APPROVED FOR PUBLIC RELEASE
DISTRIBUTION UNLIMITED
FOREWORD

This program was performed by The University of Tennessee Space Institute for the Naval Air Systems Command Advanced Aircraft Development and Systems Objectives Office (AIR-03PA) under Naval Air Systems Command Contract N00019-81-C-0508, dated 30 September 1981. Active testing began on 30 October 1981 and was completed on 30 August 1982.

A total of 37.2 hours of flying time were flown in the performance of this task along with eleven months of analytical effort.

The following key personnel were primarily responsible for the conduct of this test, the analytical effort and/or the preparation of this report.

UTSI

Principal Investigator and Project Test Pilot
Ralph D. Kimberlin, Associate Professor

Research Assistants
Uwe P. Solies
Atin K. Sinha

Instrumentation Engineer
Robert Jones

Aircraft Maintenance
Donald Freeman

Support Groups

EXECUTIVE SUMMARY

The Ball-Bartoe "Jetwing" is a single engine upper surface blowing (USB) concept which achieves supercirculation lift, thrust, and a reduction in induced drag by ducting all engine air through the leading edge of the wing and ejecting it over the top surface through a slot nozzle. This nozzle is located at approximately 30 percent of the chord and extends along about 70 percent of the wing span. A Coanda flap of 55 degrees extension capability is mounted at the trailing edge of the blown portion of the wing. In addition to the main wing, a smaller wing panel is mounted above the slot nozzle. The air passage between the main wing and the smaller upper wing acts as an ejector to increase exhaust mass flow. The concept may be used with or without the upper wing. A thrust reversing method is also incorporated into the concept. The thrust is reversed by rotating the top of the slot nozzle so as to close the nozzle and open a reverse flow path.

The "Jetwing" concept has been incorporated into a research airplane. The Jetwing aircraft is a single seat, jet aircraft of conventional design powered by a Pratt and Whitney of Canada JT15D-1 turbofan engine of 2200 pounds static thrust. The aircraft has a wing span of 21.75 feet, a wing area of 105.8 square feet, and a maximum gross weight of 3750 pounds.

This report covers the results of a flight test program with the upper wing removed, a measurement of flyover noise with and without the upper wing, and the results of an analytical study into methods for predicting the Jetwing aerodynamic coefficients. A comprehensive flight test program with the upper wing installed was previously conducted under a separate effort. Both programs were conducted for Naval Air Systems Command by the University of Tennessee Space Institute. The purpose of these efforts was to validate the NASA Ames Research Center full scale wind tunnel data on the aircraft by flight test, develop methods for predicting aerodynamic coefficients for such a concept, and to obtain performance, stability, control, and noise data sufficient to evaluate the Jetwing concept for future application to other flight vehicles.

Test results show an excellent agreement between the flight test and wind tunnel in all items except lift coefficient versus angle of attack. The disagreement between wind tunnel and flight test on this item was most likely due to measurement inaccuracies in the flight test, and the round about data reduction method required to extract flight test data for comparison.

The test results also show significant differences between the performance and handling qualities of the aircraft with and without the upper wing. The configuration without the upper wing is superior from both the performance and handling qualities standpoint. The reason for these differences is not fully understood, but it is felt to be a function of both the zero lift drag increase and the increase in thickness of the USB jet with the upper wing installed. The question concerning USB jet thickness also has implications for USB configurations other than the Jetwing.

The flyover noise levels of the Jetwing airplane are very low with the aircraft noise disappearing into the background noise in a light wind. Aircraft configuration did not appear to have significant effect upon these levels. Such low noise levels has important significance for military airplanes, particularly those involved in ground attack.

Results of the analytical study showed that lift and excess thrust (or drag) coefficients could be predicted with reasonable accuracies using relatively simple methods. Pitching moment coefficient was more difficult to predict using simple methods, and will probably require use of the more complex, panel or vortex lattice, methods.

INTRODUCTION

This report covers the results of a two part research effort on the Ball-Bartoe “Jetwing” propulsive lift concept. This effort was conducted by the University of Tennessee Space Institute, Tullahoma, Tennessee for the Advanced Aircraft Development and Systems Objectives Office (AIR-O3PA) of Naval Air Systems Command under Contract Number N00019-81-C-0506.

The first part of the effort, which is covered in Part I of this report, was a follow on to a previous effort conducted under Naval Air Systems Command Contract Number N00019-80-C-0126 and reported in UTSI Report 81-1 [1]. The effort reported herein consisted of a performance flight test with the upper wing (ejector wing) removed, and flyover noise measurements with and without the upper wing. Performance, Stability and Control flight test with the upper wing installed were a part of the previous effort.

The second part of the effort consisted of an analytical study to develop a method, or methods, to predict the aerodynamic coefficients of a “Jetwing” configured aircraft. These coefficients would be of sufficient accuracy for use in preliminary design studies. The results of this analytical effort are reported in Part II of this report.

Results of both the flight test and analytical effort are compared to full scale test results of the research aircraft in the NASA Ames Research Center 40' x 80' wind tunnel with the aim of evaluating the Jetwing concept for applications to future flight vehicles.
PART I

FLIGHT TEST REPORT
SECTION I
INTRODUCTION

This section of the report covers the flight testing of the Ball-Bartoe "Jetwing" Research Aircraft with the upper wing removed. The purpose of these tests was to evaluate the Jetwing powered lift concept for future application to other flight vehicles by:

1. Obtaining performance and $C_L$ vs. $\alpha$ data with the upper wing removed sufficient to validate the NASA Ames Research Center 40' x 80' wind tunnel data for this configuration.

2. Obtaining flyover noise data in several configurations of gear, flaps and power setting with and without the upper wing installed.

Flight tests were started on October 30, 1981 and completed on August 30, 1982. A total of 52 flights were flown for 37.2 flying hours to accomplish the test objectives. All test objectives were met and the results are given in Section V of this part of the report.

Flight testing of the aircraft with the upper wing installed was conducted under Naval Air Systems Command Contract N00019-80-C-0126 and reported in [1].
SECTION II
DESCRIPTION OF THE TEST ARTICLE

DESCRIPTION

The Jetwing STOL research aircraft is a single engine, single seat, upper surface blowing (USB) powered lift, jet aircraft with conventional landing gear (Figures 1 and 2). Figure 3 is a three view drawing of the aircraft showing its general arrangement. Table [1] lists other pertinent design features and dimensions.

The powered lift concept used on the Jetwing aircraft allows upper surface blowing (USB) from a single jet engine. Upper surface blowing has previously been limited to multi-engine configurations such as Boeing YC-14 and NASA Quiet Shorthaul Research Aircraft (QSRA). In the "Jetwing" concept USB is achieved from a single engine by ducting all engine air (both from by-pass and core exhaust) to a slot nozzle on the upper surface of the wing. The nozzle is located at approximately 30-40 percent of the wing chord and extends along approximately 70 percent of the wing span. The fan by-pass air is ducted to the outboard portion of the wing while the core exhaust is ducted to the inboard portion of the wing as is shown in Figure 4. Located above the nozzle is a separate, and much smaller wing surface. The purpose of this surface is to act as an ejector or thrust augmentor. A Coanda type, single element flap is located at the trailing edge of the wing along the portion of the wing span covered by the nozzle. A two-dimensional sketch of the arrangement is shown in Figure 5.

The concept may be used with, or without, the smaller upper wing surface which wind tunnel tests have shown to have negligible effect on powered lift capabilities (See Figures 6 and 7). All testing reported herein was conducted with the upper wing removed as shown in Figure 1.

Incorporated into the fan by-pass air nozzle is a thrust reverser which is operated as is shown in Figure 8.

Since the USB covers such a large portion of the wing span, a separate bleed air system for the ailerons is not required.

SECTION III
TEST PROCEDURES

The test procedure used to accomplish this effort followed standard flight test practice except as required to account for flight safety and test vehicle limitation.

The aircraft's aerodynamic configuration during these tests was the same as that tested in the wind tunnel at Ames Research Center (upper wing removed) except for changes necessary to install flight test instrumentation.

Prior to collecting flight test data the aircraft configuration was defined in detail. During testing a configuration log was maintained which recorded all changes made to the aircraft configuration including instrumentation and flight trim adjustments. This log was cross-referenced with aircraft flight number so that it was possible to determine the exact configuration during any test flight.

For performance testing the aircraft loading was 3691 lbs. gross weight with the center of gravity at 35.17 percent M.A.C. This loading is equidistant between the two c.g.'s tested in the wind tunnel.

Prior to the start of testing the actual aircraft weight and c.g. was determined by weighing the aircraft with pilot, fuel load and ballast on board. This weight and c.g. was used as a basis for calculation of test weight and c.g. position for data reduction.

PERFORMANCE FLIGHT TESTS. The test procedures used for measuring the performance of the Jetwing with the upper wing removed were essentially the same as those used during testing under contract N00019-81-C-0126 and reported in [1]. This procedure was to perform sawtooth climbs and descents, at various airspeeds and power settings in order to develop a map of flight path angle (\(\gamma\)) and equivalent airspeed (\(V_{eq}\)) which defined the aircraft's performance envelope for a given configuration. Sawtooth climbs or descents were performed in 10 to 15 knots increments in the following speed range and configuration.

<table>
<thead>
<tr>
<th>SPEED RANGE</th>
<th>CONFIGURATION</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. 80-170 knots</td>
<td>Gear and Flaps up</td>
</tr>
<tr>
<td>2. 10-120 knots</td>
<td>Gear down , Flaps 15°</td>
</tr>
<tr>
<td>3. 50-120 knots</td>
<td>Gear down, Flaps 30°</td>
</tr>
</tbody>
</table>
Each speed range was repeated at four power settings, when practical, which approximated the following values of gross thrust:

1. Maximum Available thrust
2. 1000 lbs.
3. 500 lbs.
4. Idle Thrust

Test altitude was varied depending upon the thrust level required. Maximum available thrust testing began at approximately 2000 ft. pressure altitude. Since the data reduction method reduced all data to a sea level standard condition, test altitude was not critical except for obtaining maximum thrust.

