ABSTRACT

A random sample is taken from a population consisting of an unknown number of distinct species. A quantity of interest is the probability of discovering a new species when an additional draw from the population is made. An estimator of this quantity was introduced by Starr (1979). We prove a conjecture of Starr's that the estimator is uniformly minimum variance unbiased and give various asymptotic properties of the estimator. A nonparametric maximum likelihood estimator is introduced which has similar asymptotic properties. A Monte-Carlo study is given which suggests guidelines for choosing an estimator under various circumstances.

AMS (MOS) Subject Classifications: Primary 92A10; Secondary 62G05, 62P10

Keywords and Phrases: U-statistics, nonparametric maximum likelihood estimator

Work Unit Number 4 (Statistics and Probability)
§1. Introduction

In many ecological studies, a population is sampled to determine the number of species that exist in the population. This quantity provides a partial description of the population and may be used in the comparison of populations over time or space. Such sampling often takes place sequentially and it is in this context that a related quantity arises: the probability of discovering a new species in a future sample based on sampling which has already taken place. By itself, this probability indirectly leads to information about the number of species in the population; it might also be used in a sequential sampling scheme where the goal is to decide when to stop sampling.

To describe the problem formally, consider a population composed of distinct species and use $M_i$ to represent the $i$th species, $i=1,2,...$. We assume that the species have no natural order and that the number of species may be countably infinite. Suppose $n$ independent drawings are made from the population, with replacement if the population is finite, and define $X_j = i$ when the $j$th draw is from $M_i$. Let $X_i^n = \sum_{j=1}^{n} I(X_j = i)$ be the number of representatives of the species $M_i$ in $n$ drawings, where $I(A)$ as the indicator function of the set $A$. The conditional probability of discovering a new species in one additional search is

*Department of Statistics, 1210 West Dayton Street, University of Wisconsin-Madison, Madison, WI 53706.

\[ U_n = \sum_i p_i I(X_i^n = 0), \tag{1.1} \]

where \( p_i = P(X_i = i) \). The corresponding unconditional probability of new species discovery is

\[ \theta = E(U_n) = \sum_i p_i q_i^n, \tag{1.2} \]

where \( q_i = 1 - p_i \).

As argued, for example, by Starr (1979), standard statistical procedures for direct estimation of a realization of the random variable \( U_n \) are inadequate. An alternative, and closely related, goal is the estimation of the parameter \( \theta_n \). Estimation of \( \theta_n \) has attracted interest in the recent literature; for example, Starr (1979), Chao (1981, correction, 1982), and Banerjee and Sinha (1985) have recently introduced estimators of \( \theta_n \). For earlier efforts on this and related problems, see Good (1953, 1965), Good and Toulmin (1956), Goodman (1949), Harris (1959, 1968), Knott (1967) and Robbins (1968).

We note that our model is not confined to sampling species from populations; related problems are discussed in Efron and Thisted (1976) and others. The sequential problem mentioned above is discussed in Goodman (1953), Rasmussen and Starr (1979), and Banerjee and Sinha (1985). A Bayesian approach can be found in Hill (1979).

Without additional constraints on the model, it is well known that there is no unbiased estimator of \( \theta_n \) based on a sample size less than \( n+1 \) (cf., Appendix A, Lemma A.1). However, if one additional search is made, Robbins (1968) noted that

\[ V_1 = (n + 1)^{-1} \sum_i I(X_i^{n+1} = 1) \tag{1.3} \]

is an unbiased estimator of \( \theta_n \). Robbins also argued that \( V_1 \) follows \( U_n \) in the sense that the expected squared difference is strictly bounded from above by
Starr (1979) gave a more general version of the Robbins estimator. Starr supposed that the initial search of size $n$ was extended by $m$ additional stages and defined

$$V_m = \sum_{k=1}^{m} \frac{(m-1)!}{k!} \frac{1}{n+m} \sum_{i} I(X_i^{n+m} = k). \quad (1.4)$$

The term $\sum_{i} I(X_i^{n+m} = k)$ is the number of species with $k$ representatives and is a part of the so-called "sampling frequency of frequencies" (cf., Good, 1953). It is important in applications because only the summary statistics $\{\sum_{i} I(X_i^{n+m} = k)\}_{k=1}^{n+m}$ need to be retained for analysis. Starr showed that $V_m$ is the unique unbiased estimator which is a linear combination of $\{\sum_{i} I(X_i^{n+m} = k)\}_{k=1}^{n+m}$ and conjectured that it is the minimum variance unbiased estimator (MVUE). This property was discussed by Chao (1981) who proposed an alternative estimator which was further modified by Banerjee and Sinha (1985). Chao's estimator was motivated by Harris's (1968) work in the important special case of equal cell probabilities.

