Abstract:

A calculation is presented to describe the response of an atomic system subjected to two strong standing wave field pulses separated in time. One finds a sequence of output pulses following the input ones, reminiscent of classical photon echoes. A physical picture of the processes involved in echo formation is presented and connection is made with the classical picture of photon echoes. The application of these techniques to collision studies is emphasized. It is shown that studies of echoes produced by standing wave fields can prove advantageous for exploring the effects of small angle scattering on both level populations and atomic coherences.
1. Introduction.

There has been recent interest in using time resolved methods in laser spectroscopy. These include time resolved saturation spectroscopy, free-induction decay, photon echo, quantum beats, coherent Ramsey beats, superradiance, and excitation in separated fields. In most of these experiments one observes the transient response of atoms to the application or removal of laser fields. In addition to providing a means for carrying out high precision spectroscopy, these methods are useful, to varying degrees, for studying relaxation processes.

In this paper we consider the response of an atomic system to excitation by separated fields, sometimes referred to as optical Ramsey fringes. To observe optical Ramsey fringes, one applies a laser-generated standing wave to atoms during a short time \( T \), at two instants separated by a delay \( T \). Experimentally, this process has been studied using gas cells as well as atomic beams for both two-photon and one-photon excitation. In the case of two-photon transitions, which are free from the Doppler effect, the evolution of the atoms after the second pulse is probed by the fluorescence decay from the upper level. For one-photon transitions, the field-induced coherence among the atomic dipoles is rapidly destroyed for different velocity subclasses of atoms owing to the Doppler effect, except at a time \( T \) after the second pulse. At this instant a coherent radiation is emitted by the gas, which is reminiscent of the classical photon echo. In either case the signals exhibit a detuning-dependent structure of width \( 1/T \), which does not exist in the usual photon echo. The ultimate resolution of separated field spectroscopy (with width \( (T)^{-1} \)) may be much better than that in saturation spectroscopy (limited by transit-time broadening).

In the last papers of the group of Novocherk. I-13 a new feature was noticed, which is the occurrence of coherent radiation, not only at time \( T \), but also at \( 2T \), \( 3T \) after the second pulse. The aim of this article is to qualitatively and quantitatively discuss the origin of the successive coherent radiation in separated fields (C R S P). The build up of echoes at successive times is directly connected with the cancellation of the Doppler phase of various spatial harmonics of both the atomic coherences and level-populations. We show that the spatial component of order \( n \) between the two pulses is the source of an echo at time \( nT \) after the second pulse. The characteristics of the phenomena in the frequency domain are investigated and the difference with the usual photon echo is elucidated. Moreover a calculation of the C R S P intensity is carried out using a simple model.

In Sect. II, the C R S P intensity is calculated, assuming that the field seen by the atoms is provided by the external fields only (i.e., polarization fields are neglected). The details of this calculation are given in Appendix A. Discussions of the origin of the various echoes and the detuning dependence of the fields is given in Sect. III and IV, respectively. Finally, the possibilities of using C R S P for collisional studies is explored in Sect. V.
II.  G R S F intensity

Consider a gas cell (Fig. 1) illuminated by two successive standing wave laser pulses. The pulses are applied at times \( t_0 \) and \( t_1 \) having durations \( \tau_0 \) and \( \tau_1 \) respectively. The laser field of frequency \( \omega \), is taken to be of the form:

\[
\mathbf{E}(x,t) = \mathbf{E}(x,t) = i \mathbf{E}_0 \cos \omega t \sin kx [\mathbf{b}(t_0) + \mathbf{b}(t_1)]
\]

where \( \mathbf{b}(t) = \{ 1 \ \mathbf{c}(t-t_0) \mathbf{x} \} \), and \( \mathbf{x} \) is a unit vector in the direction of polarization.

In the rotating wave approximation, the equations of motion for density matrix elements \( \rho(x,t) \) (only motion in the direction of the field propagation vector need be considered) are:

\[
\begin{align*}
\frac{\partial \rho_{11}}{\partial t} + v \frac{\partial \rho_{11}}{\partial z} &= i \chi (\rho_{12} e^{-i\omega t} - \rho_{21} e^{i\omega t}) \sin kx [\mathbf{b}(t_0) + \mathbf{b}(t_1)] - \gamma_{11} \rho_{11} \\
\frac{\partial \rho_{22}}{\partial t} + v \frac{\partial \rho_{22}}{\partial z} &= i \chi (\rho_{21} e^{-i\omega t} - \rho_{12} e^{i\omega t}) \sin kx [\mathbf{b}(t_0) + \mathbf{b}(t_1)] - \gamma_{22} \rho_{22} \\
\frac{\partial \rho_{12}}{\partial t} + v \frac{\partial \rho_{12}}{\partial z} &= i \chi (\rho_{22} - \rho_{11}) e^{-i\omega t} \sin kx [\mathbf{b}(t_0) + \mathbf{b}(t_1)] - \gamma_{12} \rho_{12} - i\omega_0 \rho_{12}
\end{align*}
\]

where \( \omega_0 \) is the transition frequency, \( \chi = \mu \mathbf{b} / \mathbf{c} \), \( \mu \) is the dipole moment associated with the transition 1-2 and \( \gamma_{ij} \) is the natural decay rate of \( \rho_{ij} \).

