INTRODUCTION

The complex dielectric properties of rocks are interesting scientifically and important practically. The scientific interest derives from a desire to understand the properties of materials, the electrical structure of the earth's crust, and the (electrical) loss mechanisms in the crust. The practical significance stems from potential applications in borehole logging, geothermal prospecting, mineral prospecting, and in lithospheric radiowave communications.

The dielectric properties of rocks and minerals have been reported previously by several investigators; for examples, see Parkhomenko (1967 and references cited by her), Iglesias and Westphal (1967), Saint-Amant and Strangway (1970), and Olhoeft (1979). Methods of measurement have been described by von Hippel (1954), Alvarez (1973), and General Radio (1974, undated). The real part of the permittivity ($\varepsilon'$) of a rock is an average of the permittivity of the individual minerals; the volume fraction of each mineral appears to be a suitable weighting function for most purposes. The loss factor ($\varepsilon''$) obviously depends on the various loss mechanisms present and on the frequency. In rocks, the value and behavior with temperature and frequency are dominated by the water (and dissolved ions) present in microcracks. In this study, we have removed the water from the microcracks in order to obtain data suitable for use in inferring the properties of rocks at depths where the microcracks are not present. Such depths may be as shallow as 1 km, see Feves et al. (1977) for examples and further discussion of the effect of pressure on microcracks.
NOTATION AND TERMINOLOGY

We follow the notation and terminology of von Hippel (1954). The dielectric properties of a material may be described by the complex permittivity

\[ \varepsilon^* = \varepsilon' - j\varepsilon'' \]

where \( \varepsilon' \) is the permittivity and \( \varepsilon'' \) is the loss factor. The complex relative permittivity

\[ K^* = \varepsilon^*/\varepsilon_0 = K' - jK'' \]

where \( \varepsilon_0 \) is the permittivity of vacuum, \( K' \) is the relative permittivity (also usually termed relative dielectric constant), and \( K'' \) is the relative loss factor. The loss tangent (\( \tan \delta \)) is given by

\[ \tan \delta = \frac{\varepsilon''}{\varepsilon'} = \frac{K''}{K'} \]

The dielectric conductivity, which includes all dissipative effects, is

\[ \sigma = \omega \varepsilon''. \]

In our work, we have measured \( K' \) and \( \sigma \) and report them.
THE SAMPLES

The rocks used in this study consist of a suite of igneous and metamorphic rocks. The igneous rocks are a subset of the rocks used by Feves et al. (1977) and described by Richter and Simmons (1977). The metamorphic samples have not been used in previous studies (except 1727); they are described in Appendix A of this report (except 1727). See Padovani et al. (1980) for description of 1727. The location and rock types are given in Table 1.

EXPERIMENTAL TECHNIQUES AND APPARATUS

Water was removed from the microcracks in each specimen by drying in a vacuum oven at approximately 140°C and 30 mm Hg pressure for several days.

The real part of the dielectric constant ($\varepsilon'$) and the dielectric conductivity ($\sigma$) were then measured with a General Radio model 1621 capacitance measurement system, described by General Radio (1974, undated) over the frequency range 100-50,000 Hertz. A three-terminal sample holder was used.

A home-made glove box was used to isolate the specimen and specimen holder from the water vapor present in the laboratory air during the time required for each measurement.
THE DATA ON DIELECTRIC PROPERTIES

Values of $K'$, $K''$, tan $\delta$, and $\sigma$ are given in Appendix B of this report for the suites of igneous and metamorphic rocks.

Plots of $K'$, tan $\delta$, and $\sigma$ as functions of frequency and a Cole-Cole plot (relative permittivity versus relative loss factor) for each sample are given also in Appendix B.
DISCUSSION

This discussion of the results is considered to be preliminary because the compositions of the major phases, the crack sealing phases, and the fluid inclusions have not yet been determined for the metamorphic samples. Neither has the composition of the fluid inclusions been determined for the igneous rocks. And finally, the degree of alteration of the feldspars, which is expected to be a significant factor in determining the dielectric conductivity, has not been measured. However, some features do appear worthy of mention.

The dielectric conductivities of the igneous and metamorphic rocks are all quite low, of order of $10^{-7}$ mho/m at 100 Hertz and $10^{-5}$ mho/m at 50,000 Hertz. Because the samples were chosen to be representative of the rocks in the eastern half of the United States, these values of conductivity are also likely representative.