Two climbs, or power idle descents, were done crosswind in opposite directions for each data point. An average of the two climbs was used in determining the data point to reduce wind created errors. During each climb the following data were recorded at 30 second intervals:

1. Fuel Remaining, for determination of test weight \(W_T\)
2. Indicated Airspeed \(V_i\)
3. Gross Thrust indication \(N_1, P_t/P_a, N_2, ITT\).
4. Angle of attack \(\alpha\)
5. Pitch angle \(\theta\)
6. Pressure altitude \(H_p\)
7. Time \(t\)
8. Outside air temperature \(T_a\)
9. Aircraft configuration

These data were plotted and values of rate of climb or descent determined for use in determining flight path angle. These data were reduced to standard values of flight path angle \(\gamma\), equivalent airspeed \(V_{eq}\), and gross thrust \(F_{GS}\), and plotted in the \(V - \gamma\) map as described in [1]. Further reduction to values of lift coefficient \(C_L\), and excess thrust coefficient \(C_{Fex}\), or drag coefficient \(C_D\), was also performed as outlined in [1]. Geometric angle of attack was determined by recording the pitch angle at the same time that flight path angle data were being taken. Geometric angle of attack was then calculated by subtracting flight path angle from pitch angle.
FLYOVER NOISE TESTING. The flyover noise tests were conducted on the Tullahoma Municipal Airport in an area of flat terrain having no excessive sound absorption characteristics. The noise measuring microphone was located so that there were no obstructions, which might influence the sound field from the airplane, within a conical space above the microphones. This conical space was defined by an axis normal to the ground plane, and by a half angle 75 degrees from this axis.

The testing was carried out under the following conditions:

1. Clear Air
2. Relative Humidity between 90 and 30 percent.
3. Ambient temperature between 86 and 41° F at 33 feet above the ground.
4. Wind not in excess of 10 knots at 33 feet above the ground.
5. There were no temperature inversions or wind conditions which would significantly alter the noise level of the airplane when the noise level was recorded.

The flyovers included at least six level flights over the measuring station for each configuration tested. These flyovers were at a height of 1000 feet ± 30 feet above the station, and were within ± 10 degrees of the zenith when passing overhead.

The configurations tested included:

<table>

</tbody>
</table>

The noise measuring microphone was mounted upon a tripod approximately four (4) feet above the ground so as to minimize interference with the sound being measured. The noise measured by that microphone was recorded on a strip recorder. This system for measuring and recording the sound compiled with the recommended characteristics in International Electrotechnical Commission Publication No. 170, entitled "Precision Sound Level Meters" [3] and with Federal Air Regulation 30 Appendix A paragraph A36.2 [4]. These publications also cover the calibration of such equipment. Immediately prior to and after each test a recorded acoustic calibration of the system was made with an acoustic calibrator for the purposes of checking system sensitivity and providing an acoustic reference level for analysis of the sound level data. In addition, prior to each series of tests the ambient noise, including both acoustical background and electrical noise of the measurement systems, was recorded in the test area with the system gains set at levels used for aircraft noise measurements.
The following data were recorded for each test run:

1. Ambient air temperature and humidity at 33 feet above the surface.
2. Maximum, minimum, and average wind velocities at 33 feet above the surface.
3. Aircraft noise level.
4. Test aircraft airspeed in knots.
5. Test aircraft engine power setting.
6. Aircraft height in feet.

Flight data parameters were corrected to standard conditions. Noise data were not corrected if the ambient temperature was within a range of 68°F ± 9°F, and the relative humidity was above 40 percent but not exceeding 90 percent. When conditions did not fall within the specified range, the data were corrected to 77°F and 70 percent relative humidity using an approved method.
SECTION IV
INSTRUMENTATION

The on board instrumentation used in these tests was the same instrumentation as used on the previous test reported in [1]. It was functionally checked out and recalibrated prior to the start of testing.

The types of instrumentation required for this program may be placed in groups which relate to the type of data being collected. These groups of instrumentation are:

1. Air Data Instrumentation
2. Engine Thrust Instrumentation
3. Pitch and Angle of Attack Instrumentation
4. Noise Measurement Instrumentation

AIR DATA INSTRUMENTATION. The instrumentation installed on the test aircraft which collected air data included:

1. Sensitive Airspeed Indicator calibrated in knots.
2. Sensitive Altimeter calibrated in feet.
3. Ambient Air Temperature Gauge calibrated in degrees Centigrade.

The airspeed indicator and altimeter were panel mounted as shown in Figure 9 and connected to a wingtip mounted, swivel pitot static boom shown in Figure 10. These instruments were calibrated through the airspeed and altitude ranges of interest using water and mercury manometers with traceability to the National Bureau of Standards (NBS).

The ambient air temperature gauge was calibrated from 0 – 40°C in a water bath using a laboratory thermometer which was also traceable to NBS.

Similar calibrated instrumentation was installed on the Cessna 310 and DHC-3 Otter which were used as pace aircraft during the Airspeed Calibration portion of the prior flight test program.

ENGINE THRUST INSTRUMENTATION. Instrumentation installed in the test aircraft which gave an indication of engine thrust included.

1. Main Rotor Speed Tachometer \( N_1 \) calibrated in percent RPM.
2. Gas Generator Speed Tachometer \( N_2 \) calibrated in percent RPM.
3. Interstage Turbine Temperature gauge (ITT) calibrated in °C.
4. Pressure Gauge calibrated in inches of water which measured the differential pressure between the total pressure in the hot or cold duct and the outside ambient static pressure. This was a single gauge which operated through a pressure switch in order to read hot or cold duct differential pressure.
FIGURE 9
PICTURE OF PILOT'S INSTRUMENT PANEL SHOWING AIR DATA AND ENGINE THRUST INSTRUMENTATION

FIGURE 10  FULL SWIVEL PITOT-STATIC BOOM MOUNTED ON LEFT WINGTIP, 32 INCHES FORWARD OF WING LEADING EDGE
5. SDI Hoskins Fuel Flow and Fuel Quantity Instrumentation which consists of two panel mounted instruments which contain an integral computer. Fuel flow calibration is in either gallons or pounds per hour.

All of the engine instrumentation and air data instrumentation was panel mounted for visual readout by the pilot as is shown in Figure 9.

All of the engine instrumentation listed above except for the fuel flow instrumentation was calibrated using standards traceable to NBS. The fuel flow instrumentation was calibrated at the manufacturer and guaranteed to maintain two percent accuracy in normal use. Periodic spot checks during the test program confirmed this level of accuracy.

In addition to the engine related thrust instrumentation one other piece of instrumentation was required during the thrust calibration. This instrument, a Dillon Dynamometer is shown in Figure 11 as it was installed in the thrust measuring apparatus. This instrument was readout in pounds of force and had received a traceable calibration by its manufacturer.

**PITCH AND ANGLE OF ATTACK.** The instrumentation required to measure pitch and angle of attack consisted of:

1. Angle of Attack Sensors
2. Vertical Gyro for Pitch Angle

Angle of attack information was obtained from the sensors shown in Figure 12. The angle of attack vane drives a rotary potentiometer which is connected electrically through a 12 position rotary switch to the milliammeter of Figure 13. Calibration was accomplished by measuring vane deflection angles and obtaining corresponding milliammeter readings. Zero reference was the aircraft waterline.

A vertical gyro mounted near the center of gravity and above the exhaust ducting, as shown in Figure 14, was used to determine pitch angles. Prior to installation, this device was calibrated with the instrumentation package on a calibration bench. This device was also wired to provide a visual readout through the milliammeter.

All instrument readings which could be displayed on the milliammeter could also be recorded, three at a time versus a time basis, on a cassette magnetic tape recorder. These data could then be played back on an oscillograph or strip recorder after the flight. The cassette recorder was located just aft of the pilot's seat.

Before being displayed on the milliammeter or recorded on the cassette recorder all data signals were amplified and conditioned in an instrumentation amplifier and signal conditioner located near the vertical gyro as is shown in Figure 15. Power for the electrical instrumentation was connected through an instrumentation master switch located next to the rotary selector switch.

INSTRUMENTATION AMPLIFIER AND SIGNAL CONDITIONER (ARROW)
NOISE MEASUREMENT INSTRUMENTATION. For the measurement of the flyover noise level a Bruel & Kjaer type 4133 one half inch condenser microphone was used (Figure 16). This microphone was oriented at an angle of 90 degrees (grazing incidence) with respect to the aircraft flight path. This orientation corresponds to the optimum frequency response for this microphone.

The output from the microphone was input into a Bruel & Kjaer type 2112 Audio Frequency Spectrometer (Figure 17) which provided three recording modes - Octave, 1/3 Octave, and Linear. For these measurements the 1/3 Octave filters ranging from 25Hz to 40 KHz were employed for the on-ground frequency distribution analysis of the aircraft while the Linear setting was used to record the instantaneous overall sound pressure level during the 1000 ft. flyover noise measurements.

The output of the Audio Frequency Spectrometer was fed into a Bruel & Kjaer type 2305 Graphic Level Recorder (Figure 17). This instrument supplied an amplitude (dB) versus frequency graph when utilizing the Audio Frequency Spectrometer as a 1/3 Octave analyzer, and an amplitude versus time plot when the Linear mode of the Audio Frequency Spectrometer was used.

Relative humidity during the tests was determined by use of a Sling Psychrometer and Psychrometric Charts, while wind direction and velocity were determined with the simple instruments shown in Figure 18.

SECTION V
RESULTS AND DISCUSSION

INFLIGHT PERFORMANCE

As described in the test procedures, inflight performance was determined with the upper wing removed in three configurations of landing gear and flap setting:

1. Gear and Flaps Up
2. Gear Down and 15° Flap Deflection
3. Gear Down and 30° Flap Deflection

Results of performance tests in these configurations are shown in Figures 19, 20, and 21 as weight and air density corrected plots of flight path angle (\(\gamma\)) and equivalent airspeed (\(V_{E,w}\)) for various thrust settings. As may be seen from these figures, the extreme low speed end of the performance envelope was not investigated. The reason for not continuing the investigation into this region was the reduced longitudinal stability level and tail stall potential discussed in [1]. The aircraft was flown to speeds as low as 55 knots calibrated airspeed in level flight, or a slight climb, but performance data were not recorded.

Sufficient performance data were obtained to make comparisons with the NASA Ames Research Center 40' x 80' wind tunnel data at two separate values of blowing coefficient (\(C_l\)). These comparisons are shown in Figures 22 through 27 as plots of lift coefficient (\(C_L\)) versus excess thrust coefficient (\(C_{FM}\)). The agreement between the flight test and wind tunnel data for these configurations is excellent and exceeds the good agreement obtained for the same configurations with the upper wing installed as reported in [1]. This data agreement also speaks well for the simple and inexpensive flight test method used to obtain the flight test data.

