DISTRIBUTED DEADLOCK DETECTION
FOR COMMUNICATING PROCESSES

ABSTRACT

In a distributed system where processes communicate directly, deadlock among a set $P$ of processes occurs when all processes in $P$ are idle waiting for messages from other processes in $P$ in order to start execution, but there are no messages in transit between them. For a process which suspects that it may be deadlocked to determine whether it is indeed deadlocked, it is necessary for it to query other processes. Chandy, Misra, and Haas have proposed a distributed deadlock detection algorithm which uses fixed-length queries and replies. According to this algorithm, a process which suspects it may be deadlocked initiates a query computation by querying each process from which it is waiting to receive a message. If the initiator receives one reply for each query sent out, then the initiator is deadlocked. Otherwise, if the initiator has not received all replies within a timeout period $T$, it assumes that it is not deadlocked. We present five algorithms which use variable-length queries and replies to detect deadlock. Instead of using timeout to indicate an absence of deadlock, these algorithms use explicit messages called informs to convey the absence of deadlock to the query computation initiator. One algorithm detects a deadlock if it exists when the query computation is initiated. The other algorithms will detect deadlock as deadlock conditions develop. Proofs of correctness are provided, along with a simulation study which compares the performance of the new algorithms with that of the algorithm by Chandy, Misra, and Haas.

In a distributed system where processes communicate directly, deadlock among a set \( P \) of processes occurs when all processes in \( P \) are idle waiting for messages from other processes in \( P \) in order to start execution, but there are no messages in transit between them. For a process which suspects that it may be deadlocked to determine whether it is indeed deadlocked, it is necessary for it to query other processes. Chandy, Misra, and Haas have proposed a distributed deadlock detection algorithm which uses fixed-length queries and replies. According to this algorithm, a process which suspects it may be deadlocked initiates a query computation by querying each process from which it is waiting to receive a message. If the initiator receives one reply for each query sent out, then the initiator is deadlocked. Otherwise, if the initiator has not received all replies within a timeout period \( T \), it assumes that it is not deadlocked. In this thesis, five algorithms which use variable-length queries and replies to detect deadlock are presented. Instead of using timeout to indicate an absence of deadlock, these algorithms use explicit messages called informs to convey the absence of deadlock to the initiator of a query computation. One of the algorithms detects a deadlock if it existed when the query computation was initiated. The other algorithms will detect deadlock as deadlock conditions develop. Proofs of correctness are provided for the algorithms, along with a simulation study which compares the performance of the new algorithms with that of the algorithm by Chandy, Misra, and Haas.
DEDICATION

The fear of the Lord is the beginning of knowledge.
Prov. 1:7a

For the Lord gives wisdom;
from his mouth come knowledge and understanding;
he stores up sound wisdom for the upright;
he is a shield to those who walk in integrity,
guarding the paths of justice and
preserving the way of his saints.
Prov. 2:6-8
ACKNOWLEDGEMENTS

I would especially like to thank my thesis advisor, Professor Jane W.-S. Liu, for her
guidance, support, and many suggestions when they were needed most. I would also like
to thank the other members of my thesis committee: Professors Geneva Belford, H.
George Friedman, Duncan Lawrie, and Daniel Reed. Special thanks go to all the
graduate students of Prof. Liu for their kindness, advice, and support.

My parents certainly deserve much of the credit, since it was they who always
couraged me to do my best and to pursue such high endeavors. I shall ever be grateful
for the continuing love and support of my father. Most of all, I thank my dear wife,
Heather, whose love, understanding, and encouragement has made these three years so
enjoyable. I thank all of you for your continued patience, support, and understanding
that has made it possible for me to complete this thesis.

CHAPTER 1.

Introduction

In a distributed system where processes communicate directly [Hoar78], deadlock among a set $S$ of processes can occur when all processes in $S$ are idle waiting for messages from other processes in $S$ in order to start execution. When there are also no messages in transit between any pair of processes in $S$, none of the processes in $S$ will ever receive a message. All processes in $S$ are therefore permanently idle, or deadlocked. For a process which suspects that it may be deadlocked to determine whether it is indeed deadlocked, it is necessary for it to query other processes. Many models of systems in which processes communicate via message exchanges have been developed for the purpose of studying deadlock detection [Brac85, BrTo84, ChMi79, ChMi83, ChMi85, CoLe82, DiSc80, Fran80, GISh80, Haas81, MiCh82, Misr83, Ober82, SzSh85]. Other models strictly address the problem of resource deadlocks among database transactions [BeObSi, ChMi82, ChMi83, CoEl71, Gold77, Haas81, Holt72, IsMa78, Mals80, MeMu79, MiMe84, Ober80, SiNa85, Tsai82].

In the model of diffusing computations by Dijkstra and Scholten [DiSc80], every process is ready to receive messages from all other processes at all times. Hence, all processes must be idle waiting for messages in order for termination to occur. Based on this model, Dijkstra and Scholten [DiSc80] and Misra and Chandy [MiCh82] have proposed algorithms to detect termination in diffusing computations.

Chandy, Misra, and Haas [ChMi83, Haas81] have also developed a model, hereafter referred to as the "communication model", which models systems of distributed processes
which communicate via messages. Their model is also able to model implementations of Communicating Sequential Processes as put forth by Hoare [Hoar78]. In the communication model, a process 1) is either in the idle state or in the executing state, 2) may wait selectively for messages from some (not necessarily all) other processes, and 3) may, if it is in the execution state, send a message to another process. Every idle process has associated with it a set of processes called its dependent set. An idle process will begin to execute whenever it receives a message from any process in its dependent set. While a process is idle, it may not change state or its dependent set. With this model, deadlock exists whenever any subset of processes wait for each other.