It is assumed that the applied pulses are well separated \( (t_1 - t_0 \gg \mathbf{x}) \), and that the detuning \( \Delta = \omega - \omega_0 \), and decay rates \( \gamma_{ij} \) satisfy \( |\Delta| \ll 1, \gamma_{ij} \ll 1 \), respectively, as is common experimentally. Moreover, to insure that the Doppler dephasing between pulses is complete, one assumes that \( kx T \gg 1 \), where \( u \) is the width of the thermal velocity distribution. Finally, the effect of the polarization fields on the atoms is neglected, which is valid provided that the echo fields are much less intense than the external ones. In these limits Eqs. 1 are solved in Appendix A.

All spatial harmonics are contained in the atomic polarization

\[
P = \mu (\mathbf{P}_{12} + \mathbf{P}_{21})
\]

which is of the form:

\[
P(x,z,t) = \mathbf{P}_0 (v_x z, t) \cos \omega_0 t + \mathbf{P}_1 (v_x z, t) \sin \omega_0 t
\]

where \( \mathbf{P}_0 \) and \( \mathbf{P}_1 \) are slowly varying functions of time, compared with \( \cos \omega t \). However, it follows from this form of the polarization and Maxwell's equations that only the component of \( P(x,z,t) \) proportional to \( \sin kx \) gives rise to a significant electric field (i.e., the absence of polarization frequencies \( \omega_0, 2\omega_0, ... \) implies that polarization components varying as \( \sin 3kx \), \( \sin 5kx \) ... are negligible). Thus it suffices to consider:

\[
P(x,z,t) = \frac{2\mu}{\mathbf{c}^2} \int_0^\infty \sin k(z-s) \mathbf{P}(v_x z', t) \mathbf{d}s
\]

where \( \mathbf{P}(v_x z, t) \) is now a slowly varying function of \( z \), compared with \( \sin kx \). The echo field is then determined from Maxwell's Eqs. as:

\[
\mathbf{E}(x,t) = \frac{2\mu}{\mathbf{c}^2} \int_0^\infty \sin k(z-s) \mathbf{P}(v_x z', t) \sin \omega_0 t + \mathbf{P}_1 (v_x z', t) \cos \omega_0 t \sin kx
\]

where:

\[
\mathbf{P}_1 (v_x z, t) = \frac{2\mu}{\mathbf{c}^2} \int_0^\infty \mathbf{P}_1 (v_x z', t) \sin k(z-s) \mathbf{d}s
\]

and \( \mathbf{d} \) is the length of the sample. The echo amplitude given by:

\[
\mathbf{E}(x,t) = i \mathbf{E}_0 \cos \omega t \sin kx [\mathbf{b}(t_0) + \mathbf{b}(t_1)]
\]
\[ \mathcal{E}(s,t) = \int 2 \pi s \left[ \frac{1}{2} \left( \frac{\partial}{\partial s} \left[ \Phi_{0}(v_{s},s,t,t) \right] + \Phi_{1}(v_{s},s,t,t) \right) \right] \cos \Delta \tau + B \ e^{-\gamma t} \]  

is calculated in Appendix A (using the simplifying, but not critical, assumption that \( \gamma_{11} = \gamma_{22} = \gamma \)) as:

\[ \mathcal{E}(s,t) = 4 \pi s \int d v_{s} \ H_{0}(v_{s},s,t,t) \left( \frac{A e^{-\gamma_{11} t}}{\cos \Delta \tau + B e^{-\gamma t}} \right) \]  

where

\[ H_{0}(v_{s},s,t,t) = P_{22}(v_{s},s,t,t) - P_{11}(v_{s},s,t,t) \]

is the population difference density at \( t = t_{0} \), just before the first pulse, and

\[ A = \begin{cases} \text{odd} & J_{n+1} \left[ \frac{4 \pi}{\nu_{y}} \sin \left( \frac{\nu_{y} \tau_{1}}{2} \right) \right] \times J_{n} \left[ \frac{4 \pi}{\nu_{y}} \sin \left( \frac{\nu_{y} t_{0}}{2} \right) \right] \times \exp \left[ -\gamma_{12}(t-t_{1}) \right] \cos \left[ \nu_{y}(n \tau - (t-t_{1})) \right] \end{cases} \]

The physical content of this equation will be discussed in the next two sections. We may note here some general features of the solution. The echo amplitude is a maximum for \( t = t_{1} = n \tau \) (\( n \) integer).

For other times, the velocity integration leads to a negligible echo amplitude. The maximum amplitude of the \( n \)th echo is given by:

\[ \mathcal{E}_{\max}(s,t_{1} + n \tau) = (-1)^{n} 4 \pi s \int d v_{s} \ H_{0}(v_{s},s,t_{1} + n \tau) \]

\[ \times J_{n+1} \left[ \frac{4 \pi}{\nu_{y}} \sin \left( \frac{\nu_{y} \tau_{1}}{2} \right) \right] \times J_{n} \left[ \frac{4 \pi}{\nu_{y}} \sin \left( \frac{\nu_{y} t_{0}}{2} \right) \right] \times \exp \left[ -\gamma_{12}(t-t_{1}) \right] \cos \left[ \nu_{y}(n \tau - (t-t_{1})) \right] \cos \Delta \tau + B \ e^{-\gamma t} \]  

For odd \( n \) the maximum amplitude oscillates as a function of detuning \( \Delta \), with the fringes having a width \(-1/2\). For even \( n \), the signals do not exhibit this detuning dependence. From Eqs. 7, 8, one can see that the duration of a given echo in time is \( [\nu_{y} \Delta v_{y}]^{-1} \) where \( \Delta v_{y} \) is the range of significant \( v_{y} \) entering the integration in Eq. (7); the range \( \Delta v_{y} \) is a function of \( \nu_{y}, \nu_{x}, \tau_{0}, \tau_{1} \). The general qualitative features of the results are illustrated schematically in Fig. 2.