LIFT COEFFICIENT VERSUS ANGLE OF ATTACK

At the same time that the flight path angle versus airspeed data of Figures 19 thru 21 was being obtained, the aircraft pitch angle was recorded. By subtracting the flight path angle (\(\gamma\)) from the pitch angle (\(\theta\)) the geometric angle of attack (\(\alpha\)) can be obtained. However, one problem arises when trying to compare these data with that obtained in a wind tunnel.

The problem is that for a powered lift airplane like the Jetwing, the lift coefficient is a function of both angle of attack and blowing coefficient.

\[
C_L = f(\alpha, C_l)
\]

In a wind tunnel, the angle of attack and blowing coefficient can be varied independently. This is accomplished by holding tunnel airspeed and airplane gross thrust constant (\(C_l\) constant) while varying angle of attack.

In free flight, airspeed, gross thrust, blowing coefficient, and angle of attack are all interrelated, and cannot be varied independently. As a result, the classic \(C_L\) versus \(\alpha\) plots at a constant blowing

FLIGHT TEST
coefficient cannot be obtained directly by flight test.

To attempt to overcome this problem, and compare the flight test and wind tunnel results, the flight test data must be crossplotted on a plot of $C_L$ versus $C_D$ for various $\alpha$ such as is shown in Figures 28 through 30. Since the lines of constant angle of attack must be estimated from the angle of attack of individual data points, considerable error may be introduced by this plot. This error is compounded by the error involved in measuring aircraft pitch angle.

The results of such a comparison for the Jetwing with the upper wing removed are shown in Figures 31 through 36. These results do not compare as well as the excess thrust data shown in Figures 22 through 27. In light of the past discussion this discrepancy might be expected. Most of the difference is probably due to the measurement and crossplotting errors just discussed. However, there may be some error in the tunnel data due to wall effects which has not been accounted for. Such an error might help to explain the consistent difference in lift curve slope shown between the flight test and wind tunnel data.

**Comparison with Upper Wing Installed Data**

Figures 37, 38 and 39 show the results of performance tests reduced to sea level standard conditions with and without the mini-wing installed. These results show two interesting features.

First, for all configurations the airspeed at which best angle of climb occurs decreases with an increase in gross thrust or blowing coefficient. This change indicates a reduction in induced drag with thrust (or blowing coefficient) increase as is indicated by the theory [1]. Such a drag reduction has interesting applications for air-combat maneuvering, and means that in order to fly steep approaches at low airspeeds additional zero lift drag is needed.

The second interesting feature of these figures is that at every thrust setting and flap configuration the airplane with the upper wing installed is outperformed by the airplane without the upper wing. This difference in performance generally increases with an increase in thrust setting, particularly in the case with 30 degrees flap deflection. Although, most of this difference in performance may be explained by the fact that with the upper wing installed the airplane has more zero lift drag, it may not be the complete story. If the increase in $C_{D_0}$ were totally responsible for the performance difference, there should be an increase in the performance difference with an increase in airspeed. However, this does not appear to be true in all cases. In fact, the difference appears to decrease at higher airspeeds when the flaps are deflected. In addition, static thrust calibrations [1] showed a slight increase in static thrust with the upper wing installed. This thrust difference should tend to reduce the performance difference at the lower speeds. It then appears that the performance difference may be a function of induced drag in addition to the difference in $C_{D_0}$.

One item which may affect induced drag is the thickness of the USB jet. With the upper wing installed the jet is greater than twice as thick as with the upper wing removed. Recent wind tunnel studies [5] have shown that high aspect ratio nozzles (thin blowing jet) provide better USB performance than those with low aspect ratio (thick blowing jet). An analysis of wind tunnel results of Jetwing configurations showed that the supercirculation portion of the total lift was from 5 to 7 percent higher when the upper wing was off. These results are shown in Figure 40. It is difficult to determine if USB jet thickness is a significant factor in the performance difference shown in Figures 37, 38 and 39 but it does appear to beg further investigation.

HANDLING QUALITIES

A complete quantitative handling qualities evaluation of the aircraft was previously conducted with the upper wing installed and reported on in [1]. With the upper wing removed, handling qualities were qualitatively evaluated and compared with the upper wing installed configuration. This was done because changes in handling qualities due to the configuration change were thought to be small. In addition, the same test pilot would fly both series of tests.

Differences in handling qualities between the two aircraft configurations were confined to the longitudinal motions. One of the most noticeable changes was in longitudinal static stability. With the upper wing installed the aircraft had static margins of from 0 to --3% depending upon flap position and power settings. With the upper wing removed the aircraft's static margins became less negative and for some cases became slightly positive. The reason for this phenomenon has not been determined and further investigation appears warranted.

Another difference in longitudinal handling qualities occurred at low power setting. With the upper wing removed a light to moderate airframe buffet occurred anytime the power setting was reduced to values below 50%N1. The power setting where the onset of this buffet occurred appeared to be a function of airspeed and flap position with the highest power setting for buffet onset occurring at airspeeds above 150 knots with the flaps up. Although the source of this buffet was not positively determined, the most likely source is a turbulent shear layer which develops between the blowing jet and the free stream flow whenever the speed of the jet drops below that of the free stream. This buffet was not observed with the upper wing installed.

NOISE MEASUREMENT

The Graphic Level Recorder provided two kinds of data: 1. Sound pressure level (SPL) (amplitude) versus time (t) plots from the 1000 ft flyover measurements and; 2. Sound pressure level (SPL) versus frequency (F) from the static ground measurements.

The flyover data were crossplotted as sound pressure level (SPL) versus relative distance (RD). Relative distance was determined by correlating the airspeed from the flight data with the time intervals on the amplitude versus time graph. At the point where the noise of the approaching aircraft started to rise above the background noise level, the relative distance was set to zero.

Marks were put on the graph when the JETWING crossed overhead the microphone. From this mark the approximate position of the microphone on the SPL vs. RD plot could be determined.

Representative plots for a take-off and three flyovers with different configurations are shown in figures 41 and 42.

FIGURE 42
1000 FT. FLYOVER SOUND PRESSURE LEVEL SPL VS. RELATIVE DISTANCE RD
The data and results of the flyover noise measurements are listed in Table 2. From these data, the following average values for the peak noise pressure levels can be calculated:

a) Upper wing installed:
   - Clean configuration: 71.5 dB
   - Gear down, flaps 30°: 71.5 dB

b) Upper wing removed:
   - Clean configuration: 71.2 dB
   - Gear down, flaps 15°: 71.2 dB
   - Gear down, flaps 30°: 71.7 dB

These values show that neither the upper wing, nor flap or gear position, have any significant effect on the flyover noise level. The overall peak noise of 71.7 dB proves the JETWING to be a very quiet jet aircraft.

Figure 43 shows the frequency spectrum of the JETWING while stationary on the ground, at idle power. The spectra were taken from three different positions relative to the aircraft (front, side, and rear), each from a distance of 60 feet.

As expected, in the rear spectrum the low frequency noise (100 - 500 Hz) dominates, coming from the exhaust nozzles and the turbulent interaction of the jet sheet with ambient air and aircraft structure.

The front spectrum is clearly dominated by the higher frequency noise (2,000 - 10,000 Hz) of the JT-15 engine compressor, while in the side spectrum both noise sources have similar amplitudes.

The upper wing panels show some effect in reducing the noise level, particularly in the side and rear spectra. For the lower frequencies, this can be explained by the fact that the upper wing panels act as ejectors, thereby thickening and slowing down the jet sheet. The turbulent break-up of this slower and thicker jet sheet is less noisy than the break-up of the thinner jet sheet with higher velocity of the plain wing without winglet.

The reduction of high frequency noise may be due to shielding effects.

SOUND PRESSURE LEVEL (SPL) VS. FREQUENCY (F) FOR DIFFERENT JETWING POSITIONS
PART II

ANALYTICAL STUDY
SECTION I

INTRODUCTION

Analytical methods to predict forces of lift and drag as well as pitch, yaw and rolling moments on wings are essential for design purposes and have been developed for unblown wings to a high degree of accuracy and sophistication (e.g., finite element or panel methods). Some of these have been modified to include the effects of "powered lift", considering specific concepts like externally blown flaps, jet flaps, upper surface blowing etc. [6,7]. At this time, the consideration of such methods would be beyond the scope of this report and must be left to later investigations. Instead, the focus was on some less sophisticated methods that include simplifying assumptions and are likely to lead to results of lesser accuracy. However, these are valuable tools for the engineer who is concerned with preliminary design.

The basic theoretical properties of a thin two-dimensional jet in inviscid flow were formulated by Maskell and Gates [8], together with the overall momentum relations satisfied by the two-dimensional jet flapped aerofoil. Subsequently, jet flap theories were developed for the case of the thin wing and jet in inviscid incompressible flow, excluding mixing between the mainstream and the jet. The two-dimensional problem was solved by Spence using a treatment akin to classical "mean line" theory, both for ejection from the trailing edge [9] and over a plain hinged flap [10]. This treatment was extended to the case of a finite aspect ratio wing with a full span jet flap by Maskell and Spence [11], following the classical Prandtl lifting line theory; the equations being made tractable by prescribing an elliptic spanwise distribution of both wing chord and jet momentum with constant jet angle over the span. Yet in another approach, it was suggested to replace the jet by an equivalent mechanical flap extension in the plane of the flap [12] and treating the resulting wing just as any other wing.

The methods used by Williams [13], Wertz [14], and Jacobs [15] are based on this background, empirical methods [16], and experimental results. These three methods have been investigated and slightly modified for JETWING specifics and are presented in the following pages.
SECTION II
PREDICTION METHOD 1 (WILLIAMS)

This method closely follows a paper that was published by Williams, Butler and Wood [13] in 1963, which allows computation of not only the lift coefficient $C_L$ as function of $\alpha$, $\delta_F$ and $C_j$, but also the drag coefficient $C_D$ vs. $C_L$.