Chandy, Misra, and Haas [ChMi83, Haas81] have proposed a distributed deadlock detection algorithm, hereafter referred to as the CMH Algorithm, which uses fixed-length queries and replies. According to this algorithm, a process which suspects it may be deadlocked initiates a query computation by querying all the processes in its dependent set. This process is referred to as the initiator. After querying all processes in their respective dependent sets and receiving replies from them, each idle process in the dependent set of the initiator replies to the initiator that the process is idle waiting for messages from other idle processes. An executing process discards any queries received. If the initiator receives one reply for each query sent out, then the initiator is deadlocked. Otherwise, if the initiator has not received all replies within a timeout period $T$, it assumes that it is not deadlocked. This algorithm does not work correctly when conditions such as network failures, a large backlog of messages, or a process being aborted, etc., prevent any reply from being received within the timeout period $T$. Since occurrences of these conditions are unavoidable in any distributed system, this shortcoming of the CMH Algorithm is a serious one.
This thesis first discusses the CMH Algorithm based on the communication model [ChMi83, Haas81]. Five algorithms which use variable-length queries to detect deadlock are presented. Instead of using timeout to indicate an absence of deadlock, these algorithms use explicit messages called *informs* to convey the absence of deadlock to the initiator of a query computation. One of the algorithms detects a deadlock if it existed when the query computation was initiated. The other algorithms will detect deadlock as deadlock conditions develop. A simulation study was done to compare their performance with that of the CMH Algorithm. Proofs of correctness are also provided for the algorithms.

This thesis is organized as follows: Chapter 2 describes in detail the communication model used by Chandy, Misra, and Haas to develop their algorithm. Their algorithm will then be presented. Chapter 3 presents the proposed new algorithms for detecting deadlock among communicating processes. Chapter 4 contains proofs of correctness for the algorithms. The results of a simulation study are presented in Chapter 5, and Chapter 6 contains conclusions and recommendations for future study.
CHAPTER 2.
Background, Assumptions, and Definitions

2.1. Introduction

The deadlock detection algorithms developed in this proposal are based on the communication model developed in [ChMi83, Haas81]. It models a system of processes which communicate via messages. It is assumed that the network is reliable, in that the following conditions hold [DiSc80]: (1) All message delays are arbitrary but finite; (2) Messages are transmitted and received correctly. That is, message contents are never corrupted; and (3) Sequenced message delivery is guaranteed. That is, messages sent by process A to process B are received in the order sent. These assumptions are valid in most modern data communication networks [Tane81].

2.2. The Communication Model

According to Hoare's Communicating Sequential Processes, process A can send a message to process B only if process B is waiting to receive a message from process A. In the communication model, a process may be in one of two states, idle or executing. An executing process A may send one or more messages at any time to other processes. When a process changes state from executing to idle, it waits selectively for messages from some processes. This set of processes is called the dependent set of the process. An idle process may receive messages only from processes in its dependent set, whereupon its state changes to executing. The dependent set of an idle process does not change. It is further assumed that processes execute reliably in that they do not fail, abort, or otherwise abnormally terminate [FiLy85]. This model can also be used to model CSP
Consider as an example, a set of processes \( \{ B, C, D\} \) which jointly serve resource management requests. Process \( A \) is idle waiting for a resource grant from process \( B \) and a grant from either process \( C \) or process \( D \). Processes \( B, C, \) and \( D \) are in the dependent set of process \( A \). When process \( B \) sends a message containing a resource grant to process \( A \), process \( A \) will execute and determine that it still needs a resource grant from process \( C \) or process \( D \). Process \( A \) will then become idle and wait for a message from processes \( C \) or \( D \). Its dependent set now contains only processes \( C \) and \( D \). Now, suppose process \( C \) sends a resource grant message to process \( A \). Process \( A \) determines that all its requests have been satisfied. It then sends a message to process \( D \) to tell process \( D \) that it is no longer waiting for a message from it. Process \( A \) then proceeds to carry out more computations, determines a new dependent set, and returns to the idle state.

If an idle process will never receive a message from any process in its dependent set, it is permanently idle, or deadlocked. More formally, a nonempty set \( S \) of processes is deadlocked [ChMi79] if and only if

1. All processes in \( S \) are idle;
2. The dependent set of every process in \( S \) is a subset of \( S \); and
3. There are no messages in transit between processes in \( S \).

A set \( S \) satisfying these three conditions is referred to as a deadlocked set.

When any of the deadlock detection algorithms discussed in this thesis is used, processes use two different methods for communication. The first is via exchange of message as described above. An idle process needs to receive a message in order to
execute. The other method is called query computation. A query computation is carried out by processes in order to determine whether they are deadlocked. To carry out a query computation, queries and replies are exchanged by processes. Processes may exchange queries and replies while they are in the idle state.

2.3. The CMH Algorithm

According to the CMH Algorithm, an idle process initiates a query computation by sending a query to each process in its dependent set. Information on the query initiator, a sequence number, the sender, and the receiver are contained in the query header. When an idle process receives a query, it will propagate queries to all the processes in its dependent set unless it has already done so. It counts the number of queries sent out. After receiving the same number of matching replies, it will send a reply to the process from which it received the query. If a process is executing, it simply discards the query. When some queries are discarded, the initiator will not receive the required number of replies. Therefore, deadlock will not be declared.

Consider, as a brief example, a system shown as a directed graph in Figure 1. Nodes in this graph represent processes. Executing processes are shown as a double circle. A directed edge from A to B means that process A is waiting for process B, and therefore B is in the dependent set of A. If, for some process C, there is a directed path from A to C, then C is said to be reachable from A, and is in the reachable set of A. In the example shown in Figure 1, the reachable set of A is \{B, C, D, E\}. (Many details have been omitted from this example in order to show, as simply as possible, the main points of the CMH Algorithm.) As can be seen from this graph, the set of processes \{B, C, D\} is deadlocked. Suppose process B initiates a query computation by sending a query to
every process in its dependent set (processes C and D). It will then wait for the two corresponding replies. Process D, upon receiving the query from process B, will send a query to process C. Process C, upon receiving the query from process B, will send a query to process D. After receiving the query from process D, process C will send a reply to process D. Similarly, process D, after receiving the query from process C, will send a reply to process C. Both processes will then send a reply to process B. Once process B receives both replies, it will declare itself deadlocked. If process A initiates a query computation, it will not receive a reply matching the query sent to process E. Therefore, process A will not declare itself deadlocked. Suppose that process E later sends a message to process F and then becomes idle, waiting for process C. Process A will then be deadlocked (along with processes B, C, D, and E). However, process A might never learn it is deadlocked without initiating another query computation. It may be more efficient, however, to have process C or D break the deadlock, and for process E to know that it cannot possibly break the deadlock by acting alone.