One can determine the most suitable values of parameters \( \tau_{0}, \tau_{1}, \nu_{x} \) in order to maximize the intensity of a given echo. As a first attempt of this choice of parameters, consider the simple situation where all the velocity classes are equally excited by the pulses, i.e., \( \nu_{x} \tau \ll 1 \). In this limit the arguments of the Bessel functions reduce to \( 2\nu_{x} \tau_{0} \) and \( 2\nu_{x} \tau_{1} \) respectively. Taking a Maxwellian distribution for \( H_{0} : \)

\[ H_{0}(v_{y}) = (2\pi)^{-1/2} \nu_{y} \exp \left( -v_{y}^{2}/2\nu_{y}^{2} \right) \]

one obtains the echo:

\[ \mathcal{E}(t) = 4 \pi s \nu_{y} \left( \frac{\nu_{y}}{\nu_{x}} \right)^{2} \left[ \frac{A e^{-\gamma_{11} T}}{\cos \Delta \tau + B e^{-\gamma T}} \right] \]

\[ = \begin{cases} \text{odd} & J_{n+1} \left( 2\nu_{x} \tau_{1} \right) J_{n} \left( 2\nu_{x} \tau_{0} \right) \times \exp \left[ -\gamma_{12}(t-t_{1}) \right] \cos \left( \nu_{y}(n \tau - (t-t_{1})) \right) \cos \Delta \tau + B \ e^{-\gamma t} \end{cases} \]

The duration of each of these echoes (at half maximum) is \( 3.4/\nu_{x} \), and to maximize \( \mathcal{E}(t) \), \( \tau_{0} \) and \( \tau_{1} \) must be chosen so that the Bessel functions of the observed echo have their first maximum for \( 2\nu_{x} \tau_{0} \) and \( 2\nu_{x} \tau_{1} \).
\[ x v_0 = 0.9 \text{ and } v_1 = 1.72v_0 \text{ for } n=1 \]
\[ x v_0 = 1.55 \text{ and } v_1 = 1.35v_0 \text{ for } n=2 \]

In the limit \( ku \tau \ll 1 \) under consideration, this optimization procedure requires field strengths \( \chi \gg ku \).

The ratio \( R_n \) of the optimized intensity of the first echo to that of the others is shown on Table 1.

Table 1

If \( ku \tau \gg 1 \), Eq. 7 must be evaluated by a numerical integration. Figures 3 and 4 show \( \phi_{\text{max}} \) for the two first echoes, as a function of \( ku v_1 \) for several values of \( \chi \). In this calculation the ratio between \( v_0 \) and \( v_1 \) is fixed at the optimum value which has been determined previously for the limiting case \( ku \tau \ll 1 \). It turns out that the intensity maxima shown by Fig. 3 and 4 are approximately located at the same values of \( x v_0 \) and \( x v_1 \), as in the \( ku v_1 \ll 1 \) case. The echo amplitude maximum is decreased by a factor 2 (first echo) or a factor 2.8 (second echo) when the Rabi frequency is changed from 2\( ku \) to 1/2\( ku \).

Figures 5 and 6 represent the time evolution of the echoes around the instant \( t_1 = nT \). For each value of \( x \), \( v_0 \) and \( v_1 \) are chosen to give the maximum intensity. The duration of the echoes (at half maximum) is increased from about 3.5/\( ku \) to \( 9/ku \) (first echo) and 3.5/\( ku \) to 12/\( ku \) (second echo) when \( x \) varies from 2\( ku \) to \( 2ku \). The physical implications of the above results are discussed in the next two sections.

III. Physics of echo formation.

To investigate the physical origin of the echoes, we first consider the limiting case \( ku \tau \ll 1 \) (all velocity sublattices excited by the pulse). For an initial given phase \( ks \) of the applied field at \((s, t_0)\), the phase of the \( n \)-order spatial harmonic of the induced polarization is \( nks \) (n odd). From time \( t_0 \) to \( t \) with the field off, the atoms keep the same phase \( nks \). Owing to their motion the atoms at \((s, t)\) are the ones which were at \((s_0 = s - v_{s}(t-t_0), t_0)\). Consequently the spatial phase of atoms with velocity \( v_{s} \) at \( s \) is:

\[ \phi_{s}(v_{s}, s, t) = nks = nks - nk\nu_{s}(t-t_0) \]