The igneous rocks, considered as a group, show surprisingly little variation — one order of magnitude for a given frequency. There appears to be little dependence on rock type; the values for gabbro and diabase are approximately equal to the values for granite and rhyolite. Clearly, within the igneous group, the major determinant is not gross lithology.

The dielectric conductivities of the metamorphic rocks are generally lower (by roughly an order of magnitude) than the values for the igneous rocks. Obviously, there exist several exceptions: Troy granite (83) and the calc-silicate rock from Maine (2434).

The thickness of the specimen has little effect on the measured values. Although we measured $K'$ and $\sigma$ for a 'thick' and a 'thin' disc of each specimen, we report typical values for a single sample only (2426-1 and 2426-2). The two discs were 33 mm and 6 mm thick, respectively. At 100 Hz, the values of $\sigma$ are 2.2 and $1.9 \times 10^{-8}$ mho/m, respectively. At 50,000 Hertz, they are
1.5 and $1.3 \times 10^{-8}$ mho/m. The chief source of the differences of values between 'thick' and 'thin' specimens is believed to be the presence of trace amounts of water that remained in the microcracks of the 'thick' specimen.
CONCLUSIONS

The dielectric conductivity of igneous and metamorphic rocks from eastern United States is of order $10^{-7}$ mho/m and $10^{-8}$ mho/m, respectively, at a frequency of 100 Hertz, temperature of 20°C, and at simulated crustal conditions such that the microcracks are chemically closed.
REFERENCES

APPENDIX A

Sample Descriptions
Preliminary petrographic and microcrack descriptions of the samples that have not been described previously are included in this appendix. We have examined both polished thin sections and crack sections with the petrographic microscope and the SEM. We follow the terminology and procedures of Simmons and Richter (1976) and Richter and Simmons (1977).

Sample: 2383
Location: Adirondack Mountains

Petrographic and Microcrack Description:

Sample 2383 is an unequigranular, unfoliated garnet-hornblende-hypersthene (pyroxene)-plagioclase granulite with lesser amounts of clinopyroxene, K-feldspar, and pyrite. Garnet, hornblende, and clinopyroxene occur as subhedral, fine-grained (0.5 mm) aggregates separated by coarse hypersthene and plagioclase. Hypersthene occurs as medium-grained isolated crystals with large zones of abundant inclusions. Plagioclase ranges from coarse, isolated grains with spotty sericitized zones to fine-grained polycrystalline aggregates. Minor biotite is present as clusters of subhedral grains typically associated with pyrite.

Intragrain cracks (IGC) and grain boundary cracks (GBC) are the most abundant crack types. In garnet, open IGC are several microns wide and extend to the grain boundary whereas IGC in plagioclase are short and narrower. Partially healed IGC occur in several hornblende grains and appear as planes of microtubes (figure A-1A). A network of open and sealed GBC ranging in width from 2-20 microns is developed around the garnet-hornblende-clinopyroxene aggregates (figure A-1B). Walls of many of these cracks are jagged and appear to have been widened by alteration and/or dissolution (figure A-1C). Extensive pyrite mineralization has occurred along many grain boundaries (figure A-1D). Occasional isolated fluid inclusions are present in plagioclase and quartz.
Figure A-1A. Sample 2383. Partially healed intragrain crack (IGC) in hornblende. IGCs appear as a set of subparallel microtubes. Scale bar is 40 microns. Transmitted light photomicrograph.
Figure A-1B. Sample 2383. Open grain boundary cracks (GBC) around hornblende-pyroxene aggregate. GBCs in this sample are best developed around these phases. BSEI.
Figure A-1C. Sample 2383. Enlargement of portion of figure A-1B. Grain boundary
cracks between adjacent hornblende and pyroxene grains. Walls of the GBC are
jagged and appear to have been widened by dissolution. The large bright grain
is pyrite. BSEI.
Figure A-1D. Sample 2383. Extensive pyrite mineralization (bright phase) along grain boundary cracks around hornblende-pyroxene-garnet plagioclase aggregates. BSEI.
Sample: 2390

Location: Adirondack Mountains, Northern New York

Petrographic and Microcrack Description:

Sample 2390 is a medium to coarse-grained unfoliated quartz-K feldspar-plagioclase-garnet rock. Figures A-2A and A-2B show typical textures. Quartz and perthite are anhedral, occur as coarse individual grains or medium-grained polygonal aggregates and comprise approximately 80% of the sample. Garnet occurs as coarse (5.0 mm), rounded porphyroblasts containing abundant mineral inclusions. Biotite is present as aggregates of subhedral, elongate crystals and as isolated platy grains. Minor phases include chloritized hornblende, magnetite, rutile, and sphene.