![Diagram](image-url)

**Figure 1**
System of Processes as a Directed Graph
More specifically, queries in the CMH Algorithm have the form $Q(i, m, j, k)$ where

- $i$ is the process which initiated the query computation (*initiator*) and is the process trying to discover if it is deadlocked or not.
- $m$ is a sequence number (counter) which is incremented by one each time process $i$ initiates a new query computation. The sequence number is used to ensure old queries do not interfere with any newer ones initiated by the same process.
- $j$ is the process which sends the particular query (*sender*).
- $k$ is the process which will receive the query (*receiver*).

Replies to queries have the form $R(i, m, j, k)$ in which fields have the same meaning as in a query. For any given set of values of $i, m, j,$ and $k$, process $P_j$ will send only one query $Q(i, m, j, k)$ to process $P_k$. Likewise, process $P_k$ will send only one reply $R(i, m, k, j)$ in response to the query $Q(i, m, j, k)$ from process $P_j$.

Each process maintains four arrays of local variables. Each array is one-dimensional of length $N$, where $N$ is the number of processes in the system. The four arrays, as maintained by process $P_k$, are described below.

**LATEST($N$)**

The entry $LATEST(i)$ holds the largest (most recent) sequence number $m$ for any query $Q(i, m, j, k)$ received by process $P_k$ or query $Q(i, m, k, j)$ sent by process $P_k$. Note that it is possible for process $P_k$ to initiate a query, in which case $i = k$ in the query $Q(i, m, k, j)$ sent by $P_k$. For each process, array $LATEST$ is initially set to zeros.
ENGAGER(N)

The entry ENGAGER(i) holds the identity of some process $P_j$ ($j$ not necessarily different from $i$) which caused $LATEST(i)$ to be set to its current value by sending query $Q(i, m, j, k)$ to process $P_k$. This array is used to store the information on which process sent the query so that the corresponding reply may be sent back to that process. The initial value of ENGAGER(i) is arbitrary. For the case where $i = k$, ENGAGER(i) is not used by the algorithm.

NUM(N)

The entry NUM(i) holds the total number of queries of the form $Q(i, m, k, j)$ which were sent by process $P_k$ for which no reply has yet been received. When a process queries the processes in its dependent set, NUM(i) will start out containing the number of these processes. As each corresponding reply $R(i, m, j, k)$ is received and is verified ($m = LATEST(i)$), NUM(i) is decremented by one. When NUM(i) becomes zero, all replies have been received. Process $P_k$ then sends reply $R(i, m, k, ENGAGER(i))$ to the process from which it originally received the query. The initial value of NUM(i) is also arbitrary.

WAIT(N)

The entry WAIT(i) shows whether or not process $P_k$ has been continuously idle since $LATEST(i)$ was last updated. If so, then WAIT(i) is true, otherwise it is false. The array WAIT is initialized to false.

The following seven events affect the detection of deadlock. These events are listed together with the actions taken by the process.
(1) An executing process receives a query — An executing process discards all queries received.

(2) An executing process receives a reply — An executing process discards all replies received.

(3) An idle process receives a query — When an idle process $P_k$ receives query $Q(i, m, j, k)$, it performs the following:

\[
\begin{align*}
\text{if } m &> \text{LATEST}(i) \\
\text{then begin} & \\
& \quad \text{LATEST}(i) := m; \\
& \quad \text{ENGAGER}(i) := j; \\
& \quad \text{WAIT}(i) := \text{true}; \\
& \quad \text{for all processes } P_r \text{ in the dependent set } S \text{ of } P_k, \\
& \quad \quad \text{send query } Q(i, m, k, r) \\
& \quad \quad \text{NUM}(i) := \text{number of processes in } S; \\
& \text{end} \\
\text{else if } \text{WAIT}(i) \text{ and } m = \text{LATEST}(i) & \quad \text{then send reply } R(i, m, k, j) \text{ to process } P_j; \\
& \text{endif} \\
& \text{endif} \\
\end{align*}
\]

(4) An idle process receives a reply — If an idle process $P_k$ receives a reply $R(i, m, j, r)$ from process $P_r$, process $P_k$ performs the following:

\[
\begin{align*}
\text{if } m & = \text{LATEST}(i) \text{ and } \text{WAIT}(i) \\
\text{then begin} & \\
& \quad \text{NUM}(i) := \text{NUM}(i) - 1; \\
& \quad \text{if } \text{NUM}(i) = 0 \\
& \quad \quad \text{then if } i = k \\
& \quad \quad \quad \text{then declare } P_k \text{ deadlocked} \\
& \quad \quad \text{else send reply } R(i, m, k, j) \text{ to process } P_j \\
& \quad \quad \quad \text{where } j = \text{ENGAGER}(i) \\
& \quad \quad \text{endif} \\
& \text{endif} \\
& \text{end} \\
\text{else discard the reply;} \\
& \text{endif}
\end{align*}
\]
(5) An idle process receives a message — When an idle process receives a message, it sets \( WAIT(i) \) false for all \( i \) and begins executing.