In §2 we answer the issues raised by Chao (1981, 1982) and Banerjee and Sinha (1985) by proving Starr's conjecture that $V_m$ is the MVUE. The technique is to use some results of Halmos (1946) on unbiased estimation and show that $V_m$ is a U-statistic. Several other properties of $V_m$ are also immediately available based on the theory of U-statistics and are described in §2. In §3 we introduce a nonparametric maximum likelihood estimator (NPMLE) as an alternative to $V_m$. Although the NPMLE is biased in finite samples, we show that it has similar large-sample properties. Some heuristic arguments in addition to the simulation results of §4 suggest that the NPMLE may be a desirable alternative to Starr's estimator in certain situations. We close in §5 with some general remarks. Appendices A and B provide details of the proofs of the technical results of §2 and §3, respectively.
§2. Properties of Starr’s Estimator

For convenience, we begin by stating some results of Halmos (1946). A direct consequence of these results is the verification of Starr’s conjecture. Another consequence is that \( V_m \), defined in (1.4), is a U-statistic. This property has further consequences which we exploit.

To state Halmos’s results, define \( \Pi^* \) to be the class of all probability distributions on \( \mathbb{R} \), the real line. Let \( E \) be a Borel subset of \( \mathbb{R} \). Define \( \Pi(E) \) to be the class of all \( P \in \Pi^* \) that assign probability to some finite subset of \( E \) and let \( \Pi \) be some subset of \( \Pi^* \) that contains \( \Pi(E) \). For each \( P \in \Pi \), let \( X_1, \ldots, X_N \) be an i.i.d. random sample. Let \( \{i_1, \ldots, i_k\} \) be a subset of size \( k \) of \( \{1,2,\ldots,N\} \) and let \( \sum_{\mathcal{C}} \) be the sum over all \( \binom{N}{k} \) distinct combinations of \( \{i_1, \ldots, i_k\} \). A linear functional \( F(P) \) is said to be homogeneous of degree \( k \) if there exists a mapping \( h \) from \( \mathbb{R}^k \) to \( \mathbb{R} \) such that

\[
F(P) = \mathbb{E}_P h(X_{i_1}, \ldots, X_{i_k}) = \int \cdots \int h(x_{i_1}, \ldots, x_{i_k}) \, dP(x_{i_1}) \cdots dP(x_{i_k})
\]

for all \( P \in \Pi \) and if the integer \( k \) is minimal.

**Lemma 2.1** (Halmos, 1946, Theorems 3 and 5)

Let \( F(P) \) be homogeneous of degree \( k \) over \( \Pi \) with \( F(P) = \mathbb{E}_P h(X_{i_1}, \ldots, X_{i_k}) \).

(a) If \( f(X_1, \ldots, X_N) \) is a symmetric, unbiased estimate of \( F(P) \), then for every point \( (x_1, \ldots, x_N) \) with \( x_i \in E \),

\[
f(x_1, \ldots, x_N) = \binom{N}{k}^{-1} \sum_{\mathcal{C}} h(X_{i_1}, \ldots, X_{i_k}).
\]

(b) Among all unbiased estimators of \( F(P) \), \( \binom{N}{k}^{-1} \sum_{\mathcal{C}} h(X_{i_1}, \ldots, X_{i_k}) \) has minimum variance.

To prove Starr’s conjecture, define \( E = \{1,2,\ldots,\} \), \( N = n+m \) and let \( \Pi \) be the set of all probability distributions defined on \( E \). We shall find the form of \( h(\cdot) \) which is appropriate for this application. To motivate the discussion, we note that the indicator of the \( i \)th species having one representative
can be expressed by

\[ I(X_1^{n+1}) = \sum_{j=1}^{n+1} I(X_j = i) \prod_{k=1 \atop k \neq j}^{n+1} I(X_k \neq i). \quad (2.1) \]

We use the kernel function of size \( n+1 \) defined by

\[ h(X_1, \ldots, X_{n+1}) = (n+1)^{-1} \sum_{i \neq j}^{n+1} I(X_j = i) \prod_{k=1}^{n+1} I(X_k \neq i), \quad (2.2) \]

that is, the proportion of species with one representative. It is easy to see that \( h(\cdot) \) is symmetric and unbiased for \( \theta_n \). The proof that \( \theta_n \) is homogeneous of degree \( k = n+1 \) over \( \Pi \) is standard and is given in Appendix A (Lemma A.1).