In a standing wave field, populations as well as off-diagonal density matrix elements acquire phases. Thus the phase of an arbitrary density matrix element harmonic at \( t = t_1 \), is \( nks = nk\nu_{s}(t_1-t_0) \) where \( n \) can be even (population) or odd (polarization). The second pulse causes each \( n \)-th harmonic, present at time \( t_1 \), to drive the \( m \)-th harmonic of the polarization. The phase of the \( m \)-th harmonic after the pulse is obtained by adding \( (n-m)ks \) to the phase of the \( m \)-th harmonic before the pulse. This leads to:

\[ \phi_{m}(v_{s}, s, t_1) = nks - nk\nu_{s}(t_1-t_0) \]
This total phase differs from the value of \( \theta_n \) before the pulse by a phase jump \((n-\pi)k_v(t_1-t_0)\). Note that the phase of the \( n \)th harmonic after the pulse actually reflects the time development of the \( n \)th harmonic, and not that of the \( n \)th harmonic, between \( t_0 \) and \( t_1 \). In the same way that the phase at time \( t \) after the first pulse was obtained, one can calculate the spatial phase at time \( t > t_1 \), as:

\[
\theta_n(y, x, t) = 2\pi n - k_v(nT_0 + nT_0 - t_0)
\]

All the velocity-classes of the polarization combine their contributions to produce coherent radiation of the gas after the second pulse. The spatial average gives rise to negligible contributions from the various harmonics (providing the dimension of the sample is much larger than the radiation wave length) except for the component having spatial phase \( 2\pi n \). Thus, the signal originates from components such that \( n = \pm 1 \), with a phase:

\[
\theta_{\pm 1}(y, x, t) = 2\pi n - k_v(nT_0 + nT_1)
\]

In the integration over \( v \), the atomic polarization is small, owing to the Doppler phase \( k_v(nT_0 + nT_1) \), except at times \( t = t_1 + \pm nT \) when this Doppler phase is zero. Thus an echo occurs at time \( nT \) after the second pulse and reflects the build-up of either polarization (\( n \) odd) or population (\( n \) even) harmonics in the \( t_0 \rightarrow t_1 \) region. Figure 7 represents this result for the case \( n = \pm 1 \), \( n = \pm 1 \), \( n = 0 \). The result is analogous to that in classical photon echoes — independent of velocity, all dipoles are in phase at a specific time where an echo is observed. Since the \( n \)th harmonic

is either a population or a polarization component depending on whether \( n \) is even or odd, coherent radiation in separated fields is an extension of photon echo in traveling wave fields, where only the lowest polarization components may be excited. The usual interpretation of photon echo in gases considers the effect of the second pulse as a reversal of the Doppler phase:

\[-k_v(t_1-t_0) - k_v(t_1-t_0)\]. This result is a limiting case of the more general result in C R S P where the second pulse induces a change of \((\pm n) k_v(t_1-t_0)\) in the Doppler phase (for classical photon echo \( n = -1 \)). Thus, the presence of the various echoes may be explained by the simple "phase-jump" picture.

The time duration of C R S P may also be explained using a simple picture. The atomic dipoles lose their relative phase coherence in a time equal to the inverse of the frequency bandwidth excited by the laser fields. If \( k_v \ll 1 \), all velocity subclases are equally excited by the field, giving an excitation bandwidth of \( k_v \) and consequently, an echo duration of \( \sqrt{k_v} \). For larger values of \( k_v \), such that \( k_v \gtrsim 1 \), the excitation bandwidth approaches \( k_v^{-1} \), leading to an echo duration \( \sqrt{k_v + k_v} \). This effect is clearly seen in Figs. 5 and 6 as the echo duration increases with \( k_v \).

Excitation bandwidth is also an important factor in explaining the decrease in echo amplitude with decreasing field strength shown in Figs. 3 and 4. For large field strengths leading to optimization pulse widths such that \( k_v \ll 1 \), all velocity subclases are equally excited and the parameters \( k_v \) can be chosen to
to maximize each echo intensity independently of velocity [see Eq. (9) in which the Bessel function arguments are velocity independent for $k u \tau_2 < 1$]. As the field strength decreases, the optimal pulse widths are such that $k u \tau_2 > 1$. The condition $k u \tau_2 > 1$ corresponds to atoms moving through at least one wavelength of the standing wave field pattern during the pulses. Each atom starting at $(x_0, t_0)$ then experiences an average field (see Appendix B)

$$\langle x(x_0, t_0-t) \rangle_{t_0, t_0+t} = \frac{2}{k v} \sin \left( k_0 \frac{v}{2} \right) \sin \left( k_0 \frac{v}{2} \right)$$

which is velocity dependent if $k u \tau_2 > 1$. Thus a set of parameters which is optimal for one velocity subclass is not optimal for another [see Eq. (9) in which the Bessel function arguments depend on $v_0$ if $k u \tau_2 > 1$]. One is effectively using fewer atoms to provide the echo signal (atoms having $k v \tau_2 < 1$ are most efficient) as $k u \tau_2$ increases, leading to a decrease in echo amplitude.

IV. Detuning dependence.

Following the first pulse, the induced atomic polarization oscillates freely at frequency $\omega_0$ while the level populations exhibit no oscillatory behaviour [see Eqs. (1) for $\rho_{12}$ and $\rho_{21}$, respectively]. When the second pulse acts on the system (assuming that both pulses arise from the same CW laser) the atomic dipoles have acquired a temporal phase difference $\Delta \phi$ with the field. For C R S P echoes driven by polarization harmonics (odd $n$), the echo amplitudes are maximal if this phase difference is an integral multiple of $2\pi$ and they oscillate as a function of $\Delta \phi$ with period $T$ giving rise to "fringes" of width $1/T$. For C R S P echoes driven by population harmonics (even $n$), the phase difference plays no role and no fringes appear.

