speeds agree to better than 1% and the attenuation rates to within 0.2 decibels per megameter, which is quite good.

The relative phase speeds predicted by the theory of Booker and Lefèuvre for the same profile are approximately 0.95 at both frequencies, which is substantially higher than the full-wave values. We have not attempted to calculate their attenuation rates, which requires integration over the conductivity profile to estimate the contribution from Joule heating below $h_1$. However, an important assumption on which their approximation is based is clearly at variance with our analysis. They calculate the fraction of energy removed from the horizontal flow by Joule heating at a given altitude, and identify the attenuation rate with the average value of this quantity between the ground and $h_1$. This identification relies on the assumption that the horizontal flow of energy is approximately uniform between the surface of the earth and the level of reflection. However, the lower ionosphere solutions presented here show that, while the horizontal magnetic field remains essentially constant in this region, the vertical electric field falls off quite rapidly above $h_0$. To lowest order in $\zeta_0/h_0$, the rate of horizontal flow of energy is

$$\text{Re}(E_z B_1^*) = \frac{\omega^2}{\mu_0 c} \text{Re}(S) |S|^2 |A_0|^2 \left[ 1 + \left( \frac{\sigma_0}{\varepsilon_0 \omega} \right)^2 \right]$$  \hspace{1cm} (57)
Table 1. Comparison of Approximate- and Full-Wave Propagation Constants for the Hypothetical Daytime Ionosphere Described in Section 4.

where we have assumed $\sigma_0$ to be real. For an exponential conductivity profile, the horizontal flow rate is essentially constant to an altitude $h_0$, above which it falls off rapidly. The Joule heating rate is given by

$$
\sigma_0 |E_z|^2 = \frac{\omega^2 |S|^4 |A_0|^2 \sigma_0}{1 + \left( \frac{\sigma_0}{\varepsilon_0 \omega} \right)^2},
$$

which exhibits a very sharp maximum at $h_0$, and becomes very small within a scale height or so on either side of this altitude. (These points are illustrated graphically in I.) For the profile given by Eq. (18), the heating and flow rates can be integrated over altitude analytically. Since the integrands fall off very rapidly above $h_0$, little error is made by extending the upper limit to infinity. The result is

$$
\frac{\int_0^\infty \sigma_0 |E_z|^2 \, dz}{\int_0^\infty \text{Re}(E_z B_1^*) \, dz} = k \frac{\pi}{2} \frac{\zeta_0}{h_0} \text{Re}(S),
$$

which agrees exactly with the horizontal attenuation rate due to heating as calculated from Eq. (41).

Although essentially all of the heating dissipation takes place in a narrow altitude region around $h_0$, the local attenuation rate (i.e., the ratio of the local heating rate to the horizontal flow rate at the same level) is an increasing function of altitude. Thus, an unweighted average of the local attenuation rate will exceed the actual horizontal attenuation rate. For a given profile, the difference
between the two values increases with decreasing frequency
due to the lowering of the altitude $h_0$. This perhaps accounts
for the difficulty experienced by Booker and Lefeuvre (1978)
in reconciling the observability of the nighttime Schumann
resonance with generally accepted nighttime profiles.