Thus, by Lemma 2.1 we immediately have the following properties.

Property 2.1

The statistic \( V_m \) is a U-statistic with kernel \( h(\cdot) \) and degree \( n+1 \), i.e.,

\[ V_m = \binom{n+m}{n+1}^{-1} \sum_{i \neq j}^{n+m} h(X_1, \ldots, X_i, \ldots, X_{n+1}). \quad (2.3) \]

Property 2.2

Based on a random sample of size \( n+m \), \( V_m \) is the MVUE for \( \theta_n \) over \( \Pi \).

A consequence of Property 2.2 is that \( V_m \) has desirable properties as an estimator of \( \theta_n \) for any fixed number \( m \) additional searches. If the number of additional searches is large, from Property 2.1 and the theory of U-statistics it immediately follows that \( V_m + \theta_n \) with probability one, as \( m \to \infty \). Thus, the estimator converges to the parameter of interest. The rate of convergence can further be described by
Property 2.3.

Define \( \sigma^2 = (n+1)^2 \left( \sum_{i=1}^{n} p_i q_i^{n-2} (n p_i - q_i)^2 - \left( \sum_{i=1}^{n} p_i q_i^{n-1} (n p_i - q_i) \right)^2 \right) \). Then,

\[
V_m = \frac{\theta}{n} + \frac{(n+m)^{-1/2}}{\sigma Z + o_p((n+m)^{-1/2})}
\]

as \( m \to \infty \), where \( Z \) is a standard normal random variable.

Remark: The proof of Property 2.3 is standard in the theory of U-statistics (cf., Serfling, 1980, page 192). One only needs to check the calculation of the asymptotic variance which is provided in Appendix A (Lemma A.2). Perhaps the most interesting aspect of Property 2.3 is the fact that in the case of equal species probabilities, it can easily be shown that \( \sigma = 0 \). Indeed, by another application of U-statistic theory in Appendix A, we have

Property 2.4.

Suppose \( p_1 = p_2 = \ldots = p_{1/\mu} = \mu \) for some \( \mu > 0 \). Then,

\[
V_m = \frac{\theta}{n} + \frac{(n+m)^{-1/2}}{\sigma Z + o_p((n+m)^{-1/2})}
\]

as \( m \to \infty \), where \( X^2 \) is a chi-square random variable with 1 degree of freedom.

Thus, the rate at which \( V_m \) approaches \( \theta / n \) in the important special case of equal probabilities is of a different order of magnitude (with respect to weak convergence to a nondegenerate distribution) than the general case. This characteristic is important since a comparison of various alternative estimators in this special case can be misleading when drawing conclusions about their relative performance in the more general set-up of unequal probabilities. In other situations, Starr (1979), Chao (1981), and Banerjee and Sinha (1985) use the equiprobable case as examples of their results. It should also be noted that the equiprobable cells model is unlikely to arise in nature when
sampling for species although it arises naturally in the cataloging problem of, for example, Harris (1959).

§3. An Alternative Nonparametric Estimator

Starr's estimator $V_m$ is attractive computationally, since it is the linear combination of the "frequency of frequencies," and it has desirable theoretical properties since it can be described as a U-statistic. However, because it is derived from summary statistics, there may be some loss of information in a finite number of additional searches, in some sense. For example, if we set $m = 1$, then from (1.3) we see that $V_1$ is the sample proportion of species with one representative. Note that this estimator treats species with 0, 2, 3, ..., $n+1$ representatives equally. Motivated by these heuristic arguments, we introduce the following nonparametric estimator of $\theta_n$ based on an initial sample size $n$ and additional search $m$. Define

$$p_i = (n+m)^{-1} \sum_{j=1}^{n+m} I(X_j = i)$$

and $q_i = 1 - p_i$, $i = 1, 2, \ldots$. The NPMLE of $\theta_n$ is defined to be:

$$\hat{\theta}_m = \frac{1}{m} \sum_{i} p_i q_i \hat{\theta}_n^i.$$ (3.1)