LIFT COEFFICIENT

In their paper, "The Aerodynamics of Jet Flaps", they discussed historical, theoretical and experimental aspects of jet flaps in general and honored Spence's, Gate's and Maskell's work. Without further derivation the following formulas are then presented. The lift coefficient for a two-dimensional thin flat plate at angle of attack $\alpha$, with blowing over a hinged flap to provide a jet deflection $\delta$, is given by

$$C_L = C_{\delta \alpha} \delta + C_{\alpha \alpha} \alpha \quad (II - 1)$$

with

$$C_{\delta \alpha} = \frac{\partial C_L}{\partial \delta} = 4\pi C_j (1 + 0.151 C_j^{1/2} + 0.139 C_j)^{1/2} \quad (II - 2)$$

and

$$C_{\alpha \alpha} = \frac{\partial C_L}{\partial \alpha} = 2\pi (1 + 0.151 C_j^{1/2} + 0.219 C_j) \quad (II - 3)$$

where

$$C_j = C_j \frac{S}{S'} \quad (II - 4)$$

is the mean sectional (2-D) blowing coefficient and $S'$ is the wing reference area of the blown portion; $C_j'$ being the overall (3-D) blowing coefficient (see also Appendix I).

To obtain the three-dimensional lift coefficients for a finite aspect ratio wing, the two-dimensional values can be multiplied by the correction factor

$$C(A, C_j) = \frac{A + (2 C_j / \pi)}{A + (2 / \pi) C_j' \alpha - 2(1 + \alpha)} \quad (II - 5)$$
with

\[ \sigma = \frac{(1 - \zeta)(C_f/\pi A)}{\zeta - (1 - \zeta)(C_f/\pi A)} \quad (II - 6) \]

where

\[ \zeta = \frac{2C_f/(\delta + \alpha)}{\pi A + 2C_{t0} - 2\pi(1 + \sigma)} \quad (II - 7) \]

For small \( C_f \) or large \( A \)

\[ G(A, C_f) \approx \frac{A + (2C_f/\pi)}{A + 2 + 0.604C_f^{1/2} + 0.876C_f} \quad (II - 8) \]

The simultaneous equations (II - 6) and (II - 7) in the two unknowns \( \sigma \) and \( \zeta \) are transformed into a transcendental equation in \( \zeta \) alone as

\[ \zeta \left( \pi A + 2C_{t0} - 2\pi \left[ 1 + \frac{(1 - \zeta)(C_f/\pi A)}{\zeta - (1 - \zeta)(C_f/\pi A)} \right] \right) = \frac{2C_t}{\delta + \alpha} \quad (II - 9) \]

Allowance for part-span flaps and fuselage cut-out is included by introducing spanwise extent factors \( \lambda \) and \( \nu \), where

\[ \lambda = \frac{S'}{S} \quad (II - 10) \]

and

\[ \nu = \frac{S'C_{t0} + (S - S')C_{t0} }{SC_{t0}} \quad C_{t0} = C_{t0} |_{C_f=0} \quad (II - 11) \]

The effect of thickness to chord ratio \( t/c \) is taken into account by increasing the sectional pressure lift in the proportion \( (1 + t/c) \), roughly corresponding to the ratio of the sectional \( C_f \) vs. \( \alpha \) curve slope without blowing to the value \( 2\pi \) for a thin flat plate.

With these semi-empirical arguments, the lift on a jet-flap wing finally may be written as

\[ C_{l_{u}} = G[(1 + t/c)(\lambda C_{t0} \delta + \nu C_{t0} \alpha)] - (t/c)C_f(\delta + \alpha) \quad (II - 12) \]
THRUST AND DRAG COEFFICIENTS

The excess thrust coefficient given by linearized inviscid flow theory for full-span jet flap wings becomes

\[ C_{F_{ex}} = C_J - \frac{C_L}{\pi A + 2C_J} \]  

(II - 13)

where the last term on the right represents the "trailing vortex" drag associated with an elliptic spanwise distribution of loading. To examine the actual thrust deficiency in viscous flow, a more general form of equation (II - 13) can usefully be considered:

\[ C_{F_{ex}} = rC_J - C_{D0} - k\frac{C_L^2}{\pi A + 2C_J} \]  

(II - 14)

Here the "sectional thrust" is for convenience expressed as a proportion \( r \) of the theoretical value \( C_J \), while the drag associated with finite aspect ratio effect is expressed as a proportion \( k \) of the theoretical value \( C_L^2/\pi A + 2C_J \). The term \( C_{D0} \) represents the drag at zero lift, without flap deflection and blowing, as usual.

With a part-span jet flap, additional lift-dependent drag \( \Delta C_{DP} \) can arise because of the departure from the normal spanwise distribution of lift, so equation (II - 14) may be rewritten as

\[ C_{F_{ex}} = rC_J - C_{D0} - k\frac{C_L^2}{\pi A + 2C_J} - \Delta C_{DP} \]  

(II - 15)

As a crude estimate the loss can be written

\[ \Delta C_{DP} = \frac{\kappa \Delta C_L^2}{\pi A} \]  

(II - 16)

However, there is yet no sound theoretical basis for its prediction. Hence for estimation of excess thrust coefficient \( C_{F_{ex}} \), \( \Delta C_{DP} \) has been neglected and the factors \( r \) and \( k \) have been assumed to be unity in equation (II - 15).

RESULTS

A FORTRAN program was developed using equation (II - 12) for computation of \( C_L \) vs. \( \alpha \) employing JETWING parameters. For our calculation of correction factor \( G(A, C_J) \) equation (II - 8) was used for values of \( C_J < 1 \). For values of \( C_J > 1 \), equation (II - 5) was used with \( \alpha \) obtained from equation (II - 6) after solving equation (II - 9) for \( \zeta \) by a multivariate search program [17] for error minimization. For the computation of excess thrust coefficient \( C_{F_{ex}} \) equation (II - 15) was used. The zero lift drag coefficient \( C_{D0} \) was taken from wind tunnel data. The resulting \( C_L \) vs. \( \alpha \) and \( C_L \) vs. \( C_{F_{ex}} \) curves were plotted and are shown in figure 44 thru figure 51. For comparison, the NASA full scale wind tunnel data for the JETWING with upper wing removed were also plotted on these figures.

SECTION III

PREDICTION METHOD 2 (WERTZ)

This method follows an approach done by R. D. Wertz [14] in 1976, where he used the then known design parameters of the JETWING to predict the lift coefficient as functions of blowing coefficient, flap deflection and angle of attack. Since this work was done, some of the design features have changed. These were incorporated into Wertz's method and equations were modified accordingly to account for actual JETWING data.

SUMMARY

In his paper “Application of Spence’s Methods and Data to Prediction of Lift Coefficients of the JETWING,” Wertz started out with Spence’s formula for two dimensional blown jet flap lift [10] and separated the total lift into three contributions:

- aerodynamic lift of airfoil due to angle of attack and flap deflection
- supercirculation lift due to blowing
- direct jet lift due to the vertical component of jet momentum

In going to three dimensions, Wertz used Maskell and Spence’s techniques [11] and the Rockwell method described in Woodlard’s paper [16]. At several points Wertz departed from these procedures and used empirical curves [18] or JETWING specific data [19]. His final equation then is of the following form:

\[ C_L = (C_{LA0} + C_{LFA}) \sin(\alpha - \alpha_0) + (C_{LAB} + C_{LFB}) \sin \delta + C_J \sin(\alpha + \delta) \]

To account for the actual difference between flap and jet deflection angles, Wertz’s approach was modified and the following equation derived:

\[ C_L = (C_{LA0} + C_{LFA}) \sin(\alpha - \alpha_0) + C_{LAB} \sin \delta_F + C_{LFB} \sin \delta_J + C_J \sin(\alpha + \delta_F) \]

DERIVATION

1. Breaking up Two-Dimensional Lift into Components.

The starting point is equation (35) in Spence’s paper [10],

\[ C_{I} = 2\pi(1 + 2B_0)\alpha + 2(\chi + \sin \chi + 2\pi D_0)\delta \]  \hspace{1cm} (III – 1)

This assumes potential flow over a flat plate with flap, therefore the geometric and aerodynamic angle of attack coincide as well as the jet and flap deflection angle.
In this equation the conventional aerodynamic lift coefficients for the basic airfoil are contained in

\[ C_{c_{0}} = 2\pi\alpha + 2(\chi + \sin \chi)\delta \quad (III - 2) \]

where the \( \chi \) terms are defined in Spence [10] as:

\[ \chi = 2\sin^{-1}\sqrt{c_{f}/c} \]

The jet terms including the direct jet lift are contained in

\[ C_{e_{j}} = 4\pi(B_{0}\alpha + D_{0}\delta) \quad (III - 3) \]

where the \( B_{0} \) and \( D_{0} \) terms are leading Fourier coefficients developed in Spence [9,10].

In order to separate direct jet lift from supercirculation lift, equation (III - 3) is rewritten

\[ C_{e_{j}} = C_{er} + C_{j}\sin(\alpha + \delta) \quad (III - 4) \]

where \( C_{er} \) is the section supercirculation lift coefficient. For small angles we can write

\[ C_{e_{j}} = C_{er} + C_{j}(\alpha + \delta) \quad (III - 5) \]

Now from equation (III - 3)

\[ C_{er} = 4\pi(B_{0}\alpha + D_{0}\delta) - C_{j}(\alpha + \delta) \]

or

\[ C_{er} = (4\pi B_{0} - C_{j})\alpha + (4\pi D_{0} - C_{j})\delta \quad (III - 6) \]

and the total lift coefficient is then

\[ C_{e} = C_{c_{0}} + C_{er} + C_{j}(\alpha + \delta) \quad (III - 7) \]
2. Airfoil Pressure Lift Correction for Three Dimensions

Equation (III - 2) gives:

\[ C_{l_{a}} = 2 \pi \alpha + 2(\chi + \sin \chi) \delta \]

or in general:

\[ C_{l_{a}} = C_{l_{ao}}(\alpha - \alpha_0) + C_{l_{a0}} \delta \]  (III - 8)

and for three dimensions:

\[ C_{L_{a}} = C_{L_{ao}}(\alpha - \alpha_0) + C_{L_{a0}} \delta \]  (III - 9)

From Perkins and Hage [18], pp. 84 we get:

\[ C_{l_{a0}} = a_0 \frac{\alpha_0}{1 + \frac{57.3 a_0}{\pi A}} \]  (III - 10)

where \( \alpha_0 \) is a representative section lift curve slope per degree. For a NACA 23015 airfoil \( \alpha_0 = 0.104 \) per degree or \( C_{l_{ao}} = 5.953 \) rather than \( C_{l_{ao}} = 2 \pi \) as given in equation (III - 2). The factor \( f \) is a function of the taper ratio \( c_t/c_r \) which is 0.46 for the JETWING. Figure 2-55 in Perkins and Hage [18] gives an \( f \) of approximately 1. With the JETWING aspect ratio \( A = 4.48 \) we get:

\[ a_W = C_{L_{ao}} = 0.0731 \]  (III - 11)