(6) An idle process initiates a query — A process, upon becoming idle for time \( T_1 \) will initiate a query to determine if it is deadlocked. The parameter \( T_1 \) is non-negative and may be set as desired. To initiate a query, process \( P_i \) must do the following:

\[
\begin{align*}
\text{begin} \\
LATEST(i) &:= LATEST(i) + 1; \\
WAIT(i) &:= \text{true}; \\
\text{For all processes } P_j \text{ in the dependent set } S \text{ of } P_i, \\
&\quad \text{send query } Q(i, LATEST(i), i, j) \text{ to } P_j \\
NUM(i) &:= \text{number of processes in } S; \\
\text{end};
\end{align*}
\]

(7) An idle process has waited time \( T_2 \) since last initiating a query computation — If an idle process waits for some specified time \( T_2 \) and still has not received all the required replies (ie \( NUM(i) > 0 \)), it assumes that it was not deadlocked when the last query computation was initiated. Therefore, the process may continue waiting for some time \( T_3 \) before initiating a new query computation. Parameter \( T_3 \) is determined in a manner similar to parameter \( T_1 \). It is possible, of course, that there is some type of failure in the system. (Recall that message delays may be arbitrary but finite).

Several observations can be made concerning the CMH Algorithm [ChMi83, Haas81]. If a process is deadlocked when it initiates a query computation, it will eventually declare itself deadlocked (assuming, of course, there is no failure in the network or system). Also, if every process initiates a new query computation whenever it becomes idle (or idle for time \( T_1 \)), at least one process (namely, the last process in the set to become idle) in every
deadlocked set will report "deadlock". Note, however, that this algorithm does not guarantee that every process in the deadlocked set discovers or is informed that it is deadlocked. Once a process declares itself deadlocked, it only knows that the processes in its dependent set are also deadlocked. The processes in its deadlocked set must be discovered/notified by other means. If $e$ is the number of communicating pairs in the system, then no more than $e$ queries and replies will be required for a single process to declare itself deadlocked. If $N$ is the number of processes and each process has at most $k$ processes in its dependent set, then $e \leq k \cdot N$. In a system where $k$ is $O(N)$, the CMH Algorithm requires $O(N^2)$ queries and replies for each complete query computation.
CHAPTER 3.

Five Deadlock Detection Algorithms

3.1. Introduction

In this chapter, we describe five new algorithms for detecting deadlock among communicating processes. Each successive algorithm implements a major modification to its predecessor, making it easier to understand how each algorithm works. Algorithm I uses depth-first search techniques instead of breadth-first as in the CMH Algorithm. Algorithm I also introduces the use of the inform and the concept of the query trace list. The inform is introduced to allow an executing process to inform the initiator of a query computation that it is not deadlocked. Algorithm II shows that query computations do not need to be terminated when encountering an executing process. Algorithm III introduces a priority scheme into query computations to reduce the number of queries and replies. Algorithm IV makes use of relevant information from other query computations, and Algorithm V can be used to find all minimal deadlocked sets.

3.2. Design Goals of the New Algorithms

Several aspects of the CMH Algorithm can be improved. The following goals are established to guide the development of improved algorithms.

(1) All true deadlocks are detected, with no false detections.

(2) Once a process in a deadlocked set declares itself deadlocked, it knows the identity of the other processes in the deadlocked set.
A process which has initiated a query will receive some type of response confirming the presence or absence of deadlock.

The number of queries and replies should be minimized.

The amount of information passed during query computations should be minimized.

A query computation should identify all minimal deadlocked sets (defined in Section 3.8, page 51) in the reachable set of the initiator. Any process declaring deadlock should also learn if it must take action to break the deadlock.

During the course of the query computation, at least one process in each minimal deadlocked set should also learn the identity of all other processes in its minimal deadlocked set, since at least one process from the minimal deadlocked set will be involved in a scheme to break the deadlock. By identifying all processes in a minimal deadlocked set, an optimizing deadlock breaking scheme could be implemented more easily.

The new algorithms, in performing query computations, use four different types of inter-process communication. These four, called queries, replies, cancels, and informs, will be referred to collectively as query traffic. Queries are sent from an idle process (the engager process) to a process in its dependent set (the target process) to ask whether or not that process and all processes in its reachable set are idle. A reply contains an affirmative response to a query, i.e., the process sending the reply and all processes in its reachable set are idle. Cancels are used to stop a query computation once it has been verified that deadlock condition does not exist. When an executing process receives a query, it sends an inform to the initiator of the query computation telling it that it is not deadlocked. Since query traffic formats differ for the five algorithms, specific formats will
be presented prior to the presentation of each algorithm.

3.3. Additional Assumptions

The communication model as presented in [ChMi83, Haas81] is used with the following three additional assumptions about the system and processes in the system:

(1) Each computer in the network maintains its own clock. There is no single system-wide clock available. Each of the independently-maintained clocks can be synchronized to within a desired tolerance of $T_c$ [LaMe85].

(2) An executing process can be interrupted to process query traffic if it is not already processing query traffic. An executing process already busy processing query traffic queues up all subsequent query traffic awaiting processing.

(3) Associated with each process is a priority (not necessarily unique).

The definition of deadlock remains the same as mentioned in Chapter 2.

3.4. Algorithm I

The first deadlock detection algorithm presented, Algorithm I, uses only queries and replies to carry out deadlock detection. CXLs are used to reduce the number of queries and replies passed once it has been determined that the initiator of a query computation is not deadlocked. Informs are used to tell the initiator that it is not deadlocked. After the initiator discovers it is not deadlocked, it may initiate a new query computation at a later time. This algorithm differs from the CMH Algorithm in that a process receiving a query will not attempt to simultaneously query every process in its dependent set. Rather, one process in the dependent set is queried at a time. The
corresponding reply must be received before the next process in the dependent set is queried. Also, information on which processes have seen the query computation is passed in the queries and replies.

3.4.1. Query Traffic Formats for Algorithm I

Queries have the form

\[ Q(\text{Sender, Receiver, } M, \text{QTL}) \]

In each query,

1. Sender is the process sending the query.
2. Receiver is the process receiving the query.
3. \( M \) is the sequence number of the query computation and shows the query belongs to the \( M \)th query computation of the initiator.
4. \( QTL \) is a list of processes \( P_{i_1}, P_{i_2}, \ldots, P_{i_t} \). A process \( P_k \) is in this list if it has been queried during the current query computation. \( QTL \) referred to as the query trace list. Processes appear in this list in the order they were queried. Hence, the query initiator \( P_i \) is the first process in the \( QTL \) (i.e. \( P_i = P_{i_1} \)). The sender of a query appears in the query trace list.