Unlike $V_m$, $\hat{\theta}_m$ is a biased estimator of $\theta_n$. Since $(n+m)\hat{q}_i$ is a binomial random variable, it is straightforward to explicitly write out the bias as a linear combination of powers of $q_i$ and Stirling numbers of the second kind. Finite sample properties of $\hat{\theta}_m$ are further discussed in §4. Asymptotically (as $m \to \infty$), $\hat{\theta}_m$ behaves similarly to $V_m$. By the strong law of large numbers, with probability one, $q_i + \hat{q}_i$, and it is not hard to show that $\hat{\theta}_m \to \theta_n$ with probability, one as $m \to \infty$. We also have the following two asymptotic properties.
Property 3.1

Let $\sigma^2$ be as defined in Property 2.3. Then

$$\hat{\theta}_m = \frac{\theta}{n} + (n+m)^{-1/2} \sigma \frac{z}{\sigma} + o_p((n+m)^{-1/2})$$

as $m \to \infty$.

Property 3.2

Suppose $p_1 = p_2 = \ldots = p_{1/u} = \mu$ for some $\mu > 0$. Then,

$$\hat{\theta}_m = \frac{\theta}{n} + (n+m)^{-1}(n+1)(1-\mu)n^{-2}(2n+1)^{-1}[n(\chi^2-1) + (1-\mu)]$$

$$+ o_p((n+m)^{-1})$$

as $m \to \infty$.

The proof of Properties 3.1 and 3.2 are in Appendix B. Comparing Properties 2.3 and 3.1, we see that $V_m$ and $\hat{\theta}_m$ are asymptotically equivalent to the first order (i.e., $(n+m)^{-1/2}$). An advantage of the NPMLE $\hat{\theta}_m$ is that, since strongly consistent estimators of $q_i$ and hence $\sigma$ can be constructed, we have as an immediate corollary of Property 3.1 large sample interval estimates of $\theta_n$. Comparing Properties 2.4 and 3.2, we see that $V_m$ and $\hat{\theta}_m$ are of the same order of magnitude and have same variance in their respective asymptotic distributions. The estimator $V_m$ is slightly superior to $\hat{\theta}_m$ in the sense that the asymptotic distribution of $V_m - \theta_n$ has mean zero unlike that of $\hat{\theta}_m - \theta_n$. We remark that in this special case of equiprobable cells, Chao's (1981) extension of Harris's (1968) estimator is MVUE for fixed $m$ and hence is a strong competitor to $V_m$ and $\theta_m$.

As noted, the rate of convergence of $V_m$ and $\hat{\theta}_m$ is markedly different in the equiprobable case in comparison to the general case. Moreover, in some
sense the equiprobable case is the only one in which this can happen. Specifically, we have the following result.

Property 3.3

Consider $\sigma^2$ defined in Property 2.3 and suppose that the number of species exceeds $n$. Then, $\sigma^2 = 0$ if and only if $p_1 = p_2 = \ldots = p_{1/\mu}$ for some $\mu > 0$.

§4. Small Sample Properties

In this section we investigate the behavior of Starr's estimator, $V_m$, and the NPMLE, $\hat{\theta}_m$, when $m$ is small via a Monte-Carlo simulation. We look at their bias and mean square error as estimates of $\theta_n$ and make some comments regarding modifications of $\hat{\theta}_m$ which have desirable properties. Finally, we investigate modifications of $V_m$ and $\hat{\theta}_m$ suitable for use when $m = 0$. All computations were done on a VAX 11/750 owned and operated by the Department of Statistics at the University of Wisconsin-Madison. The simulations were performed using the National Bureau of Standard's Core Math Library (CMLIB) pseudo-uniform random number generator UNI.

Two classes of distributions were used to construct the probability distribution $\{p_i; i > 1\}$. These were: (1) equiprobable, with $p_1 = \mu$, $1 < i < 1/\mu$; and (2) truncated geometric, with $p_i = qp^{i-1}/(1-p^c)$, $1 < i < c$, $0 < p < 1$, $q = 1 - p$. For the equiprobable cells model, values of $\mu = .1, .02, .01$ were used; for the truncated geometric model, values of $p = .1, .5, .9$ and $c = 10, 100$ were used. For each assignment of $\{p_i\}$, $\theta_n$ was determined and 1,000 simulations were performed. For each simulation, this involved drawing a sample of size $n$ and a subsequent sample of size $m$. The pairs $(n,m) = (10,1), (10,10), (50,1), (50,10), (50,50)$ were included. For each sample, $\hat{\theta}_m$ and $V_m$ were computed. Tables 4.1-4.2 show the mean values of $\hat{\theta}_m$ and $V_m$ over the
1,000 samples denoted in the tables as $E\hat{\theta}_m$ and $EV_m$, respectively. (The rows corresponding to $m = 0$ will be discussed below.) In addition, the estimated root mean square error of the estimates, denoted by RMSE ($E\hat{\theta}_m$) and RMSE ($V_m$), respectively, are given in Tables 4.1-4.2. Of course, since $V_m$ is unbiased, RMSE ($V_m$) is also an estimate of the standard error of $V_m$.