The structure is typical of Ramsey fringes in which one creates a polarization phase difference by sampling a field at two separate times. This effect is also present in traveling wave photon echoes, but in a less useful way. For traveling wave fields, the detuning always enters as $A - k v$ so that, in order to achieve the Doppler phase cancellation necessary for echo formation, the detuning dependence as well as the Doppler phase, vanishes at $t = 2T$. The traveling wave echo exhibits a detuning dependence of $\cos \Delta (t-2T)$ which, for $t \approx 2T$, gives a fringe pattern of width $1$ (echo duration) $\gg T^{-1}$. Thus C R S P is much better suited for high precision spectroscopy than traveling wave photon echoes.

The fringe pattern in C R S P extends for a range of detuning $|A| \tau \leq 1$, after which it disappears. This result is in contrast to typical Ramsey fringe patterns where only the central fringe may be seen (the other fringes are lost owing to phase destruction arising from different values of $T$ for different velocity groups).
V. Collisions.

C R S F offers some interesting possibilities for collisional studies. Echo formation is intimately related to the spatial phases acquired by atoms as a result of their motion following application of the field. An echo corresponds to the rephasing of the signal at some particular instant \( t = t_1 + 2nT \) when the atoms of velocity \( V_n \) are at distance \( nT V_n \) from their position at the time of the second pulse (see Fig. 7). Collisions during the time of flight, which prevent the atoms of a given \( V_n \) from being at the right position at the right time, result in a decrease of the echo intensity. This phenomenon of "Collisional Doppler dephasing" was already observed in photon-echo experiments. In that case the signal reflects only the evolution of the first spatial harmonic of the atomic coherence. In C R S F, the spatial harmonics of the population difference, as well as coherences, contribute to the echo formation. Thus the C R S F method extends the possibility of observing a "Collisional Doppler dephasing effect" to the population difference. Moreover, the spatial structure may be probed systematically since every spatial harmonic produces a C R S F echo. However, the relative contribution of an harmonic decreases with increasing \( n \) since the detected atom has a phase associated with the \( n \)th harmonic during the time between the two pulses only and this delay is smaller and smaller in comparison with the total time of flight \( (n+1)T \) as \( n \) increases. Therefore most of the interest of the method seems to be concentrated in the first few echoes.

It is true that the observed microscopic collisional process – namely the velocity-changing process – is the same one which can be investigated in steady state saturation spectroscopy (SSS). However in SSS the contribution of the coherence and of the level population are mixed in the same signal. This may present difficulties of interpretation when coherence and level populations are both sensitive to the velocity changing effect. In contrast in C R S F the occurrence of distinct echoes enables one to separate the coherence and the level population signals.

In order to illustrate the physics involved in collisional Doppler dephasing, we adopt a simple model with the following features:

1. Binary foreign gas collisions in the impact approximation,
2. Equal natural decay and inelastic collisional rates for levels 1 and 2,
3. Inelastic collisions that can be accounted for by one rate constant \( \Gamma_{12} \) for all density matrix elements,
4. Short-pulse times \( \hbar n \ll 1 \) such that all velocity subclasses are equally excited.

With these assumptions we need consider only elastic collisions and do so using three collision models.

(A) In the first model, collisions are assumed to produce only instantaneous phase changes on atomic coherences. This model is valid generally for electronic and vibrational transitions. For echoes driven by coherences, the effect of collisions is to replace \( \gamma_{12} \) by a collision broadened \( \Gamma_{12} \) and \( \Delta \) by a collisionally shifted \( \Delta' \) giving a maximum echo amplitude

\[
E_{\text{max}}(t_1 + nT) = (-)^n \times 4 \times k \times \int d\alpha \times \alpha_0(\alpha, z) \times \frac{e^{-\Gamma_{12}(1+nT) \cdot t}}{\Gamma_{12}(1+nT) \cdot t} \cos \Delta' \cdot T
\]
For echoes driven by populations, the Doppler phase factor
\( \exp \left[ \int_0^\ell \text{inkv}_z \, dt \right] \) developed between \( t_0 \) and \( t_1 \) by the \( n \)th harmonic
(a even), must be averaged over velocity changing collisions. Following
Ref. 4, we can obtain:

\[
\mathcal{E}_{\text{max}}(t_1, n\ell) = (-)^n 4\pi k \ell \int d\nu_z \, P_0(\nu_z, z, t_0) 
\times J_{n+1}(2\pi \tau_0) \times J_{n}[2\pi \tau_1] \exp \left[ -\tau_1(1+\alpha) \right] 
\times e^{-\gamma T} \times \frac{e^{-\gamma T} (n \kappa \Delta u)^2 \gamma^3}{\kappa \Delta u T \ll 1} 
\times \frac{e^{-\gamma T} \kappa \Delta u T \gg 1}{e^{-\gamma T}}
\]

where \( \Gamma \) is the elastic collision rate, \( \Delta u \) is the rms change in
velocity per collision and \( \alpha \) is a constant of order unity which depends
on the specific collision kernel describing the collisions. Thus, one
can probe elastic velocity changing collisions with this method by
studying the maximum echo amplitude of even harmonics as a function
of pulse separation \( T \). Note the possibility of a different functional
dependence on \( T \) for even and odd harmonics.