Grain boundary cracks (GBC) around quartz, perthite, and plagioclase and various types of intragrain cracks (IGC) are the most abundant microcracks in this sample. Opened, partially healed (i.e. bubble planes) and rutile sealed IGC are present in quartz (figure A-2C). Bubble planes are typically subparallel, occur in sets and consist of fluid inclusions of varying sizes (figures A-2A and A-2B). Occasional plagioclase grains contain partially healed IGC that appear as bubble planes or as partially sealed cracks (figure A-2D). GBC between quartz and feldspar are 1-3 microns wide and have straight, even walls. Isolated, randomly oriented fluid inclusions occur in quartz and to a lesser degree in plagioclase.
Figure A-2A. Sample 2390. Subparallel set of healed intragrain cracks (i.e. bubble planes) in quartz (central grain). Note the presence of numerous isolated fluid inclusions within this same grain. Transmitted light photomicrograph. Scale bar is 200 microns.
Figure A-2B. Sample 2390. Subparallel planes of fluid inclusions (i.e. bubble plane) in quartz. The bubble plane in the center of the micrograph intersects an open intragrain crack. Open grain boundary cracks between adjacent feldspar grains and between quartz and feldspar are abundant in this sample. BSEI.
Figure A-2C. Sample 2390. Open grain boundary crack between adjacent quartz and plagioclase grains which is crosscut by a rutile(?) sealed transgranular crack (TGC) in quartz. BSEI.

Figure A-2D-2. Sample 2390. Enlargement of the healed IGC. Note the irregular shape of the fluid inclusions along the crack. BSEI.
Sample: 2422
Location: Central Maine

Petrographic and Microcrack Description:

This sample is a fine-grained (less than 0.1 mm), non-foliated calcareous metasandstone (low grade) with small amounts of clay, mica, and an opaque mineral. Calcite occurs as subhedral crystals surrounded by polycrystalline quartz which appears as large continuous grains. Abundant pores, which vary from round to angular, are present in both quartz and calcite.

Grain boundary cracks (GBC) are the most common type of crack in this sample. GBCs between adjacent quartz grains and between quartz and calcite are poorly developed, vary from open to partially healed, and are less than 0.5 microns in width. Occasional intragrain cracks are present in calcite and, to a lesser extent, in quartz.
Sample: 2425
Location: Waterville, Maine

Petrographic and Microcrack Description:

Sample 2425 is a medium-grained, non-foliated quartzo-feldspathic metaigneous rock. Typical textures are shown in figures A-3A and A-3B. Quartz and plagioclase comprise about 75% of the sample; alkali feldspar, garnet, and biotite are present in lesser amounts. Quartz occurs as individual grains and as coarse, polycrystalline aggregates of optically discontinuous grains. Plagioclase grains are equant to elongate, extremely sausseritized and contain abundant solid and liquid inclusions which account for the highly porous texture observed in SEM micrograph (figure A-3B). Clusters of biotite, chlorite, and sericite occur within these highly altered zones. Radiogenic mineral inclusions are common in biotite.

Intragrain cracks (IGC) and grain boundary cracks (GBC) are abundant in this sample and are best developed within and around quartz, plagioclase, and garnet. GBC between adjacent quartz grains vary from open (5.0 microns) to almost totally healed. Delicate bridges across these GBC and trails of fluid inclusions, which appear continuous with grain boundaries, are common (figure A-3C). Two distinct types of IGC are observed in plagioclase. The first type varies from open to almost totally healed and is coincident with twin planes; these IGC are only a fraction of a micron wide. The second type is 5.0 microns or less in apparent width, are randomly oriented, and either open or partially sealed with blades of chlorite (figure A-3A). Occasional transgranular cracks (TGC) of varying widths (figure A-3D) occur within this sample. An individual microcrack rarely intersects more than two grain boundaries.