Generally, in the equiprobable case, $V_m$ has lower root mean square error than $\hat{\theta}_m$. Comparing Properties 2.4 and 3.2, we have up to order $(n+m)^{-1}$,

$$E(V_m-\theta)^2 = E(\hat{\theta}_m-\theta)^2 = 2\mu^2/(3\mu^2-2\mu+1).$$

Thus, for $\mu$ small, RMSE ($V_m$) will be approximately $2\mu^2$ times RMSE ($\hat{\theta}_m$). While the differences in RMSE for $V_m$ and $\hat{\theta}_m$ in Table 4.1 are not all of this magnitude, we do see that $V_m$ is a better estimator of $\theta$ in terms of RMSE.

The situation is reversed to a large extent when the truncated geometric is used for $p_i$. These results appear in Table 4.2. It is evident in this case, as in Table 4.1, that $\hat{\theta}_m$ tends to underestimate $\theta$ and that the bias can be considerable. From the results of sections 2 and 3, we expect $\hat{\theta}_m$ and $V_m$ to have the same asymptotic mean square error. From Table 4.2, it appears that, when $p$ is not too large, the mean square error of $\hat{\theta}_m$ is less than $V_m$, sometimes considerably so. That this can fail when $p$ is large is not surprising since the truncated geometric distribution tends to the equiprobable case when $p$ tends to one. Specifically, $q_p^1/(1-p^c) + 1/c$ for each $i$ as $p$ tends to one.

That $\hat{\theta}_m$ dominate $V_m$ in terms of the truncated distribution when $p$ is small can be seen in an example: Let $c = 2$, $m = 1$, and $n = 2$, so $p_1 = q(1-p^2)$ and $p_2 = qp/(1-p^2)$. Then $\hat{\theta}_2 = p_1p_2$ and it is easy to show that $E\hat{\theta}_1 = 2/3 p_1p_2$, which represents a considerable bias. For this example it can be shown that

$$E(\hat{\theta}_1-\hat{\theta}_2)^2 = (4p_1p_2-9p_1^2 p_2^2)/27$$

and

$$E(V_1-\theta)^2 = p_1p_2(p_1-p_2)^2.$$

It follows that $E(V_1-\theta)^2 > E(\hat{\theta}_1-\hat{\theta}_2)^2$ if $p_2 < \frac{1}{2} - \sqrt{77}/66$, or equivalently, if $p < .5799$.

While $\hat{\theta}_m$ may be an attractive estimator in the truncated geometric case in terms of its mean square error, it has already been noted that its bias can be considerable. In fact,

$$E(\hat{\theta}_m) = \frac{\theta}{n} + (n+m)^{-1}\left[ \left(\begin{array}{c} n+m \\ 2 \end{array}\right) \theta_{n-1} - \left(\begin{array}{c} n+1 \\ 2 \end{array}\right) \theta_n \right] + o((n+m)^{-1}).$$

This suggests that the quantity $\hat{\theta}_m + (n+m)^{-1}\left[ \left(\begin{array}{c} n+1 \\ 2 \end{array}\right) \hat{\theta}_m - \left(\begin{array}{c} n \\ 2 \end{array}\right) \sum_i \hat{p}_i q_i \right]$ would be a better estimator of $\theta$ than $\hat{\theta}_m$ alone. For the size of the samples discussed here, $\sum_i \hat{p}_i q_i \ldots \hat{n}$ tends to underestimate $\hat{\theta}_{n-1}$ too severely and a better estimator can be obtained by replacing $\sum_i \hat{p}_i q_i \ldots \hat{n}$ by $\hat{\theta}_m$, leading to the estimator

$$\hat{\theta}_m = \hat{\theta}_m \left(1 + n/(n+m)\right).$$

Values of $E(\hat{\theta}_m)$ and RMSE ($\hat{\theta}_m$) are given in Tables 4.1-4.2. Generally, $\hat{\theta}_m$ has good bias properties and compares favorably with $V_m$ in terms of RMSE, even for the equiprobable case.