(3) - In the second collision model, valid generally for rotational
and some vibrational transitions, collisions are assumed to be velocity-
changing in their effect on coherences. In this model, the elastic
scattering amplitudes are identical for levels 1 and 2; a state
independent collision interaction can lead only to velocity-changes
(as instantaneous phase changes) associated with level coherences.
Collisions affect populations and coherences in the same manner in this
model, resulting in a maximum echo amplitude depending on an average of

\[
\exp \left[ \int_0^\ell \text{inkv}_z \, dt \right] - \frac{1}{2} \left( \frac{\nu_z}{\nu_z} \right) \text{ over collisions, and given by}^{1,19}
\]

\[
\mathcal{E}_{\text{max}}(t_1, n\ell) = (-)^n 4\pi k \ell \int d\nu_z \, P_0(\nu_z, z, t_0) 
\times J_{n+1}(2\pi \tau_0) \times J_{n}[2\pi \tau_1] \exp \left[ -\tau_1(1+\alpha) \right] 
\times \frac{e^{-\gamma T} (n \kappa \Delta u)^2 \gamma^3}{\kappa \Delta u T \ll 1} 
\times \frac{e^{-\gamma T} \kappa \Delta u T \gg 1}{e^{-\gamma T}}
\]

(4) - A modified collision model, valid for collision interactions that
are nearly state independent allows for both a velocity change and
small phase shift to occur in level coherences as a result of a collision.
This model, which may be valid for some vibrational transitions, can be
described by replacing \( \tau_{12} \) and \( \Delta \) appearing in Eq. (14) by collision-
ally modified values \( \tau_{12}^{\text{col}} \) and \( \Delta^{\text{col}} \). It should be noted that even
small collisional shifts may be important in high precision spectroscopy.

An examination of Eqs. (3) and (4) reveals the special functional
dependence on \( T \) in the factor which comes from velocity changes in
small angle scattering. Thus \( C R S P \) could be very useful to extract
this latter effect from the background of other collisional contributions
(inelastic collisions, phase-rupturing collisions, strong collisions).
Photon echo in traveling waves has already proved useful for that
purpose but, as it has been said previously, coherences only may be
probed using classical photon echoes, while \( C R S P \) allows a study of
collisional effects on level populations as well. The same possibility
of studying small velocity changes is also present in time resolved
saturation spectroscopy, but the signal is then an intricate mixture
of contributions from both coherences and level populations. An
alternative method for studying the effects of velocity-changing
collisions on level populations using stimulated photon echoes has
recently been reported.

Challenge Fund.

Appendix A.

Solution of the equations of motion.

The first step is to solve the non stationary equations of motion
in the presence of a permanent standing-wave field. We seek a solution
to describe the evolution of the system within a short time \( \tau \) after
the field has been switched on assuming the following conditions

\[ |\sigma| \tau \ll 1 \quad , \quad |\tau| \ll 1 . \]

Starting with Eq. (1), and using the new variables:

\[
\begin{align*}
\bar{\rho}_{12} &= \rho_{12} e^{i \omega t} \\
\bar{D} &= \bar{D}_{12} - \bar{D}_{21} \\
\bar{S} &= \bar{S}_{12} + \bar{S}_{21} \\
N &= \rho_{22} - \rho_{11}
\end{align*}
\]

we obtain

the set of equations:

\[
\begin{align*}
\dot{N} + \nu_2 \frac{\partial}{\partial \omega} N &= 21 \chi \bar{D} \sin \omega \tau \\
\dot{D} + \nu_2 \frac{\partial}{\partial \omega} D &= 21 \chi \bar{S} \sin \omega \tau \\
\dot{S} + \nu_2 \frac{\partial}{\partial \omega} S &= 0
\end{align*}
\]

The spatial derivative is eliminated by substitution using Fourier-
series developments for the variables \( N, D, S \):

\[
\begin{align*}
\tilde{N}_n &= \int_0^\tau N \cos n \omega \tau \ dw \\
\tilde{D}_n &= \int_0^\tau D \cos n \omega \tau \ dw \\
\tilde{S}_n &= \int_0^\tau S \cos n \omega \tau \ dw
\end{align*}
\]

where the Fourier components are defined by:

\[
A_n = \int_0^\tau \cos n \omega \tau \ dw \quad , \quad A = D, S, N
\]

At \( \tau = 0 \), \( D_0 = 0 \) and \( N_0 \neq 0 \). It then follows from Eqs. (A3),
that \( N_n \) is non zero for even \( n \) only and \( D_n \) is non zero for odd \( n \) only. Consequently, the two first equations of (A3) may be written
in the form:

\[
\dot{N}_n + i \nu_2 \gamma N_n = \chi (\gamma_{n-1} - \gamma_{n+1})
\]

where \( \gamma_n = N_n \) for even \( n \) and \( \gamma_n = D_n \) for odd \( n \).