Fluid inclusions are common in quartz (predominantly bubble planes) and extremely abundant in altered plagioclase. Pores in plagioclase are irregular in shape and range in size from 15 microns to tenths of a micron.
Figure A-3A. Sample 2425. Open and chlorite sealed intragrain cracks (IGC) in an altered plagioclase grain. Clusters of fluid inclusions are abundant and unevenly distributed within this grain. BSEI.
Figure A-3B. Sample 2425. Altered plagioclase grain with a high abundance of fluid inclusions. Note the open intragrain cracks which crosscut this grain. BSEI.
Figure A-3C. Sample 2425. Partially healed grain boundary cracks (GBC) around adjacent quartz grains. Note the delicate mineral bridges which cross the GBC and the trail of fluid inclusions continuous with GBCs. These bridges indicate that the microcracks were open in situ. BSEI.
Figure A-3D. Sample 2425. Adjacent quartz (smooth, dark), plagioclase (porous texture), and biotite (bright phase) grains. Note the transgranular crack (TGC) which crosscuts a quartz-biotite grain boundary and the partially healed grain boundary cracks in quartz. Central portion is enlarged in figure A-3C. BSEI.
Sample: 2426
Location: Rockport, Maine

Petrographic and Microcrack Description:

Sample 2426 is a metaquartz conglomerate with a bimodal grain size distribution. Typical micrographs are shown in figure A-4A. Matrix quartz, which is medium-grained (0.2 mm or less), occurs as irregularly shaped, interlocking grains. Rounded, elongated pebbles (greater than 2.0 mm), composed of aggregates of interlocking quartz, are unevenly distributed throughout the sample. The matrix portion is characterized by (1) angular pores which vary from 5 to 75 microns, typically occur at the junction of grain boundaries and are either empty or filled with clusters of a micaceous mineral in association with clay, (2) open or sealed grain boundary cracks (GBC) less than 2 microns in apparent width, the sealing phases are a mica and clay, (3) abundant fluid and mineral inclusions. Figure A-4A illustrates these features.

Microstructurally, the polycrystalline quartz pebbles differ from the matrix quartz in that (1) no intergrain pore spaces are present, (2) GBC are either open or partially healed, i.e. intergrain mica is absent, and (3) fluid and mineral inclusions are less abundant.

An extensive, anastomosing network of sealed multigrain cracks (MGC) extends the entire length of the thin section; the predominant crack sealing phase is an Fe-Mg bearing mineral (figure A-4B). The MGC intersects several coarse (2.0-5.0 mm) prismatic Fe-Mg sulfide crystals which are rimmed and brecciated by the Fe-Mg crack sealing phase. Occasional fractured, elongated muscovite grains occur within the MGC.
Figure A-4A-1. Sample 2426. Representative area of the matrix quartz fraction of the metaconglomerate. Muscovite (brighter phase) occurs as clusters between quartz grains and occasionally along grain boundaries.
Figure A-4A-2. Sample 2426. Enlargement of portion of figure A-4A-1. Grain boundary cracks vary 1-10 μm open to partially healed. BSEI.
Figure A-4B-1. Sample 2426. Extensive, anastomosing multigrain crack (MGC) network intersecting prismatic Fe-Mg sulfide crystals. The sulfide crystals are rimmed and fractured by an Fe-Mg crack sealing phase (see figure A-4B-3 for EDS pattern) which is the major crack sealing phase. BSEI.
Figure A-4B-2. Sample 2426. Enlargement of an area in figure A-4B-1. The bright phase is composed of Fe and Mg. Occasional muscovite (elongate crystal) occurs within the MGC network. The dot marks the location of the EDS analysis given in figure A-4B-3. BSEI.
Figure A-4B-3. Sample 2426. EDS spectrum of crack sealing phase shown in figure A-4B-2. The peaks (left to right) are MgK (1.3 KeV), SiK (1.7 KeV), KK (3.3 KeV), FeK (6.4 KeV), and FeK (7.1 KeV).
Sample: 2428
Location: Camden, Maine

Petrographic and Microcrack Description:

Sample 2428 is a metaquartz conglomerate with a bimodal grain size distribution. Typical micrographs are given in figures A-5A and A-5B. The matrix quartz fraction is composed of irregularly shaped, interlocking grains with apparent grain sizes between 0.2 and 0.4 mm. The pebble fraction consists of coarse (greater than 2.0 mm) rounded, elongated, polycrystalline grains which can be subdivided into two types based on the size of individual quartz grains. The first type is fine-grained (0.1 to 0.2 mm), occurs in irregularly shaped pebbles and contains abundant inclusions. The second type is coarser-grained (0.6 to 1.0 mm), occurs in well-rounded pebbles and contains fewer inclusions. Biotite and muscovite are present as platy or elongated crystals within grain boundaries or as irregularly shaped clusters (figure A-5B); occasional pyrite occurs within these clusters.