The flap term can be written as:

\[ C_{L_{a0}} = \frac{S' a_W}{S} C_{l_{ao}} = \frac{S' a_W}{S} a_0 \frac{2(\chi + \sin \chi)}{\alpha_0} \]  (III - 12)

With the JETWING data, flapped wing area \( S' = 77 ft^2 \), wing area \( S = 105.6 ft^2 \), \( \chi = 1.22/\text{rad} \),

\[ C_{l_{a0}} = 2.23/\text{rad} = .0388/\text{deg} \]  (III - 13)

This yields:

\[ C_{L_{a}} = 0.0731(\alpha - \alpha_0) + 0.0388/\text{deg} \]  (III - 14)
Wertz mentioned that because the airfoil was altered from the NACA 23015 to accommodate the jet slot, Bartoe had used for \( a_W \) an estimate of 0.065. Adjusting equation (III - 14) by that factor results in

\[
C_{LA} = 0.065(\alpha - \alpha_0) + 0.0345(\delta_F) \quad (III - 15)
\]

with angles in degrees and

\[
C_{LA} = 3.7(\alpha - \alpha_0) + 2.0(\delta_F) \quad (III - 16)
\]

with angles in radians.

Wertz thought that the flap term still appeared too large, so using the elevator effectiveness curve of Perkins and Hage [18] p. 250, he determined that the \( C_{LAf} \) should not be more than 0.5\( C_{LAo} \). Therefore using this assumption:

\[
C_{LA} = 3.7(\alpha - \alpha_0) + 1.4(\delta_F) \quad (III - 17)
\]

3. Supercirculation Lift Correction for Three Dimensions

Equation (III - 6) gives:

\[
C_{\Gamma \Gamma} = (4\pi B_0 - C_j)\alpha + (4\pi D_0 - C_j)\delta
\]

or in general

\[
C_{\Gamma \Gamma} = C_{\Gamma \Gamma,\alpha}(\alpha - \alpha_0) + C_{\Gamma \Gamma,\delta}(\delta) \quad (III - 18)
\]

and for three dimensions:

\[
C_{LR} = C_{LR,\alpha}(\alpha - \alpha_0) + C_{LR,\delta}(\delta) \quad (III - 19)
\]

Equation (14) of Woodlard's paper (Rockwell's method) [16] writes:

\[
C_{LR} = (1 + t/c)F[\nu C_{2H}\alpha + \lambda C_{2H}\sin \delta] \quad (III - 20)
\]

Instead of using the thickness correction \((1 + t/c)\), Wertz used \((a_0/2\pi)\), with \( a_0 \) being the specific wing section characteristic.
For calculation of the derivatives and 3-D correction factors, the overall three-dimensional blowing coefficient $C_j$ is modified, using Rockwell's method [16] (see also Appendix I):

$$C_j = C_j \frac{S}{S''}$$  \hspace{1cm} (III - 21)

where

$$S'' = S' + \frac{1}{2} (S - S')$$  \hspace{1cm} (III - 22)

For the JETWING this yields

$$C_j = 1.19C_j$$  \hspace{1cm} (III - 23)

Rockwell also modifies the section lift coefficients by coefficients $\lambda$ and $\nu$, to correct for partial span flaps and blowing.

$$\lambda = \frac{S''}{S}$$  \hspace{1cm} (III - 24)

For the JETWING

$$\lambda = 0.84$$  \hspace{1cm} (III - 25)

The coefficient $\nu$ is a function of $\lambda, C_j, C_{\alpha,\omega}$ and Wertz assumed it to be

$$\nu = 1$$  \hspace{1cm} (III - 26)

From Woolard's paper [18] we have

$$F(A, \eta C_j) = G + \frac{2G^2\sigma}{A + (2/\pi)C_j}$$  \hspace{1cm} (III - 27)

where $\eta$ is the jet turning efficiency. It is assumed to be 1. Spence has used in [11]

$$G = \frac{A + 0.037C_j}{A + 2 + 0.054C_j \sqrt{2} + 0.876C_j}$$  \hspace{1cm} (III - 28)
Also
\[
\sigma = \frac{(1 - \sigma)(C_j/\pi A)}{(1 - \sigma)(C_j/\pi A)} \quad (III - 30)
\]

where
\[
\sigma = \frac{(2/\pi)C_j/\alpha}{A + (2/\pi)C_{t0} - 2} \quad (III - 31)
\]

To get an estimate for \( \sigma \), Wertz assumed the following:

a) Let
\[
\frac{C_t}{(\alpha + \delta)} = \frac{C_{t0}}{\alpha} = \frac{\partial C_t}{\partial \alpha} = C_{t0} = 2\pi,
\]
then
\[
\sigma = \frac{(2/\pi)2\pi}{A + (2/\pi)2\pi - 2} = 0.62 \quad (III - 31)
\]

b) Let
\[
\frac{C_t}{(\alpha + \delta)} = \frac{C_{t0} + C_{t0}}{2} = \frac{2\pi(1 + 0.5)}{2} = 1.5\pi,
\]
then
\[
\sigma = \frac{(2/\pi)1.5\pi}{A + (2/\pi)1.5\pi - 2} = 0.55 \quad (III - 32)
\]

Arguing that the \( \sigma \) term is small compared to the other terms for the 3-D correction, Wertz felt justified to use an average value of
\[
\lambda = 0.6 \quad (III - 33)
\]

This yields
\[
\sigma = \frac{0.1C_j}{0.6\pi - 0.1C_j} \quad (III - 34)
\]

Now the function \( F' \) can be computed for parametric blowing coefficients. The derivatives in equation (III - 20) can be expressed through equation (III - 31): 
\[
C_{t\Gamma\alpha} = 4\pi B_0 - C_j \quad (III - 35)
\]

and
\[
C_{t\Gamma\delta} = 4\pi D_0 - C_j \quad (III - 36)
\]
The Fourier coefficient terms $B_0$ are evaluated for a number of blowing coefficients in Spence [9], Table 1, p.58. From equation (III-1) we know that

$$C_{68} = 2(\chi + \sin \chi + 2\pi D_0)$$

and the terms $D_0$ can be determined by

$$D_0 = \frac{C_{68} - 2(\chi + \sin \chi)}{4\pi}$$

where values of $C_{68}$ are contained in Spence [10], Table 1, p.294. It is a function of the flap chord to wing chord ratio $c_f/c$ and the blowing coefficient $C_j$, and has to be interpolated for JETWING values ($c_f/c = 0.33$). Knowing the coefficients $B_0$ and $D_0$ for a number of $C_j$, the derivatives $C_{L\alpha}$ and $C_{L\theta}$ can be computed also.

The three-dimensional derivatives $C_{L\alpha}$ and $C_{L\theta}$ can then be calculated as

$$C_{L\alpha} = \frac{a_0}{2\pi} FC_{L\alpha}$$

and

$$C_{L\theta} = \frac{a_0}{2\pi} FC_{L\theta}$$

These can be substituted into equation (III-19)

$$C_L = C_{L\alpha}(\alpha - \alpha_0) + C_{L\theta}(\theta).$$

4. Final Equation

Starting out from two-dimensional lift components, equation (III-7), Wertz arrived at the equation for the three-dimensional lift coefficient:

$$C_L = C_{LA} + C_{LF} + C_j \sin(\alpha + \theta)$$

For the total lift, he then let the basic aerodynamic and supercirculation lift terms also vary with the sine of the angle. He gave no explanation, but for justification it may be argued, that for higher angles of attack and higher flap angles the lift generation becomes nonlinear due to partial separation and non perfect turning of the jet. Therefore, the idea of linear terms variation with the sine of the angles, may be a reasonable approximation that accounts for these effects.
We have then

\[ C_L = [C_{L\alpha} + C_{Lr\alpha}] \sin(\alpha - \alpha_0) + [C_{L\delta} + C_{Lr\delta}] \sin \delta + C_J \sin(\alpha + \delta) \quad (III - 41) \]

This assumes, that the thrust line is parallel to the flap chord. Actually, the upper surface of the flap is inclined 90° to the flap chord (\(\delta_j = 90°\)). This can be corrected in the jet lift terms by setting

\[ \delta_j = \delta_p + \delta_j \quad (III - 42) \]

This, together with the zero lift angle of attack \(\alpha_0 = -1°\) from NACA 23015 airfoil data makes the final equation write:

\[ C_L = [3.7 + C_{Lr\alpha}] \sin(\alpha + 1) + 1.4 \sin \delta_p + C_{Lr\delta} \sin \delta_j + C_J \sin(\alpha + \delta_j). \quad (III - 43) \]

**RESULTS**

A Fortran program was written, using Table 1 from [9] and Table 1 from [10] for interpolation, and equation (III - 43) for calculating the lift coefficient \(C_L\) vs. \(\alpha\) and parametric values of flap deflection \(\delta_p\) and blowing coefficient \(C_J\). Wertz method also permit the total lift coefficient to be broken up into contributions from basic aerodynamic lift, supercirculation lift and lift from jet reaction. The corresponding components of the wind tunnel data were determined as follows:

- \(C_L(AE)\), the basic aerodynamic lift of the wing was taken from a no blowing data run.
- \(C_L(J)\), the lift from jet reaction was determined from

\[ C_L(J) = C_J \sin(\alpha + \delta_j) \]

- \(C_L(TOT)\), the total lift was taken directly from wind tunnel data.
- \(C_L(S)\), the supercirculation lift was determined from

\[ C_L(S) = C_L(TOT) - C_L(AE) - C_L(J) \]

Data from the NASA full scale wind tunnel tests with upper wing removed are plotted together with the theoretical results in figures 52 thru 55. Some of these wind tunnel data are broken up into components and compared to similar components derived by Wertz method. These comparisons are shown in figures 56 thru 59.