It should be noted that $\hat{\theta}_m$ and $V_m$ are, in some sense, "retrodictors." That is, they predict, on the basis of $n+m$ observations, what would be observed for the last $m$ observations. In Starr (1979), an argument is given that this is not a vacuous exercise; $V_m$ can be used effectively to predict, on the basis of an initial sample size $n$ and a subsequent sample of size $m$, what will occur in a large future sample of size $M$. This argument applies equally well to the NPMLE $\hat{\theta}_m$. However, it can be argued that the principle interest of estimators such as $\hat{\theta}_m$ and $V_m$ is in their properties as true predictors. For example, Rasmussen and Starr (1979) used the estimator $V_o = n^{-1} \sum_1^n I(X_i = 1)$ to consider a rule for sequentially sampling a population. Similarly, the estimators $\hat{\theta}$ and $\hat{\theta}^*$ could also be used in such a capacity. We leave the examination of such sequential rules to a future paper and consider here only the properties of $V_o$, $\hat{\theta}_o$ and $\hat{\theta}^*_o$ as estimates of $\theta_n$. Simulation results appear...
in Tables 4.1-4.2. In terms of mean square error, again we see that, in the
equiprobable case, $V_o$ dominates $\hat{\theta}_o$ and that $\theta^*$ compares favorably with $V_o$. In
the truncated geometric case, both $\hat{\theta}_o$ and $\theta^*$ dominate $V_o$ except when $p$ is near
one in which case $V_o$ tends to be a better estimator than $\hat{\theta}_o$.

§5. Summary and Discussion

This paper has focused on nonparametric estimators of $\theta_n$, the probability
of discovering a new species. We have shown $V_m$ to be a minimum variance
unbiased estimator with a high rate of convergence in the equiprobable case.
The nonparametric maximum likelihood estimator, $\hat{\theta}_m$, has similar asymptotic
properties. In small samples, $V_m$ is a better estimator than $\hat{\theta}_m$ in the equi-
probable cell case with respect to mean square error; this is reversed for
truncated geometric distributions when $p$ is not large. An estimator with
somewhat less bias than $\hat{\theta}_m$ is $\theta^*_m$ defined in (4.1); it compares favorably with
$V_m$ in terms of mean square error.

Besides the theoretical interest in $\hat{\theta}_m$ as an estimator which competes
well with $V_m$ in the truncated geometric case, we argue that this has practical
implications. For example, data collected by Andrews (1985) of the species
abundance of epiphytic fungi on apple leaves fit a truncated geometric distri-
bution quite well with $p = .77$. Arguments are given by Pielou (1977) that a
geometric distribution, or more generally, a negative binomial distribution is
appropriate in some situations for modeling species distributions. It remains
to be seen how $V_m$ and $\hat{\theta}_m$ compare over a wider class of distributions.
Appendix A. Proof of §2 Results

Lemma A.1

The parameter $\theta_n$ is homogeneous over $\Pi$ and is of degree $n + 1$.

Proof:

Sufficient for the proof is to show that $\sum q_i^k$ is homogeneous of degree $k$. Since $E_P(\sum q_i^k I(X_i \neq i)) = \sum q_i^k$ for all $P \in \Pi$, we have that $\sum q_i^k$ is homogeneous of degree $< k$. We now suppose that $\sum q_i^k$ is homogeneous of degree $h$ and show that $h > k$. Thus, assume there exists $\phi(x_1, \ldots, x_h)$ so that

$$\sum q_i^k = E_P(\phi(X_1, \ldots, X_h))$$  \hspace{1cm} (A.1)

for all $P \in \Pi$. Suppose $\Pi_1$ is a subset of $\Pi$ so that

$$P_1(1) = q \text{ and } P_1(2) = 1 - q$$

and $\Pi_1 = \{ P \in \Pi, 0 < q < 1 \}$. With the choice of $P_q$ the left-hand side of (A.1) is a polynomial in $q$ of degree $k$ while the right-hand side is a polynomial in $q$ of degree, say, $h_1 < h$. Since these polynomials are must be of the same degree, we have $k = h_1 < h$. \hspace{1cm} \dagger$

Define $h_{1n}(X_1) = E(h(X_1, \ldots, X_n)|X_1) - \theta_n$. The proof of Property 2.3 is complete with $\sigma^2 = (n+1)^2 \var(h_{1n}(X_1))$ and the following