Grain boundary cracks are the most abundant crack type in this sample. GBC around matrix quartz and fine-grained polycrystalline grains vary from open to sealed, have apparent width less than 0.5 microns, and contain abundant biotite and muscovite (figure A-5C). Many of the GBC are continuous around irregularly shaped pores, which are abundant in this sample. GBC around the coarse, polycrystalline grains are wider (0.5 to 10 microns) and contain open or partially sealed (with rutile) segments (figure A-5D); interstitial muscovite and biotite are absent. Occasional intragrain cracks, which appear as planes of fluid inclusions, occur only within the coarser fraction (figure A-5A).
Figure A-5A. Sample 2428. Subparallel set of bubble planes which are continuous across a quartz-quartz grain boundary. Area is within a polycrystalline quartz pebble. Transmitted light micrograph. Scale bar is 200 microns.
Figure A-5B. Sample 2428. Matrix (right) and pebble (left). This micrograph illustrates the great variation in abundance and distribution of (a) interstitial biotite (bright phase) and muscovite (light gray) and (b) pores between the matrix and pebble fractions. A typical area in the matrix is enlarged in figure A-5C. BSEI.
Figure A-5C. Sample 2428. Grain boundary cracks (GBC) around matrix quartz grains. GBCs vary from open to partially healed and commonly terminate at the intersection of a biotite or muscovite grain. BSEI.
Figure A-5D-1. Sample 2428. Grain boundary cracks (GBC) and intragrain cracks (IGC) associated with polycrystalline quartz grains in the pebbles. GBCs are partially sealed with rutile (bright phase). A plane of fluid inclusions trends subparallel to an open GBC. BSEI.
Figure A-5D-2. Sample 2428. Enlargement of the central area of figure A-5D-1. Note the presence of several, randomly oriented fluid inclusions. BSEI.
Sample: 2432

Location: Camden, Maine

Petrographic and Microcrack Description:

Sample 2432 is a foliated metaquartz conglomerate composed of elongate, polycrystalline pebbles (individual grains are 0.3 mm) in a fine-grained (less than 0.15 mm) matrix of quartz and muscovite. Muscovite occurs as aggregates of blade-like crystals which appear as subparallel, discontinuous grains aligned with schistosity between quartz grains; these aggregates vary from 0.01 to 0.20 mm in apparent width. A typical view of quartz grains and matrix is shown in figure A-6A. Numerous angular cavities (less than 75 microns) occur in the matrix fraction (figure A-6B) and to a lesser extent in the polycrystalline pebbles. These cavities vary from empty to totally filled with intergrown muscovite and clay (figure A-6B). Isolated pyrite crystals occur in association with these phases.

Grain boundary cracks (GBC) are the most abundant type of crack in this sample. GBC around matrix quartz grains are less than 0.5 microns in apparent width, vary from partially healed to partially sealed with muscovite blades, and typically terminate at a cavity wall (figures A-6A and A-6C). GBC around quartz pebbles are wider (2-15 microns) and contain abundant muscovite and clay (figure A-6A). Solid and fluid inclusions are abundant in both matrix and pebble quartz grains.
Figure A-6A. Sample 2432. Muscovite-clay sealed grain boundary crack around a rounded, slightly elongate quartz grain. Note the low density solid or fluid inclusions in this grain. BSEI.
Figure A-6B-1. Sample 2432. Representative area in fine-grained matrix portion of this sample. Grain boundary cracks between adjacent quartz grains are poorly developed. Note the abundance of angular cavities. BSEI.
Figure A-68-2. Sample 2432. Enlargement of central portion of figure A-68-1. Cavities range from empty to filled with clay and/or muscovite. Arrow denotes location of figure A-6C. BSEI.
Figure A-6C. Sample 2432. Partially healed grain boundary crack between adjacent quartz grains in the matrix. Abundant fluid inclusions are present in quartz. BSEI.
Sample: 2434
Location: Camden, Maine