Replies have the form

\[ R(\text{Sender, Receiver, } M, \text{QTL}) \]

Each field in a reply has the same meaning as in a query. Both the sender and the receiver of the reply appear in the query trace list.
Cancels have the form

\[ C (\text{Sender}, \text{Receiver}, M, P_{i_i}) \]

In each cancel,

1. Sender and receiver have the same meaning as in a query.

2. \( M \) is the sequence number of the query computation being stopped.

3. \( P_{i_i} \) is the initiator of the query computation being stopped.

Informs have the form

\[ I (\text{Sender}, \text{Receiver}, M, T) \]

In each inform,

1. Sender and receiver have the same meaning as in a query. Since informs will always be sent to the query computation initiator, the receiver is the initiator.

2. \( M \) is the sequence number of the query computation which enables its initiator to discover that it was not deadlocked at the time the query computation was initiated.

3. \( T \) is a timestamp which shows the time the query initiator was verified to be not deadlocked.

3.4.2. Local Variables for Algorithm I

Each process maintains seven arrays of local variables and three scalar variables. Each array is one-dimensional of length \( N \), where \( N \) is the number of processes in the system. The seven arrays and three scalar variables, as maintained by process \( P_k \) when
processing a query computation initiated by $P_i$, are described below.

LATEST(N)

The entry $LATEST(i)$ holds the largest (most recent) sequence number $M$ for any query $Q$ (Sender, Receiver, $M$, QTL) sent or received by process $P_k$. The initial value of $LATEST(i)$ is zeros.

ENGAGER(N)

The entry $ENGAGER(i)$ holds the identity of some process $P_r$ (r not necessarily different from i) which caused $LATEST(i)$ to be set to its current value by sending a query $Q$ ($P_r$, $P_k$, $M$, QTL) to process $P_k$. This array is used to show from which process a query has been received (engager process) so the corresponding reply may be sent back to the engager. The initial value of $ENGAGER(i)$ is zeros.

TARGET(N)

The entry $TARGET(i)$ holds the identity of some target process $P_r$ to which process $P_k$ sent query $Q$ ($P_k$, $P_r$, $M$, QTL) and which has not yet sent back the corresponding reply. A process considers a query to be outstanding after it is sent until the corresponding reply is received or the query computation is cancelled. The initial value of $TARGET(i)$ is also zeros.

DEPENDENT(N)

The entry $DEPENDENT(i)$ is a boolean flag which shows whether or not process $P_i$ is in the dependent set of process $P_k$. The initial value of $DEPENDENT(i)$ is FALSE. The array $DEPENDENT$ may only be changed when $P_k$ is executing.
REACHABLES(N)

The entry REACHABLES(i) is a boolean flag which shows whether or not process \( P_i \) is in the reachable set of process \( P_k \) when \( P_k \) knows it is deadlocked. The initial value of REACHABLES(i) is FALSE. The array REACHABLES may only be changed when \( P_k \) receives a reply which causes \( P_k \) to declare deadlock.

WAIT(N)

The entry WAIT(i) shows whether or not process \( P_k \) has been continuously idle since LATEST(i) was last updated. If so, then WAIT(i) is true, otherwise it is false. The array WAIT is initialized to false.

EDGETYPE(N)

The entry EDGETYPE(i) in the boolean array shows whether the query from the query computation initiated by \( P_i \) and sent to the process in TARGET(i) is a tree edge (TRUE) or not. EDGETYPE(i) is FALSE if there is no outstanding query or if the query outstanding created a forward, back, or cross edge in the DFS tree [ReNi77]. EDGETYPE is initialized to FALSE.

LASTTIME

The variable LASTTIME stores the time at which the process last confirmed it was not deadlocked. A process may confirm that it is not deadlocked either because it is executing, or because it receives an inform from an executing process.

STATE

The variable STATE is a boolean flag which shows if process \( P_k \) is in the executing (TRUE) or idle (FALSE) state.
DEADLK

The variable DEADLK is a boolean flag which shows if process \( P_k \) knows it is deadlocked (TRUE). If \( P_k \) does not know, then DEADLK is FALSE. DEADLK is initialized to FALSE.

3.4.3. Events for Algorithm I

For Algorithm I, the following events are of interest:

(1) An idle process receives a message.

(2) A process receives a query.

(3) A process receives a reply.

(4) A process receives a cancel.

(5) A process receives an inform.

(6) A process sends a message.

(7) An executing process changes state to idle.

(8) A process becomes idle for time \( T_1 \) since last executing or last receiving an inform.

The actions taken by a process when each of these events occurs are described below. It is assumed, but not shown, that all query traffic received is first checked for validity. The variable \( N \) contains the number of processes in the system. The pseudo code for Algorithm I is listed in Appendix A.

(1) When an idle process \( P_r \) receives a message and begins executing, it takes the following actions:
(a) Changes its state to executing.
(b) Reinitializes the array \textit{WAIT} to FALSE.
(c) For each outstanding \textit{query}, sends an \textit{inform} to the query initiator.
(d) Cancels all outstanding \textit{queries} which, when sent, created tree edges (sent to a process not yet in the query trace list).
(e) Removes all evidence of \textit{queries} received.