SECTION IV
PREDICTION METHOD 3 (JACOBS)

EQUIVALENT FLAP THEORY

SUMMARY

An approximate method was presented by Jacobs [12,15] for calculating the lift and pitching moment of an airfoil with a mechanical flap and a jet issuing at the trailing edge of the flap into the main stream. The jet may form any angle with respect to the flap or the free stream. In the case of a two dimensional airfoil the effect of the jet on the lift forces was related to that of an equivalent mechanical flap extension in the plane of the existing flap with the lift on the equivalent flap being equal to the vertical component of jet reaction. In the case of a three-dimensional wing, the effect of induced downwash field was considered in the form of a decrease in effective angle of attack distribution. Hence, jet reaction lift would decrease, which in turn would reduce the length of the equivalent mechanical flap, as both the jet reaction lift and the lift on the equivalent flap have to be the same. The method described here employs the equivalent flap theory of Jacobs to calculate the equivalent mechanical flap extension of every spanwise section knowing the corresponding jet blowing velocity and then uses the well known Multhopp's lifting line theory to predict the spanwise load and induced angle of attack distribution. The approach adopted here calls for an iteration on induced angle of attack distribution, starting with zero throughout the span. The equivalent wing shape is determined by going through lifting line theory to predict the load and new induced angle of attack distribution. The equivalent wing shape is then recalculated along with corresponding load, and induced angle of attack distribution, until the process converges. Once the circulation distribution is known, pitching moment is easily obtained as the integrated (spanwise and chordwise) result of the product of density, velocity, circulation and distance from the moment center. Pitching moment of the fuselage is also calculated from an empirical formula. The method has the capability of handling leading edge flap along with the more conventional trailing edge flap.
CALCULATION OF LIFT

From geometric consideration, the following relations can be derived.

\[ z = \frac{c'}{2}(1 + \cos \psi) \]

\[ c_f = c' - c = c' - \frac{c'}{2}(1 + \cos \psi_1) = \frac{c'}{2}(1 - \cos \psi_1) \]

\[ c = c' - c_f = c' - \frac{c'}{2}(1 - \cos \psi_1) = \frac{c'}{2}(1 + \cos \psi_1) \]

\[ \frac{c_f}{c} = \frac{1 - \cos \psi_1}{1 + \cos \psi_1} \]

Again,

\[ c_f = c' - \frac{c'}{2}(1 + \cos \psi_o) = \frac{c'}{2}(1 - \cos \psi_o) \]

\[ c_f = c_f'(1 - \cos \psi_a) - \frac{c_f'}{c}(1 - \cos \psi_1) = \frac{c_f'}{c}(\cos \psi_1 - \cos \psi_a) \]

\[ \frac{c_f}{c}(1 + \cos \psi_1) = \cos \psi_1 - \cos \psi_a \]

\[ \cos \psi_a = \cos \psi_1 - \frac{c_f}{c}(1 + \cos \psi_1) \quad \text{(IV - 1)} \]

The circulation distribution \( \gamma(\psi) \) over a thin airfoil with leading edge flap deflection \( \delta_n \), trailing edge flap deflection \( \delta_F \) and overall angle of attack \( \alpha \), is given by Glauert as,

\[ \gamma(\psi) = \frac{2V_T}{\pi} \left[ -\delta_n \left\{ (\pi - \psi_m) \tan \frac{\psi}{2} - \ln \left| \frac{\sin \frac{\psi + \psi_m}{2}}{\sin \frac{\psi - \psi_m}{2}} \right| \right\} \right. \]

\[ \left. + \delta_F \left\{ \psi \tan \frac{\psi}{2} + \ln \left| \frac{\sin \frac{\psi + \psi_m}{2}}{\sin \frac{\psi - \psi_m}{2}} \right| \right\} \right. \]

\[ \left. + \alpha \left\{ \pi \tan \frac{\psi}{2} + \ln \left| \frac{\sin \frac{\psi + \psi_m}{2}}{\sin \frac{\psi - \psi_m}{2}} \right| \right\} \right]\quad \text{(IV - 2)} \]

As per Jacobs equivalent flap theory, the length of the equivalent flap extension can be calculated by equating the integrated lift over its length with the vertical component of jet reaction lift.

\[ L_{fj} = \rho V_T \int_c^c' \gamma(x)dx = \frac{M_j V_j}{2} \sin(\delta_F + \psi_j + \alpha) \quad \text{(IV - 3)} \]

Substituting \( \gamma(x) \) from equation (IV - 2) into equation (IV - 3) and setting leading edge flap deflection \( \delta_n \) to be zero, we get,

\[ \frac{M_j V_j}{2 \rho V_T} \sin(\delta_F + \psi_j + \alpha) = \frac{2}{\pi} \int_0^\pi \left[ \delta_F \left\{ \psi \tan \frac{\psi}{2} + \ln \left| \frac{\sin \frac{\psi + \psi_m}{2}}{\sin \frac{\psi - \psi_m}{2}} \right| \right\} \right. \]

\[ \left. + \alpha \left\{ \pi \tan \frac{\psi}{2} + \ln \left| \frac{\sin \frac{\psi + \psi_m}{2}}{\sin \frac{\psi - \psi_m}{2}} \right| \right\} \right] \sin \psi d\psi \quad \text{(IV - 4)} \]

The integral on the right hand side of equation (IV - 4) has been evaluated separately.
Defining the blowing coefficient with respect to the equivalent chord \( c' \) as,

\[
C'_j = \frac{M_j V_j}{\frac{1}{2} \rho V_T^2 c'}
\]

we can rewrite equation (IV - 4) as:

\[
C'_j \sin(\delta_F + \delta_j + \alpha) = \frac{2}{\pi} \left[ (\delta_F \psi_o + \alpha \pi)(\psi_1 - \sin \psi_o) + \delta_F \left\{ \psi_1 \sin \psi_o + (\cos \psi_1 - \cos \psi_o) \ln \frac{\sin \frac{\psi_o - \psi_1}{2}}{\sin \frac{\psi_o + \psi_1}{2}} \right\} \right]
\]

Knowing the relation between \( c \) and \( c' \), we can write

\[
C'_j = C_j \frac{1 + \cos \psi_1}{2}
\]

where \( C_j \) is obtained by the procedure given in Appendix II.

Hence, equation (IV - 5) transforms to:

\[
C_j \frac{1 + \cos \psi_1}{2} \sin(\delta_F + \delta_j + \alpha) = \frac{2}{\pi} \left[ (\delta_F \psi_o + \alpha \pi)(\psi_1 - \sin \psi_o) + \delta_F \left\{ \psi_1 \sin \psi_o + (\cos \psi_1 - \cos \psi_o) \ln \frac{\sin \frac{\psi_o - \psi_1}{2}}{\sin \frac{\psi_o + \psi_1}{2}} \right\} \right]
\]

Equation (IV - 7) is valid for a 2-D airfoil. The three-dimensional effects express themselves only in changes of angle of attack. For a 3-D wing, Equation (IV - 7) should be modified as:

\[
C_j \frac{1 + \cos \psi_1}{2} \left\{ \sin(\delta_F + \alpha + \delta_j - \alpha \psi_1 - \sin \alpha \psi_1) \right\} = \frac{2}{\pi} \left[ (\delta_F \psi_o + \alpha \pi)(\psi_1 - \sin \psi_o) + \delta_F \left\{ \psi_1 \sin \psi_o + (\cos \psi_1 - \cos \psi_o) \ln \frac{\sin \frac{\psi_o - \psi_1}{2}}{\sin \frac{\psi_o + \psi_1}{2}} \right\} \right]
\]

Equations (IV - 1) and (IV - 8) must be solved simultaneously for the two unknowns \( \psi_o \) and \( \psi_1 \). This problem is transformed into finding one unknown in one equation as described below.

Let:

\[
\cos \psi_1 = y \\
\sin \psi_1 = \sqrt{1 - y^2}
\]
From equations (IV - 1),

\[ \cos \psi_e = y - \frac{c_f}{c}(1 + y) \]

and

\[ \sin \psi_e = \sqrt{1 - \left( y - \frac{c_f}{c}(1 + y) \right)^2} \]

Also,

\[ \sin \left( \frac{\psi_e - \psi_i}{2} \right) = \sin \frac{\psi_e}{2} \cdot \cos \frac{\psi_i}{2} - \cos \frac{\psi_e}{2} \cdot \sin \frac{\psi_i}{2} \]

\[ = \sqrt{1 - \cos \psi_e} \cdot \sqrt{1 + \cos \psi_i} - \sqrt{1 + \cos \psi_e} \cdot \sqrt{1 - \cos \psi_i} \]

and

\[ \sin \left( \frac{\psi_e + \psi_i}{2} \right) = \sqrt{1 - \cos \psi_e} \cdot \sqrt{1 + \cos \psi_i} + \sqrt{1 + \cos \psi_e} \cdot \sqrt{1 - \cos \psi_i} \]

Substituting these in Equation (IV - 8) we get,

\[ C_f \left( \frac{1 + y}{2} \right) \left\{ \sin(\delta_F + \delta_J + \alpha - \alpha_t) \cdot \sin \alpha_t \right\} = \frac{2}{\pi} \left[ \left\{ \delta_F \cdot \cos^{-1} \left( y - \frac{c_f}{c}(1 + y) \right) + \alpha \right\} \cdot (\cos^{-1} y - \sqrt{1 - y^2}) \right. \]

\[ \left. + \delta_F \cdot \left\{ \cos^{-1} y \cdot \sqrt{1 - \left( y - \frac{c_f}{c}(1 + y) \right)^2} \right. \right. \]

\[ + \frac{c_f}{c(1 + y)} \cdot \ln \frac{\sqrt{1 + y - (c_f/c)(1 + y)} \cdot \sqrt{1 + y - (c_f/c)(1 + y)} - \sqrt{1 - y}}{\sqrt{1 + y - (c_f/c)(1 + y)} \cdot \sqrt{1 + y - (c_f/c)(1 + y)} + \sqrt{1 - y}} \right] \]

\[ (IV - 9) \]