Lemma A.2.

$$\var(h_{1n}(X_1)) = \sum_i (p_i - (n+1)^{-1})^2 p_i q_i 2n-2 - (\theta_n - (1+n^{-1})^{-1}\theta_{n-1})^2.$$

Proof:

Use (2.2) to get

$$E(h(X_1, \ldots, X_{n+1})|X_1) = (n+1)^{-1} \sum_i p_i^{n-1} [np_i(X_i \neq i) + q_i I(X_1 = i)].$$
Thus, by rearranging terms

\[ h_{1n}(X_i) = (n+1)^{-1} \sum_i q_i^{-1} (p_i - (n+1)^{-1})(p_i - I(X_i = i)). \]

Hence,

\[ \mathbb{E} h_{1n}(X_i)^2 = (n+1)^{-2} \left( \sum_i p_i q_i^{-1} (p_i - (n+1)^{-1})^2 \right. \]

\[ - \sum_{i \neq j} p_i q_i^{-1} q_j^{-1} (p_i - (n+1)^{-1})(p_j - (n+1)^{-1}) \]

which gives the result upon a rearrangement of terms.

To prove Property 2.4, we need to examine the properties of the following projection of \( h \),

\[ h_{2n}(X_1, X_2) = \mathbb{E}(h(X_1, \ldots, X_{n+1}) | X_1, X_2) - h_{1n}(X_1) - h_{1n}(X_2) - \theta_n \]

\[ = (1-\mu)^{n-2}(\mu-2(n+1)^{-1}) [I(X_1 = X_2) - \mu]. \]  \hfill (A.2)

To see (A.2), first note that it is easy to check that \( \theta_n = (1 - \mu)^n \) and that \( h_{1n}(X_1) = h_{1n}(X_2) = 0 \). Now, use (2.2) to get

\[ \mathbb{E}(h(X_1, \ldots, X_{n+1}) | X_1, X_2) \]

\[ = (n+1)^{-1}(1-\mu)^{n-2} \left( \sum_i \left[ (n-1)\mu I(X_i \neq i) I(X_2 \neq i) \right. \right. \]

\[ + (1-\mu)(I(X_1 = i) I(X_2 \neq i) + I(X_1 \neq i) I(X_2 = i)) \]

\[ = (1-\mu)^{n-2} \left[ 1 - 2\mu n/(n+1) + (\mu-2(n+1)^{-1}) I(X_1 = X_2) \right] \]

after some algebra. Subtracting \( \theta_n \) yields (A.2). The proof of Property 2.4 is now an application of a result independently due to Gregory (1977) and Serfling (see Serfling, 1980, page 192).
Proof of Property 2.4:

Let \( K = (1-\mu)^{n-2}(\mu-2(n+1)^{-1}) \) so that \( h_{2n}(X_1, X_2) = K(I(X_1=X_2) - \mu) \). It is immediate that \( \text{Var}(h_{2n}(X_1, X_2)) = K^2\mu(1-\mu) > 0 \). Now, let \( g \) be an arbitrary, measurable function such that \( E(g(X))^2 < \infty \) and let \( x, \lambda \) be real constants. The forms of \( g(\cdot) \) and \( \lambda \) satisfying

\[
\lambda g(x) = E\{h_{2n}(x, X)g(X)\}
\]

\[
= Ku\{\sum_i I(x=i)g(i) - Eg(X)\} = Ku\{g(x) - Eg(X)\}
\]

are of two types. If \( E g(X) \neq 0 \), then

\[
g(x) = E g(X)/(1 - \lambda/K \mu)
\]

is a constant (\( \neq 0 \)) and thus \( \lambda = 0 \). If \( E g(X) = \mu \sum_i g(i) = 0 \), then \( \lambda = Ku \).

Thus, for example, by Serfling (1980, page 194), we have the result.
Appendix B. Proof of §3 Results

Proof of Property 3.1:

Define \( G(x) = x(1-x)^n \) and note that \( \hat{\theta}_n = \sum_i G(p_i) \) and that \( \hat{\theta}_m = \sum_i G(\hat{p}_i) \).