Petrographic and Microcrack Description:

Sample 2434 is a metamorphosed, extremely fine-grained (less than 0.1 mm) interbedded siliceous limestone (i.e. calc-silicate). Compositional bands are discontinuous, are highly contorted and irregular, range in thickness from 0.75 to 10 mm and are divisible into three general types of mineral assemblages. The most abundant type consists of interlocking angular calcite, rounded quartz grains, and biotite blades (figure A-7A). Numerous intragrain and interstitial pores occur in and between calcite grains. The second type consists of intergrown clay and biotite and diopsidic pyroxene with lesser amounts of quartz, calcite, and sphene (figure A-7B). The third type, which occurs as narrow (0.4 mm or less) bands, consists of rounded quartz grains and muscovite with minor amounts of clay and sphene (figure A-7C). Contacts between adjacent compositional layers range from sharp to gradational.

Grain boundary cracks around adjacent calcite grains and intragrain cracks in calcite are the only microcracks in this sample. The GBC vary from open to partially healed and have apparent widths less than 0.5 microns (figure A-7D). All IGC appear as bubble planes which terminate at a grain boundary.
Figure A-7A. Sample 2434. Calcite-quartz-biotite compositional layer containing abundant angular pores. Quartz (dark phase) and biotite are evenly distributed throughout the layer. This unit grades into a more quartz-biotite rich layer to the right; the left boundary is defined by a sharp contact with a calc-silicate band containing sphene and diopsidic pyroxene. BSEI.
Figure A-7B. Sample 2434. Calc-silicate layer containing diopsidic pyroxene, sphene and intergrown clay (possibly an alteration product of muscovite) and biotite. This unit is completely devoid of any microcrack. Note the presence of clusters of fluid inclusions. BSEI.
Figure A-7C. Sample 2434. Quartz-muscovite rich layer (arrow) sandwiched be-
tween a calc-silicate unit (right) and a calcite-rich layer (left). The quartz-
muscovite mineral assemblage is present in thin, discontinuous bands. BSEI.
Figure A-7D-1. Sample 2434. Open grain boundary cracks and healed intragrain cracks (IGC) associated with calcite. These cracks are the only cracks observed in this sample. BSEI.
Figure A-7D-2. Sample 2434. Enlargement of an area in figure A-7D-1. The healed IGCs appear as planes of fluid inclusions. BSEI.
Sample: 2439  
Location: Central Maine  
Petrographic and Microcrack Description:

Sample 2439 is a medium to coarse-grained quartzo-feldspathic, biotitic migmatite. Compositional bands are continuous, range in width from 2-10 cm, and are divisible into two types of mineral assemblages. The first type, which is medium-grained, consists of quartz, plagioclase, and biotite with lesser amounts of muscovite and garnet. Parallel alignment of biotite, which occurs as clusters of subhedral, blade-shaped crystals, defines a well-developed foliation. Quartz grains tend to be elongated in the direction of foliation. Porphyroblasts of plagioclase are partially sericitized. The second type, which is medium to coarse-grained, consists of K-feldspar, quartz, and plagioclase interlayered with thin bands composed of muscovite intergrown with sillimanite needles, garnet porphyroblasts and thin granulose quartz bands. Alkali feldspar is coarse, sometimes polycrystalline and slightly sericitized.

Intragrain cracks are the most abundant crack type in this sample. Two types of IGC occur in quartz: (1) anastomosing microcracks with open and partially sealed segments, many of which are bound on either end by abrupt changes in microcrack direction (figure A-8A) and (2) healed microcracks (i.e. planes of fluid inclusions) (figure A-8B). In K-feldspar, IGC are typically isolated, subparallel and open (figure A-8B).