This is a transcendental equation in one variable \( y \). Initially we assume induced angle of attack \( \alpha_t \) to be zero throughout the span. Then knowing \( C_f, \delta_F, \delta_J, \alpha, c, c_f \) for each and every spanwise section, equation (IV - 9) is solved for \( y \) by a multivariate search program [17] for error minimization. Once \( y \) has been obtained, \( \psi_i, \psi_e, \) and \( c' \) can be determined from the relations developed earlier. That means, we can replace our jet flapped wing by the actual hard wing and a hypothetical extension of the mechanical flap in the same plane as the actual flap. Now, the spanwise lift distribution, lift curve slope and overall \( C_L \) can be calculated by the well known Multhopp's Lifting Line Theory.
The input for Lifting Line Theory will need the local chord and effective angle of attack (\(\alpha_e\)) for each spanwise section. The last term, according to Glaucert, can easily be obtained as

\[
\alpha_e = \alpha + \frac{\partial \alpha}{\partial \delta_F} \delta_F
\]

where

\[
\frac{\partial \alpha}{\partial \delta_F} = \frac{2}{\pi} \left[ \sqrt{\lambda_F(1 - \lambda_F)} + \sin^{-1}\sqrt{\lambda_F} \right], \quad \lambda_F = \frac{\delta_f}{c}
\]

The output of Multhopp's program will contain spanwise variation of induced angles of attack which then can be fed in equation (IV - 9) to obtain a new set of \(\gamma\), i.e., a new equivalent wing, which will produce another set of induced angles of attack. This process is continued until the induced angles of attack in two successive iterations matches within the desired accuracy.
CALCULATION OF PITCHING MOMENT

Pitching moment of an airfoil with jet augmented flap can be written as:

\[ M = -\rho V_T \int_0^d \gamma(x)(x + z)dz + \rho V_T \int_0^d \gamma(x)(x + z)dz - j \sin((\delta_f + \delta_j)(c + a)) \]  \hspace{1cm} (IV - 10)

\[ M = -\rho V_T \int_0^\psi \gamma(\psi)\left\{ \frac{\psi}{\psi}(1 + \cos \psi) + pc' \right\} \frac{\psi}{\psi} \sin \psi d\psi \]

\[ + \rho V_T \int_0^\psi \gamma(\psi)\left\{ \frac{\psi}{\psi}(1 + \cos \psi) + pc' \right\} \frac{\psi}{\psi} \sin \psi d\psi \]

\[ - j \sin(\delta_f + \delta_j)\left\{ \frac{\psi}{\psi}(1 + \cos \psi) + pc' \right\} \]

\[ M = -\rho V_T \frac{c'^2}{4} \int_0^\psi \gamma(\psi)(1 + \cos \psi + 2p)\sin \psi d\psi \]

\[ + \rho V_T \frac{c'^2}{4} \psi \gamma(\psi)(1 + \cos \psi + 2p)\sin \psi d\psi \]

\[ - j \sin(\delta_f + \delta_j)\frac{\psi}{\psi}(1 + \cos \psi + 2p) \]  \hspace{1cm} (IV - 11)

In non-dimensional form equation (IV - 11) can be written as:

\[ C_m = \frac{M}{\frac{1}{2}\rho V_T^2 c'^2} = -\frac{1}{2V_T} \int_0^\psi \gamma(\psi)(1 + \cos \psi + 2p)\sin \psi d\psi \]

\[ + \frac{1}{2V_T} \int_0^\psi \gamma(\psi)(1 + \cos \psi + 2p)\sin \psi d\psi \]

\[ - C_j \sin(\delta_f + \delta_j)\left\{ \frac{1 + \cos \psi + 2p}{2} \right\} \]  \hspace{1cm} (IV - 12)

The integrals in equations (IV - 12) have been evaluated separately.
The pitching moment coefficient based on the actual airfoil chord is then

\[ C_m = C'_m \left( \frac{2}{1 + \cos \psi_1} \right)^2 \]  

(IV - 13)

Rewriting equation (IV - 11) we obtain:

\[ M = -\frac{pV_o^2 c^2}{4} \left[ (1 + 4\rho)(\delta_F \psi_o + \alpha \pi) + \delta_F \sin \psi_o \left\{ 2(1 + 2\rho) + \cos \psi_o \right\} \right] 
+ \frac{pV_o^2 c^2}{4\pi} \left[ \delta_F \psi_o + \alpha \pi \right] \left\{ \psi_1 - \sin \psi_1 \cos \psi_1 \right\} + 4p(1 + 2\rho) \sin \psi_1 
+ 2(1 + 2\rho) \delta_F \psi_1 \sin \psi_o 
+ \frac{\psi_o}{\psi_1} \sin \psi_o \left\{ (1 + 2\rho) \cos \psi_o - \cos \psi_1 \right\} + \frac{1}{2} (\cos 2\psi_o - \cos 2\psi_1) 
+ \frac{\psi_o}{\psi_1} \sin \psi_o \sin 2\psi_1 \sin 2\psi_o 
\]

(IV - 14)

Equation (IV - 14) is the expression for pitching moment for unit spanwise length. First two terms of the right hand side have to be multiplied by unit length in order to get consistency in units, whereas \( \delta F \) in the last term denotes mass flow rate per unit span. All the terms in right hand side have to be divided by \( \rho \) (i.e., 32.174 lbm-ft/lbf-sec\(^2\)) if the final result is desired in English Engineering Units, i.e., ft-lbf. The contribution of the fuselage to the pitching moment can be estimated as follows. As per Max Munk, for a very slender body of revolution, the variation of the pitching moment with angle of attack in degrees is a function of the fuselage volume and dynamic pressure.

\[ \frac{dM}{d\alpha} = \frac{Volume}{28.7} \cdot q \]  

(IV - 15)

This expression is corrected by a factor \( (K_2 - K_1) \), which is a function of fuselage fineness ratio as given by Perkins and Hage [18], figure 6-13, p. 226.

\[ \frac{dM}{d\alpha} = \frac{Volume}{28.7} \cdot q \cdot (K_2 - K_1) \]  

(IV - 16)
For the JETWING aircraft the fineness ratio is 10. Correspondingly, \( K_2 - K_1 = 0.95 \). Hence, equation (IV - 16) can be written as:

\[
\frac{dM}{d\alpha} = 0.033101 \cdot \text{Volume} \cdot q \quad (IV - 17)
\]

Therefore, the pitching moment contribution of the fuselage is

\[
M_{FU} = 0.033101 \cdot \text{Volume} \cdot q \cdot \alpha \quad (IV - 18)
\]

The overall pitching moment coefficient can be calculated by summing up individual moments for all the spanwise sections of the wing along with the fuselage pitching moment, and then dividing by the product of the dynamic pressure, actual gross wing area and mean aerodynamic chord.

**RESULTS**

The method described here has been coded in FORTRAN. The code comprises of around 700 instructions and occupies a core memory of about 40 blocks (1 block = 512 bytes). The computer time required in a VAX-11/780 system for each combination of \( C_f, \delta_F, \) and \( \alpha \) (with \( \alpha \) varying between \( 0^\circ \) and \( 30^\circ \) in steps of \( 5^\circ \)) does not exceed 5 minutes for the cases for which results have been included. Figure 61 thru figure 66 show the comparison of predicted values of \( C_L \) vs. \( \alpha \) and \( C_L \) vs. \( C_M \) with that of full scale wind tunnel experiments for the JETWING aircraft with the upper wing removed. Figure 67 thru figure 71 show the predicted spanwise distribution of local \( C_L \) and local \( C_m \).

DISCUSSION OF RESULTS

METHOD 1 (Williams). As figures 44 thru 47 show, this method matches the experimental data reasonably well, the errors being less than 10 per cent for all conditions except low blowing coefficients and high angles of attack (\(\alpha > 15^\circ\)).

In these cases the losses of lift shown by nonlinearities in the wind tunnel data are obviously due to flow separation, which cannot be predicted by this method. Separation effects and incomplete turning of the jet sheet also account for the lower values of experimental data versus the theoretical curves in the case of high flap deflection (\(\delta F = 45^\circ\)), figure 47.

An inherent flaw of the method is, that for blowing coefficients \(C_J = 0\), it is insensitive to flap deflection, leading to large errors for no blowing, flaps down configurations.

The slopes of the theoretical curves are throughout slightly steeper than the experimental curves. Therefore, the method tends to underpredict at low angles of attack and overpredict in the high \(\alpha\)-range. A better slope matching can obviously be achieved by improving the \(G(\nu C_{el})\) term in equation (11 - 12). This improvement is currently being investigated.

Figures (48-51) show the lift coefficient plotted against excess thrust coefficient. Again the theory tends to overpredict the experimental data, particularly for higher flap deflections and blowing coefficients. This can largely be explained by the fact that the ram drag in the theoretical prediction method has not been accounted for. For low speed and small \(C_L\) (result of small \(\alpha\) and/or small \(\delta F\)), ram drag can be approximated as the product of density, inlet area, and square of true airspeed. This result, when divided by \(qS\), can be considered as a first approximation of \(\Delta C_{D,\text{r}}\) for ram drag. It may be further simplified to twice the inlet area divided by \(S\), a constant for all \(C_J, \alpha\) and \(\delta F\). Addition of the ram drag to the theoretical \(C_L\) vs. \(C_{F,\text{ex}}\) curves would bring them closer to the experimental curves. However, in the wind tunnel, high \(C_J\) was obtained by reducing \(q\) (i.e., slowing down the tunnel) while keeping the engine RPM constant. This procedure increases \(\Delta C_{D,\text{r}}\) for ram drag with increase of \(C_J\) as is reflected in the comparison plots (figures 48 thru 51).

Further simplifying assumptions in equation (11 - 15) neglecting losses due to jet turning and non elliptic lift distribution also can partially account for the difference between theoretical results and wind tunnel data.

METHOD 2 (Wertz). As figures 52 thru 59 show, this method generally matches the experimental data even better than method 1, the errors being less than 5 per cent for most conditions. Again, where separation or nonideal turning of the jet sheet occurs, the errors become large since the method cannot predict these effects.

At zero flap deflection this method underpredicts slightly for all blowing coefficients (figure 52). The break up into components of basic aerodynamic pressure lift, supercirculation lift and jet reaction lift (figure 56) shows, that the error stems mainly from an underprediction of supercirculation lift. A possible explanation may be the unaccounting for of some additional circulation lift due to the jet sheet blowing over the top surface of the airfoil. This will be presented in more detail under the discussion of method 3.
As figures 57 thru 59 show, for flaps down and high blowing coefficients, the supercirculation lift is somewhat overpredicted. Again, this may be partly due to separation effects and insufficient turning of the jet sheet. Another cause can be seen in the tail down load, which reduces the lift coefficients of the wind tunnel data. The slopes of all the theoretical curves also compare very well with the wind tunnel data, giving confidence for the $C_{L0}$ terms in equation (III - 43).