The \( \gamma_n \) may be regarded as the components of a vector \( \gamma \) which can
be expanded on a basis of eigenvectors of Eqs. A5. The components
\( \gamma_n \) of an eigenvector \( \gamma \) associated with the eigenvalue \( \lambda_1 \) satisfy:

\[
\dot{\gamma}_n = \lambda \gamma_n
\]

and we obtain the system of linear equations:

\[
(\lambda + i \nu_2) \gamma^T = \chi (\gamma^T_{n-1} - \gamma^T_{n+1})
\]

Equations A6 may be solved by a method analogous to that used by
Feldman and Feldman. One sets:

\[
\gamma_n = (\gamma^T)^N \ c_n^T c
\]
with \( \nu = -i \lambda / k \nu \) and \( \zeta = 2i / k \nu \), which transforms Eq. (46) into:

\[
(46) \quad c_{n+1} - c_{n-1} = \frac{2i}{\zeta} c_n
\]

The general solution of this system is:

\[
(49) \quad c_n(t) = A J_0(t) + B J_1(t)
\]

where the \( J_0 \)'s are Bessel functions. In terms of the initial variables, we obtain:

\[
x_n = (-i)^n \left[ A(\lambda, z, k\nu_0, t) J_{\nu-1}(2\lambda / k\nu_0) + B(\lambda, z, k\nu_0, t) J_{\nu+1}(2\lambda / k\nu_0) \right]
\]

As there is no damping in the initial equations, we retain only the purely imaginary eigenvalues in (46). An even more restrictive condition on the eigenvalues is placed by requiring \( x_n \to 0 \) as \( n \to \infty \) for convergence of the series (44). Since \( J_0(\lambda) \) diverges when \( n \to \infty \) and \( \nu \) is not an integer, we keep \( \lambda \) such that \( i \lambda / k \nu \) is an integer. Thus the general solution for \( y_n(t) \) given as a linear combination of the \( x_n(t) \) is:

\[
y_n(t) = (-i)^n \sum_{p=0}^{\infty} a_p(\lambda, k\nu_0) J_{\nu-p}(2\lambda / k\nu_0) e^{i p k \nu_0 (t-t_0)}
\]

In order to express \( y_n(1) \) in terms of initial conditions, Eq. (410) is inverted at \( t = t_0 \), using the closure relation of Bessel functions:

\[
(411) \quad \sum_{n=0}^{\infty} J_n(r) J_n(r) = \delta_{n,0},
\]

to obtain:

\[
(412) \quad a_p(\lambda, k\nu_0) = \sum_{n=0}^{\infty} J_{\nu-p}(2\lambda / k\nu_0) y_n(t_0)(-i)^n
\]

Substituting Eq. (412) into (410) and using the summation formula for Bessel functions:

\[
(415) \quad \sum_{n=0}^{\infty} J_n(2x \sin \frac{\theta}{2}) = \frac{\sin(\theta - \frac{\pi}{2})}{\sin(\theta / 2)}
\]

we finally obtain:

\[
y_n(t) = \sum_{n=0}^{\infty} J_n(2x \sin \frac{\theta}{2}) e^{-i n (\pi / 2)} \]

This solution is equivalent to that obtained in Appendix B by directly integrating Eqs. (42). One notes that the \( n \)th harmonic is driven by all \( n \)th harmonics present at \( t_0 \).

This result enables us to calculate the polarization of the gas sample after a sequence of two square pulses. At \( t_0 \), the only non-zero spatial component is \( N_0 = y_0 \). The external field is on until \( t_0 + \nu_0 \). At this time the atomic spatial components are:

\[
y_n(t_0 + \nu_0) = N_0(t_0) e^{-i x n \nu_0 (t_0)} J_n \left( \frac{4\pi k \nu_0 (t_0)}{2} \right)
\]

Following the pulse, the atoms evolve freely, and obey the equations:

\[
y_n(t) = e^{i \omega t} \left[ N_n + \gamma N_{n+1} + \gamma N_{n-1} \right]
\]

At time \( t_1 \), the solutions are:

\[
(15) \quad \left\{ \begin{array}{l}
\dot{N}_n + i \nu N_n + \gamma N_{n+1} + \gamma N_{n-1} = 0 \\
\dot{S}_n + i \nu S_n + \gamma S_{n+1} + \gamma S_{n-1} = 0
\end{array} \right.
\]

where, for sake of simplicity, we have assumed that \( \gamma_1 = \gamma_2 = \gamma \).
\( F_0(t_1) = F_0(t_0 + \gamma t_0^2) e^{-\gamma(t_1-t_0)} \)

\[ B_n(t_1) = B_n(t_0 + \gamma t_0) \cos(\omega t_0)(t_1-t_0) - \gamma_1(t_1-t_0) \]

\[ S_n(t_1) = i B_n(t_0 + \gamma t_0) \sin(\omega t_0)(t_1-t_0) - \gamma_1(t_1-t_0) \]

The field is switched on from \( t_1 \) to \( t_1 + t_1^* \) and \( y_n(t_1 + t_1^*) \) can be determined from Eq. (A16) using initial conditions (A16). Following this pulse the system evolves freely until time \( t \) according to Eq. (A15).

At time \( t \) one must calculate:

\[ F(v_s, v_s, t) = 2 K N \int_0^N F(v_s, v_s, t) \sin(k(t-z)) dz \]

where \( F(v_s, v_s, t) = \mu(\eta_{1,2} p_{21}) = \mu(\eta \cos wt - i \eta \sin wt) \).

Substituting (A18) into (A17) and using the Fourier expansions of \( B \) and \( S \), one finds:

\[ F(v_s, v_s, t) = F_0(v_s, v_s, t) \cos wt + F_1(v_s, v_s, t) \sin wt \]

where \( F_0(v_s, v_s, t) = i \mu(\eta_{1,2} - \eta) \) and \( F_1(v_s, v_s, t) = \mu(\eta_{1,2} - \eta) \).