By a Taylor-series expansion,

\[
\hat{\theta}_m = \hat{\theta}_n + \sum_i (\hat{p}_i - p_i) G'(p_i) + O(\sum_i (\hat{p}_i - p_i)^2),
\]

since \( G'(x) \) is bounded for \( 0 < x < 1 \). Now, since

\[
(n+m)^{1/2} E \left[ \sum_i (\hat{p}_i - p_i)^2 \right] = (n+m)^{-1/2} \sum_i p_i q_i
\]

\[
\leq (n+m)^{-1/2} \to 0,
\]

we have that \( (n+m)^{1/2} \sum_i (\hat{p}_i - p_i)^2 \to 0 \) in probability. By Fubini's Theorem, we have that

\[
\sum_i (\hat{p}_i - p_i)^2 \to 0
\]

This, the central limit theorem and Slutsky's theorem give the result. 

Proof of Property 3.2:

By a Taylor-series expansion,

\[
\hat{\theta}_m = \hat{\theta}_n + G''(\mu)/2 \sum_i (\hat{p}_i - \mu)^2 + O(\sum_i (\hat{p}_i - \mu)^3),
\]

since \( G''(x) \) is bounded for \( 0 < x < 1 \) and \( \sum_i (\hat{p}_i - \mu) = 0 \). Similarly to (B.1), we have that \( (n+m) \sum_i (\hat{p}_i - \mu)^3 \to 0 \) in probability. Thus

\[
(n+m)(\hat{\theta}_m - \hat{\theta}_n) = (n+m) G''(\mu)/2 \sum_i (\hat{p}_i - \mu)^2 + o_p(1).
\]

(B.2)
Now,
\[
\sum_i \left( p_i^2 - u^2 \right) = \sum_i \left( (n+m)^{-1} \sum_{j=1}^{n+m} I(X_j=i) \right)^2 - u
\]
\[
= (n+m)^{-1} + 2(n+m)^{-2} \sum_{j<k} I(X_j=X_k) - u
\]
\[
= (n+m)^{-1} (1-u) + (1 - (n+m)^{-1}) U,
\]
where \( U = \frac{1}{2} \sum_{j<k} I(X_j=X_k) - u \) is a U-statistic. As in the proof of Property 2.4, \( E(U|X_1) = 0 \) and
\[
\binom{n+m}{2} E(U|X_1,X_2) = (I(X_1=X_2) - u).
\]
Thus, by the same argument as in the proof of Property 2.4 (with \( K=1 \)), we have
\[
(n+m) U \overset{D}{\to} \chi^2(1).
\]
This, (B.2), (B.3) and Slutsky's Theorem yields the result. \( \dagger \)

Proof of Property 3.3

We need only show that \( \sigma^2 = 0 \) implies \( p_i = p_j \) for each \( i,j \). To do this we construct the random variable
\[
X = (n+1)(np_i-q_i^n) q_i^{n-1}
\]
with probability \( p_i \), \( i=1,2,... \)

Now, it is easy to see that \( \text{Var}(X) = \sigma^2 \) and thus, \( \sigma^2 = 0 \) means that \( (n+1)(np_i-q_i) q_i^{n-1} = (n+1)^2 (p_i - (n+1)^{-1}) q_i^{n-1} \) must be some constant \( C \) for \( i=1,2,... \) Since the number of species exceeds \( n \), we have \( p_i < (n+1)^{-1} \) for some \( i \) and \( C \) must be nonpositive. The question of whether different \( p_i \) may satisfy \( (n+1)^2 (p_i - (n+1)^{-1}) q_i^{n-1} = C \) is equivalent to finding the number of roots of
\[ h(x) = \frac{n}{n+1} - x \] \[ C_0 < x < 1. \]

Now, \[ h'(x) = nx^{n-2}((n-1)/(n+1) - x) \] is positive for \( 0 < x < (n-1)/(n+1) \) and is negative for \((n-1)/(n+1) < x < 1\). Further, \( h(0) = -C \) and \( h(1) = -(n+1)^{-1} - C \). Thus, for \(-(n+1)^{-1} < C < 0\) there is exactly one root and no roots for \( C < -(n+1)^{-1} \). \( \dagger \)

**Abstract:**
A random sample is taken from a population consisting of an unknown number of distinct species. A quantity of interest is the probability of discovering a new species when an additional draw from the population is made. An estimator of this quantity was introduced by Starr (1979). We prove a conjecture of Starr's that the estimator is uniformly minimum variance unbiased and give various asymptotic properties of the estimator. A nonparametric maximum likelihood estimator is introduced which has similar asymptotic properties. A Monte-Carlo study is given which suggests guidelines for choosing an estimator under various circumstances.