METHOD 3 (Jacobs). As figures 61 thru 64 show, the differences between the theoretical curves generated by this method and experimental results are greater than in the previous methods.

It is quite obvious that for $C_f = 0$ cases, $C_l$ is being overpredicted for all but when $\delta_p = 0$. A possible cause for this is the nozzle on the upper wing surface, causing the flow to separate, substantially reducing the lift generated. For $\delta_p = 0$, the flow may reattach itself on the upper surface somewhere downstream of a "separation bubble". In this case there would be practically no loss of lift. Again, for $C_f > 0$ cases, $C_l$ is consistently being underpredicted for all $\delta_p$. Also, this shortfall in $C_l$ increases with increasing $\alpha$ and increasing $C_f$. This can be explained by the fact that Jacob's Equivalent Flap Theory assumes the jet being issued at the trailing edge of the mechanical flap, whereas in reality the nozzle exit is situated somewhere around 33% of the chord back from the wing leading edge.

This leads to two opposing effects: First, the actual lift is lower than the theoretical lift due to scrubbing losses of the jet sheet on the upper surface. Hence, equivalent flap length and resulting theoretical lift should have been smaller if the jet velocity at the trailing edge was used instead of actual nozzle exit velocity. Second, the actual lift is higher than the theoretical value. This is due to the increase in velocity on the upper surface of the wing, induced by the jet, which also causes circulation to increase. This additional circulation is directly proportional to the velocity difference between the upper and lower wing surface, and should more than offset the loss due to scrubbing. Again, it is easy to see that with increasing $C_f$ this additional lift will also increase. This additional supercirculation lift is produced in the rear portion of the wing which generates an additional negative pitching moment. Hence, if this lift is accounted for, the predicted $C_l$ should be more positive and $C_M$ more negative than the present values. This change would bring the theoretical $C_l$ vs. $C_M$ plots closer to the experimental plots.

One possible disadvantage of the method is that the jet blowing velocity distribution as a function of thrust or engine RPM is needed as an input. For the JETWING this was measured by means of the laser velocimeter as reported in [1]. Together with thrust measured by dynamometer, it provided the required input data. But, for the design team at the conceptual design stage, this information would not be available. So this method would be more suitable to analyze the existing aircraft based on the USB concept.

Another problem for the Equivalent Flap Theory Method is that for high $C_f$, particularly if coupled with high $\delta_p$, computer convergence on the induced angle of attack may be unreasonably time consuming. However, as far as computer time is concerned, it has been found to be satisfactory up to approximately $C_f = 1$ and $\delta_p = 30^\circ$. For lower $\delta_p$, higher values of $C_f$ can be used in order to achieve comparable run time.

Multhop's Lifting Line Theory is used here because of its simplicity. Another method can be used in its place if better accuracy is desired.

Work is presently underway to predict the unaccounted for jet induced supercirculation lift.
COMPARISON OF THE METHODS.

Method 1 (Williams) is conceptually the simplest and requires the least computer time. It permits computation of $C_L$ vs. $\alpha$ as well as $C_L$ vs. $C_{F_{th}}$.

Method 2 (Wertz) requires only a little more calculation and programming than method 1 and permits the total lift to be broken down into components of basic aerodynamic pressure lift, supercirculation lift and vectored thrust lift. It shows the overall best accuracy for the JETWING $C_L$ vs. $\alpha$ plots.

Method 3 (Jacobs) requires the highest computational effort of the three. However, it can still be considered simple conceptually and from an analytical standpoint when compared to other sophisticated methods [6,7], which require much more computer storage space and time. The predicted $C_L$ values do not match the JETWING wind tunnel data as well as the two other methods do. However, this method does give pitching moments and their slopes (figures 65 and 66).
REFERENCES

CONCLUSIONS

Part I

1. With exception of lift coefficient versus angle of attack data, there is excellent agreement between the wind tunnel and flight test performance results for this configuration.

2. The agreement between wind tunnel and flight test results for lift coefficient versus angle of attack is probably as good as can be expected considering the measurement accuracies and data reduction technique required.

3. The NASA Ames Research Center wind tunnel data, as verified by this and the previous flight test, [1] is of sufficient validity to use for extrapolation to other flight vehicles employing the Jetwing concept.

4. The performance difference between the upper wing installed and upper wing removed configurations pose some interesting questions concerning the thickness of the blowing jet.

5. Longitudinal handling qualities, particularly longitudinal stability are improved by removal of the upper wing. Other handling qualities are essentially unchanged.

6. Flyover noise levels for the Jetwing aircraft are very low and disappear into the background noise levels in light wind conditions.

Part II

1. Simple analytical methods to reasonably predict lift and excess thrust coefficients for other aircraft employing the Jetwing concept have been demonstrated in this report.

2. Accurate prediction of pitching moment coefficient for Jetwing configuration is more difficult. However, a method is shown in this report which will give reasonable estimates of the longitudinal stability parameter $dC_M/dC_L$.

3. Accurate prediction of pitching moment coefficient for Jetwing configurations appears to require the use of the more complex vortex lattice methods which were beyond the scope of this effort.
RECOMMENDATIONS

Part I

1. On future programs using the Jetwing aircraft a more accurate method for measuring angle of attack should be devised.

2. The NASA Ames Research Center wind tunnel data on the Jetwing Aircraft should be used for extrapolation to other aircraft designs employing the Jetwing concept.

3. The reasons for performance and handling qualities differences of the Jetwing airplane with and without the upper wing require further investigation since they may have implications for all Upper Surface Blowing configurations.

Part II

1. Since lift and excess thrust coefficients can be reasonably predicted for Jetwing configurations (using the simple methods described in this report) future effort should be concentrated upon predicting stability and control parameters such as pitching moment coefficient and downwash.
APPENDIX I

SOME REMARKS ON BLOWING COEFFICIENT

A key parameter in the theoretical and experimental treatment of powered lift is the blowing coefficient

\[ C_J = \frac{\dot{M}_J V_J}{qS} \]

where \( \dot{M}_J V_J = J \) is the jet momentum, which can be measured experimentally and represents the product of actual values of mass flow \( \dot{M}_J \) and jet velocity \( V_J \). For design purposes these two quantities are usually determined theoretically by assuming nonviscous isentropic flow. The ideal values \( \dot{M}_\mu \) and \( V_\mu \) can be used for the definition of the blowing coefficient

\[ C_\mu = \frac{\dot{M}_\mu V_\mu}{qS} \]

This theoretical blowing coefficient \( C_\mu \) is usually higher than the corresponding actual blowing coefficient \( C_J \), since viscous effects reduce nozzle exit areas, result in scrubbing losses, etc. Therefore, for accurate predictions, appropriate corrections have to be made.

Another problem occurs through the use of the wing reference area \( S \) for partially blown wings. Basic theoretical prediction methods like Spence [9] are based on a lifting surface with full span blowing and do not consider fuselage cut-out or part-span blowing. The overall three-dimensional blowing coefficient \( C_J \) of a part-span blown wing does not represent the same blowing per unit span as the blowing coefficient \( C_J \) of the full-span blown wing.

If we compare, for example, two wings with the same reference areas, one full-span blown and the other half-span blown, then for the same blowing coefficient \( C_J \) the sectional blowing intensity per unit span \( J/b \) would be twice as high for the half-span blown wing.

In using the theoretical formulae that were derived from full-span blown wings, it is important to use similar blowing intensities for calculation of derivatives etc. Therefore the blowing coefficient has to be modified for part-span blown wings by defining a "mean sectional blowing coefficient"

\[ C_J = \frac{\dot{M}_J V_J}{qS'} \]

where \( S' \) is the wing reference area corresponding to the spanwise extent of blowing.
In our example

\[ S' = \frac{1}{2} S \]

and

\[ C_j = 2C_j \]

Then the blowing intensity \( \dot{M}_j V_j / b \) is the same for both wings. This correction is used by Williams in Method 1.

Others also consider the "carry over effect" that the blown portion of a part-pan blown wing has on the unblown areas, by defining

\[ S'' = S' + \frac{1}{2} S_{CO} \quad S_{CO} = S - S' \]

Then the modified sectional blowing coefficient becomes

\[ C_j = \frac{\dot{M}_j V_j}{qS''} = \frac{S}{S''} C_j \]

This correction is used by Wertz in Method 2. He uses as symbols \( C_j \) and \( C_j'' \), which he calls the three-dimensional configuration factor.

To avoid confusion we have used only overall three-dimensional blowing coefficients \( C_j \) and corrected two-dimensional "sectional" blowing coefficients \( C_j \) in this report. It is understood that \( C_j \) refers to experimentally measured values of the jet momentum \( J \) or properly corrected theoretical values. The sectional coefficients \( C_j \) are defined by means of reference areas \( S' \) or \( S'' \) under the particular methods.
APPENDIX II

PROCEDURE FOR EVALUATION OF SECTIONAL BLOWING COEFFICIENT IN METHOD 3

In equivalent flap theory, the following procedure has been adopted for the evaluation of spanwise variation of two-dimensional "sectional" blowing coefficient $C_j$ from the input data of jet velocity and nozzle area distribution:

From the definition of three-dimensional blowing coefficient $C_1 = \frac{F_0}{\frac{1}{2} \rho C S}$, true airspeed can be written as:

$$V_T = \sqrt{\frac{F_G}{\frac{1}{2} \rho C_j S}}$$

As laser velocimeter data of jet velocity distribution for 55\%$N_1$ were thought to be most reliable, these data were used as input. Correspondingly, $F_G$ was obtained as a function of $V_T$ at that particular RPM (i.e., 55\%$N_1$) from the thrust calibration plot (figure 40 [1]). Finally, $F_G$ and $V_T$ were obtained, for the desired value of $C_j$, as the result of an iteration between the expression of $V_T$ and the data from the thrust calibration plot. Since the laser velocimeter data were obtained at static condition, it was felt necessary to translate that data to any airspeed which was determined as a result of aforesaid iteration. Then $C_j$ for unit spanwise distance at any spanwise section was obtained as:

$$C_j = \frac{\dot{M}_j V_j F_{ao}}{\frac{1}{2} \rho V_T^2 c} = \frac{\rho a_j V_j^2 F_{ao}}{\frac{1}{2} \rho V_T^2 c}$$

where $F_{ao}$ = static thrust at 55\%$N_1$
and $a_j$ = area of the nozzle.