The quantities \( B_{21} \) and \( B_{21} \) calculated by the procedure above are:

\[ B_{21} = \frac{1}{2} [\eta \cos(\Delta t + \gamma_1 t) \cos \Delta t e^{-\gamma_1} + B_{20} e^{-\gamma t}] \]

\[ B_{21} = i \frac{1}{2} [\eta \sin(\Delta t + \gamma_1 t) \cos \Delta t e^{-\gamma_1} + B_{20} e^{-\gamma t}] \]

where:

\[ A_n = \left\{ \begin{array}{ll}
\text{odd } n & (-1)^{n-1} J_n(\nu v_s) J_n(\nu v_s) \\
\text{even } n & \Sigma J_n(\nu v_s) \sin(\nu v_s) \cos \Delta t e^{-\gamma_1} + B_{20} e^{-\gamma t}
\end{array} \right. \]

Using the symmetry properties of the Bessel functions one finds the echo amplitude:

\[ E(v_s, t) = 2 K N \int_d F_n [\rho(v_s, v_s, t)]^2 + \rho(v_s, v_s, t)]^2 \]

\[ = 4 K N \int_d F_n [A \cos(\Delta t) e^{-\gamma_1} + B e^{-\gamma t}] \]

where

\[ A = \left(1 + \SS I \sum_{n=1}^\infty (-1)^n J_n \left(\frac{4\pi}{\nu v_s} \sin \frac{\nu v_s}{2} \right) \right) \times J_n \left(\frac{4\pi}{\nu v_s} \sin \frac{\nu v_s}{2} \right) \]

\[ B = \left(1 + \SS \sum_{n=1}^\infty (-1)^n J_n \left(\frac{4\pi}{\nu v_s} \sin \frac{\nu v_s}{2} \right) \right) \times \exp(-\gamma_1) \]

Appendix B.

In Appendix A we have solved the equations in a manner which exhibits the successive echoes which are associated with the Fourier components of the solution. The equations may also be solved directly to exhibit the motion of a group of atoms starting at \( (v_s, 0 \), \( t_0 \).

Adding the two first equations in (A2) term to term we obtain:

\[ y + \frac{dy}{dt} = 21 \times y \sin k \]

\[ \frac{dy}{dt} = 21 \times y \sin k(x + v_s) \]

where \( y = N + D \).

Changing variables \( (x, t) \) to \( (x = x - v_s t, t) \) one gets:

\[ \frac{dy}{dt} = 21 \times y \sin k(\frac{x}{v_s} t) \]
The integration leads to:

\[ y(x,t) = y(x,t_0) \exp(i \int_{t_0}^{t} \sin k(x+v_s t') \, dt') \]

where:

\[ x = x-v_s t = x_0-v_s t_0 \]

With a boundary value condition at \((x_0, t_0)\), one obtains:

\[ y(x_0+v(t-t_0), t) = y(x_0,t_0) \exp(i \int_{t_0}^{t} \sin k(x_0+v(t'-t_0)) \, dt') \]

As an atom experiences the field \( y(x_0+v(t'-t_0)) = y \sin k(x_0+v(t'-t_0)) \) at time \( t' \), the integral in (L) can be understood as an average over the field amplitude along the atomic path during the pulse.

Thus:

\[ \langle x_0, t_0 \rangle < \int_{t_0}^{t} \sin k(x_0+v(t'-t_0)) \, dt' \]

and:

\[ \langle x_0+v(t-t_0), t_0 \rangle = \langle x_0, t_0 \rangle \cos \left[ \sin(2(t-t_0)) \right] - \langle x_0, t_0 \rangle \sin \left[ \sin(2(t-t_0)) \right] \]

\[ \langle x_0+v(t-t_0), t_0 \rangle = \langle x_0, t_0 \rangle \cos \left[ \sin(2(t-t_0)) \right] - \langle x_0, t_0 \rangle \sin \left[ \sin(2(t-t_0)) \right] \]

\[ \langle x_0+v(t-t_0), t_0 \rangle = \langle x_0, t_0 \rangle \sin \left[ \sin(2(t-t_0)) \right] \]

**References:**

15. The values for \( \alpha \) are close to those required to maximize the classical photon echo: \( 2 \pi \alpha t_0 = \pi / 2 \), \( 2 \pi \alpha t_1 = \pi \).

16 Unequal decay rates are treated by A. Schenzle and R. C. Brewer, Phys.

17 Longer pulses lead to a modification of the maximum echo amplitude through
Eq. (9) and to the possibility that collisions can remove atoms from
the limited velocity classes excited by a long pulse. The collisional
effect can be compensated for by an appropriate increase in \( \Gamma_c \).

18 P. R. Berman, Appl. Phys. (Germany) 5, 283 (1975).

19 For weak velocity-changing collisions \( a = \frac{3}{5} \). (Note: \( a \) in Ref. 4
= \( \frac{2}{5} \) (ah) of this work). For weak collisions, an expression for the
entire range of \( h(\alpha) \) (see Ref. 4 and A. Flasberg, to appear in Opt.
Comm.) may be obtained. Expressions of the form \( \exp(\int_{\Gamma_c}^{\infty} f \alpha \, \alpha \, d\alpha) \)
lead to an echo contribution going as

\[
\exp \left\{ - \int_{0}^{\infty} \left( 1 - \int W(v'-v) \exp[\alpha k(v-v') t] \, dv' \right) \, dt \right\}
\]

where \( W(v') \) is the collision kernel. This equation provides the limits
shown in Eqs. (13) and (14).