(2) When a process \( P_r \) receives a \textit{query} \( Q \) \( (P_k, P_r, M, QTL) \) belonging to a query computation initiated by \( P_i \), it takes the following actions:

(a) If the \textit{query} is from a query computation not seen before,
   - Updates \textit{LATEST}(i).
(b) If \( P_r \) is executing, then
   - Sends an \textit{inform} to the query initiator.
   - Discards the \textit{query}.
(c) If \( P_r \) is deadlocked, then
   - Sets \textit{WAIT}(i) to TRUE.
   - Adds \( P_r \) and all members of its reachable set to the query trace list.
   - Sends a \textit{reply} to the engager process \( P_k \).
(d) If \( P_r \) is idle and is not in the query trace list, then
   - Sets \textit{WAIT}(i) to TRUE.
   - Adds \( P_r \) to the query trace list.
   - If there is a process \( P_l \) in the dependent set which is not the engager, sends a \textit{query} to the first such process. The \textit{query} being sent creates either a tree edge (if \( P_l \) is not in the query trace list) or a different type of edge (forward, back, or cross edge). Sets \textit{EDGETYPE}(i) accordingly.
   - If the dependent set is empty or contains only the engager, sends a \textit{reply} back to process \( P_k \).
(e) If \( P_r \) is idle, and \( P_r \) is in the query trace list, then
   - If \( P_r \) has been continuously idle since receiving the query computation the first time (\textit{WAIT}(i) is TRUE), then sends a \textit{reply} to \( P_k \).
If \( P \) has not been continuously idle since receiving the query computation the first time (\( WAIT(i) \) is FALSE), then sends an inform to \( P \) and discards the query.

(3) When a process \( P \), receives a reply \( R (P_k, P_r, M, QTL) \) belonging to a query computation initiated by \( P_i \), it takes the following actions:

(a) If \( P_r \) is deadlocked
   - Adds all members of its reachable set to the query trace list.
   - Sends a reply to the engager process.

(b) If \( P_r \) is idle but does not know it is deadlocked
   - If there is a process \( P_i \) following \( P_k \) in the dependent set which is not the engager, sends a query to the first such process. The query being sent creates either a tree edge (if \( P_i \) is not in the query trace list) or a different type of edge (forward, back, or cross edge). Sets \( EDGETYPE(i) \) accordingly.
   - Otherwise, if \( P_r \) is the query initiator, declares DEADLOCK for \( P_r \) and all processes in the query trace list. For each process \( P_j \) appearing in the QTL, sets \( REACHABLES(j) \) to TRUE.
   - Otherwise (\( P_r \) is not the initiator and the dependent set has been queried except possibly the engager), sends a reply to the engager process.

(4) When a process \( P_r \), receives a cancel \( C (P_k, P_r, M, P_i) \), it takes the following actions:

(a) If \( P_r \) has an outstanding query with the same initiator and matching sequence number which was sent to a process not in the query trace list (tree edge), sends the cancel to this process.

(b) Removes all evidence of the matching query (whether or not a cancel was sent).

(5) When a process \( P_r \), receives an inform \( I (P_k, P_r, M, T) \), it takes the following actions:

(a) Updates the time that it last knew that it was not deadlocked.

(b) May initiate a new query computation at some later time in order to detect a possible deadlock.
(6) When a process $P_k$ sends a message, no query computation action is required.

(7) When an executing process $P_k$ changes state to idle, it takes the following actions:
   
   (a) Changes its STATE flag to show it is idle.
   
   (b) Sets the last time that it knew that it was not deadlocked.

(8) When a process $P_i$ becomes idle for time $T_1$ since becoming idle or since last receiving an inform, it initiates a new query computation and sends a query to the first process $P_j$ in the dependent set.

3.5. Algorithm II

In Algorithm I, a process which suspects it may be deadlocked initiates a query computation. If an inform indicating no deadlock is received and at a later time the process still suspects it is deadlocked, it must initiate another query computation. For some systems, such as interactive information retrieval programs operating on distributed databases, the ability of a process to monitor its deadlock status without having to periodically initiate query computations is desirable. This is especially true of a process which interfaces directly with a user, since a monitoring capability can reduce user anxiety during periods of apparent inactivity. Algorithm II serves this purpose.

Algorithm II also uses only queries and replies to carry out deadlock detection. C cancels and informs are used for the same purposes as in Algorithm I, although the logic controlling when to send a cancel is different. Unlike Algorithm I, according to Algorithm II an executing process does not discard a query after sending an inform to the query initiator. Rather, the query is held and the query computation may continue once the process finishes executing. Because query computations are not discarded when they encounter executing processes, an executing process can periodically inform idle processes
suspecting deadlock that they are not deadlocked. Thus, once an idle process initiates a query computation, it effectively monitors its own deadlock status by periodically receiving informs from executing processes in its reachable set.

3.5.1. Query Traffic Formats for Algorithm II

Queries have the form

\[ Q(\text{Sender}, \text{Receiver}, T, QTL) \]

In each query,

(1) Sender is the process sending the query.

(2) Receiver is the process receiving the query.

(3) \( T \) is a timestamp which shows the time the query initiator was last informed that it was not deadlocked.

(4) \( QTL \) is a list of process/sequence number pairs \( P_1, M_1; P_2, M_2; \cdots; P_i, M_i \) and is referred to as the query trace list. A process \( P_i \) which appears in this sequence has been queried during the current query computation and is assumed to be idle by the sender. \( M_i \) is the sequence number associated with process \( P_i \). Because query computations are allowed to be restarted by processes other than the query initiator, each process must have its own sequence number. This number shows the number of attempts by the process to complete the query computation which has the same query trace list (to include the same associated sequence numbers). Processes appear in the query trace list in the order they were queried. Thus, \( P_i \) is the query initiator. The sender of a query appears in the query trace list.
Replies have the form

\[ R(\text{Sender}, \text{Receiver}, T, QTL) \]

Each field in a reply has the same meaning as in a query. Both the sender and the receiver of the reply appear in the query trace list.

Cancels have the form

\[ C(\text{Sender}, \text{Receiver}, P_i, M_i, ..., P_k, M_k) \]

In each cancel,

1. Sender and receiver have the same meaning as in a query.

2. QTL is a list of process/sequence number pairs \( P_i, M_i, P_i', M_i', ..., P_k, M_k \) which make up the query trace list as seen by the initiator of the cancel. Thus, the first process \( P_i \) is the initiator of the query computation being stopped, and the last process \( P_k \) is the process which initiated the cancel. As a cancel is passed from process to process, the query trace list portion of the cancel does not expand.