Fluid inclusions in K-feldspar occur as (1) distinct planes within individual grains (figure A-8B), (2) broad bands which parallel grain boundaries (figure A-8C), (3) isolated clusters unevenly distributed within grains. Plagioclase grains contain abundant inclusions, many of which are filled with sericite (figure A-8B). Poorly developed grain boundary cracks occur between adjacent quartz grains and at the borders of feldspar (potassium and plagioclase) and quartz grains.
Figure A-8A-1. Sample 2439. Anastomosing intragrain cracks (IGC) in quartz. IGCs in quartz contain both open and partially sealed segments. They typically terminate on other cracks with low angle intersections. BSE1.
Figure A-8A-2. Sample 2439. Enlargement of central area of figure A-8A-1. Note the abundance of fluid inclusions. BSEI.
Figure A-8B-1. Sample 2439. Intersection between a partially healed (i.e. bubble plane) intragrain crack (IGC) and an open IGC in quartz. The left end of the partially healed crack is enlarged in A-8B-2. BSEI.
Figure A-8B-2. Sample 2439. Intersection between a partially healed (i.e. bubble plane) intragrain crack (IGC) and an open IGC in quartz. Enlargement of segment of bubble plane seen in figure A-8B-1. At this location, the healed IGC is defined by a series of short, overlapping bubble planes (i.e. en echelon cracks). BSEI.
Figure A-8B-3. Sample 2439. Intersection between a partially healed (i.e. bubble plane) intragrain crack (IGC) and an open IGC in potassium feldspar. Note the thin dark parallel lines which indicate cleavage. Absence of surfaces on sides of the large crack, the generally smooth surface of the crack, the failure of the 10μ-size fragment to break along cleavage directions are evidence that the crack was present in the rock in situ and was not produced by sample collecting, handling, or preparation.
Figure A-8C-1. Sample 2439. Plagioclase (porous phase) contains abundant solid and fluid inclusions. Arrow indicates area seen in figure A-8C-2. BSEI.
Figure A-8C-2. Sample 2439. Enlargement of inclusions in plagioclase. BSEI.
Figure A-8D. Sample 2439. Agglomeration of fluid inclusions around the periphery of a potassium feldspar grain. The elongate mineral is muscovite. BSEI.
Sample: 2441

Location: Camden, Maine

Petrographic and Microcrack Description:

Sample 2441 is a quartz-plagioclase-biotite-andalusite schist with a well-developed foliation defined by the parallel alignment of subhedral blades of biotite (figure A-9A). Elongate aggregates of columnar andalusite crystals occur in association with biotite. Quartz is present as coarse, elongate grains and as finer-grained, irregularly shaped crystals which together comprise quartzose bands (several mm wide) which parallel the foliation. Plagioclase is coarse, sometimes polycrystalline with large zones of extensive sericitization.

Grain boundary cracks (GBC) are best developed around andalusite and quartz (figure A-9A). GBC range from 1 to 10 microns in width, typically have jagged walls, and are either open or sealed with a clay phase (figure A-9A). Occasional GBC between plagioclase and andalusite contain brecciated material enveloped by clay and platy muscovite crystals. Quartz contains numerous open intragrain cracks (IGC) which extend from the grain boundary and terminate within the grain before intersecting another grain boundary (figures A-9B and A-9C). Many of the IGC are oriented perpendicular to the direction of elongation. Abundant subparallel sets of healed IGC (i.e. planes of fluid inclusions) are ubiquitous in quartz (figure A-9C).
Figure A-9A-1. Sample 2441. Representative area of this sample, illustrating the textural relationships between andalusite (dark gray), plagioclase (light gray), biotite (bright phase), and muscovite. Sealed grain boundary cracks (GBC) occur around columnar andalusite crystals and polycrystalline plagioclase. Central portion is enlarged in figure A-9A-2. BSEI.
Figure A-9A-2. Sample 2441. Enlargement of clay-sealed GBCs around andalusite crystals. BSEI.
Figure A-9B. Sample 2441. Open grain boundary crack (GBC) and intragrain crack in quartz. Note the abundance of fluid inclusions. Transmitted light micrograph. Scale bar is 200 microns.
Figure A-9C-1. Sample 2441. Open and partially healed intragrain cracks (IGC) in quartz. Healed IGCs (bubble planes) typically occur in subparallel sets.
Figure A-9C-2. Sample 2441. Enlargement of central area of figure A-9C-1. These fluid inclusions record many episodes of fracturing and sealing.
APPENDIX B

Dielectric Properties of Selected Igneous and Metamorphic Rocks
A table of data on the dielectric property (permittivity and dielectric conductivity) as a function of frequency is given for each specimen. The data are also given in graphical form.