Informs have the form

\[ I(\text{Sender}, \text{Receiver}, M, T) \]

In each inform,

1. Sender and receiver have the same meaning as in a query.

2. \( M \) is the sequence number \( M_i \) from the query computation which enables its initiator to discover that it was not deadlocked at the time it initiated the query.
computation.

(3) $T$ is a timestamp which shows the time the query initiator was verified by an executing process to be not deadlocked.

3.5.2. Local Variables for Algorithm II

Each process maintains eight arrays of local variables and four scalar variables. One of the arrays is two-dimensional, and the other seven arrays are one-dimensional of length $N$, where $N$ is the number of processes in the system. The eight arrays and four variables, as maintained by process $P_k$ when processing a query computation initiated by $P_i$, are described below.

$LATEST(N,2N)$

The array $LATEST$ is two-dimensional and is used to hold copies of query trace lists from queries received by process $P_k$. The entry $LATEST(i,*)$ holds a copy of the query trace list from a query received by process $P_k$ which was initiated by process $P_i$. Thus, $LATEST(i,1)$ holds the first entry in the query trace list, which is simply $P_i$, the query initiator, and $LATEST(i,2)$ holds the corresponding sequence number $M_i$. The array $LATEST$ is initialized to zeros.

$ENGAGER(N)$

The entry $ENGAGER(i)$ holds the identity of some process $P_r$ (not necessarily different from $i$) which caused $LATEST(i,*)$ to be set to its current values by sending a query $Q(P_r, P_k, T, QTL)$ to process $P_k$. This array is the same as in Algorithm I.
TIMES(N)

The entry TIMES(i) holds the value of the timestamp T carried in the most recently received query which was initiated by process P_i. Thus, TIMES(i) shows when process P_k thinks process P_i last knew that P_i was not deadlocked. It is possible, however, that more recent informs have been sent to process P_i which process P_k does not know about.

TARGET(N)

This array is the same as in Algorithm I.

DEPENDENT(N)

This array is the same as in Algorithm I.

REACHABLES(N)

This array is the same as in Algorithm I.

WAIT(N)

The entry WAIT(i) shows whether or not process P_k has been continuously idle since LATEST(i, *) was last updated. This array is the same as in Algorithm I.

EDGETYPE(N)

This array is the same as in Algorithm I.

LASTTIME

This variable is the same as in Algorithm I.

NEWQRYNUM

The variable NEWQRYNUM is a sequence number (counter) which is incremented by one each time process P_k initiates a new query computation. This number will
be used in forming the query trace list.

STATE

This variable is the same as in Algorithm I.

DEADLK

This variable is the same as in Algorithm I.

In the description of the events for Algorithm II (shown below), and in the pseudo code (listed in Appendix B), we use $QTL(2k-1)$ to denote process $P_i$ in the query trace list, and $QTL(2k)$ to denote the sequence number associated with this process. Thus, $QTL(1)$ denotes the first process $P_i$ in the $QTL$, i.e. the initiator of the query computation in question.

3.5.3. Events for Algorithm II

For Algorithm II, the following events are of interest:

1. An idle process receives a message.

2. A process receives a query.

3. A process receives a reply.

4. A process receives a cancel.

5. A process receives an inform.

6. A process sends a message.

7. An executing process changes state to idle.
(8) A process becomes idle for time $T_i$ since last executing or last receiving an inform.

The actions taken by a process when each of these events occurs are described below. The variable $N$ contains the number of processes in the system. The pseudo code for Algorithm II is listed in Appendix B.

(1) When an idle process $P_r$ receives a message from process $P_k$ and begins executing, it takes the following actions:

(a) Changes its state to executing.
(b) Reinitializes the array WAIT to FALSE.
(c) If $P_r$ initiated a query computation and has a query outstanding which created a tree edge, sends a cancel to the target process. Regardless of the edgetype, deletes the query.
(d) If $P_r$ has any other queries, either held or outstanding, sends inform to the query computation initiators.
(e) For any outstanding queries which formed tree edges, sends cancels to the target processes.
(f) Shortens each query so that $P_r, M_r$ is the last process/sequence number pair in the query trace list.

(2) When a process $P_r$ receives a query $Q (P_k, P_r, T, QTL)$, it takes the following actions:

(a) If $P_r$ is executing and has seen the query computation before i.e. it is in the QTL, it discards the query just received.
(b) If $P_r$ is executing and has not seen the query computation before,
   - Adds itself (with sequence number 1) to the end of the query trace list, updates the time field $T$ in the query, and stores a copy of the query.
   - Sends an inform to the query initiator $P_i$.
(c) If $P_r$ is deadlocked,
   - If $P_r$ is not in the query trace list, adds itself and all members of its reachable set which are not already in the query trace list to the query trace list. The sequence numbers associated with all processes added from the reachable set are 0.
- Sends a reply to process $P_k$.

(d) If $P_r$ is idle, and $P_r$ is in the QTL
- If $P_r$ has been continuously idle since receiving the query computation the first time ($\text{WAIT}(i)$ is TRUE), or the sequence number associated with $P_r$ in the QTL is 0, then sends a reply to $P_k$.
- If $P_r$ has not been continuously idle since receiving the query computation the first time ($\text{WAIT}(i)$ is FALSE), then the query will be discarded during the validity check.

(e) If $P_r$ is idle and has not seen the query computation before
- Sets $\text{WAIT}(i)$ to TRUE.
- Adds itself (with sequence number 1) to the QTL.
- If there is a process $P_i$ in the dependent set which is not the engager, sends a query to the first such process. The query being sent creates either a tree edge (if $P_i$ is not in the QTL) or a different type of edge (forward, back, or cross edge). Sets $\text{EDGETYPE}(i)$ accordingly. Updates $\text{LATEST}(i, *)$.
- Otherwise, sends a reply back to process $P_k$.

(3) When a process $P_r$ receives a reply $R (P_k, P_r, T, \text{QTL})$, it takes the following actions:

(a) If $P_r$ has queried all processes in its dependent set except possibly the engager, and $P_r$ is the query initiator, then
- Declares DEADLOCK for $P_r$ and all processes in the QTL.
- For each process $P_j$ appearing in the QTL, sets $\text{REACHABLES}(j)$ to TRUE.
- For each query outstanding, sends a cancel to the target process.
- Shortens the query trace list of each query held by $P_r$ so that $P_r$ is the last process in the query trace list. Increases the sequence number associated with $P_r$ by 1.
- For each query now being held by $P_r$, augments the query trace list to include all processes in the reachable set of $P_r$. The sequence numbers associated with all processes added from the reachable set are 0.
- Sends replies to the engager processes.
(b) If $P_r$ has queried all processes in its dependent set except possibly the engager, and $P_r$ is not the query initiator, then

- Sends a reply to the engager process.

(c) Otherwise (there is a process $P_i$ following $P_k$ in the dependent set which is not the engager),

- Sends a query to the first such process. The query being sent creates either a tree edge (if $P_i$ is not in the QTL) or a different type of edge (forward, back, or cross edge). Sets $EDGETYPE(i)$ accordingly.

(4) When a process $P_r$ receives a cancel $C(P_k, P_r, QTL)$, it takes the following actions:

(a) If $P_r$ has an outstanding query which created a tree edge and which matches the QTL of the cancel, sends a cancel to the target process.

(b) Deletes the query.

(5) When a process $P_i$ receives an inform $I(P_k, P_r, M, T)$, it updates the time that it last knew that it was not deadlocked.

(6) When a process $P_k$ sends a message, no query computation action is required.

(7) When an executing process $P_k$ changes state to idle, it takes the following actions:

(a) Changes its STATE flag to show it is idle.

(b) Sets the last time that it knew that it was not deadlocked.

(c) Processes any query being held by $P_k$ as though it had just been received, increasing by one the sequence number associated with $P_k$ in the QTL.

(8) When a process $P_i$ becomes idle for time $T$ since changing state from executing to idle, it initiates a new query computation by sending a query to the first process in the dependent set. This creates a tree edge. $EDGETYPE(i)$ is set to TRUE.

3.6. Algorithm III

The third deadlock detection algorithm presented, Algorithm III, differs from Algorithm II in that a priority scheme is used to reduce the number of queries and replies.
being passed through the system. According to Algorithm III, processes in the system are assigned priorities. A process may change its assigned priority only when it is executing. The priority of a query computation is equal to the priority of the initiator at the time the query computation is initiated. Thus, the priority of a particular query computation does not change. When a query is received, the process receiving the query holds this query if it has another query outstanding which has a higher priority. It processes this query if the query has a priority at least as high as that of any outstanding query. Therefore, the highest priority processes will always have their query computations processed and will be able to monitor their own deadlock status just as in Algorithm II. A lower priority process is not guaranteed to receive informs periodically after initiating a query computation, since its query computation may be held by other idle processes. Also, an idle process does not begin to query its dependent set until it has been continuously idle for $T_2$ time.

Higher priority query computations can cause processing of lower priority query computations to be suspended. Therefore, the possibility of starvation for lower priority query computations exists. For example, consider a set of processes with dependency relationships as shown in Figure 2. The priorities of the processes are as indicated, with 2 being the highest priority. Suppose that processes $A$ and $B$ pass messages back and forth between themselves, thus executing alternately, and that all the other processes are in fact deadlocked. In this example, processes $C$, $D$, $E$, and $F$ should all discover they are deadlocked. However, there is a possibility that $A$ and $B$ prevent $C$, $D$, $E$, and $F$ from ever discovering they are deadlock by sending higher priority queries (and possibly cancels).
In order to prevent starvation, an aging scheme is introduced. According to this scheme, each query computation has associated with it an urgency. The urgency of a suspended query computation is a monotone increasing function of the priority of the query computation and a starvation factor which is computed by a process when processing the query computation. For example, we let the urgency of a query computation be the sum of the priority of the query computation and the integer quotient of the starvation count divided by some user-chosen constant $M$. To determine how the starvation factor should be increased, we note that it should not be a function simply of the amount of time a query computation is held by a process because it has higher priority query computations outstanding, since the higher priority query computations may have reached an executing process. If this is the case, increasing the urgency of the other suspended query computations with lower priorities tends to defeat the original purpose of the priority system. Without an aging scheme, starvation can only occur when processes send higher priority queries, followed by cancels and more queries. Some processes may reply to these higher priority query computations before receiving the cancels. One reliable way to adjust the query computation urgencies is to have the
starvation factor based on the number of cancels a process receives and the number of replies a process sends in response to queries from higher priority query computations. How the starvation factor of a suspended query computation is increased will be described later in this section.

3.6.1. Query Traffic Formats for Algorithm III

Queries have the form

\[ Q(Sender, Receiver, U, T, QTL) \]

In each query,

1. All fields except \( U \) have the same meaning as in Algorithm II.

2. \( U \) shows the priority of the query initiator. Although it does not need to be included in the actual query, since it could be a function of \( P_i \) and/or \( M_i \), it is shown for clarification. Priorities of processes do not have to be unique. If all the priorities of processes are the same, Algorithm III performs much like Algorithm II.

Replies have the form

\[ R(Sender, Receiver, T, QTL) \]

Each field in a reply has the same meaning as in Algorithm II. The priority field is not used in a reply since replies are never held.

Cancels have the form

\[ C(Sender, Receiver, QTL) \]
Each field in a cancel has the same meaning as in Algorithm II.

*Informs* have the form

\[ I (\text{Sender}, \text{Receiver}, M, T) \]

Each field in an inform has the same meaning as in Algorithm II.

### 3.8.2. Local Variables for Algorithm III

Each process maintains eleven arrays of local variables and five scalar variables. One of the arrays is two-dimensional, and the other ten arrays are one-dimensional of length \( N \), where \( N \) is the number of processes in the system. The eleven arrays and five variables, as maintained by process \( P_k \) when processing a query computation initiated by process \( P_i \), are described below.

**IATEST(N,2N)**

This array is the same as in Algorithm II.

**ENGAGER(N)**

This array is the same as in Algorithm II.

**PRIOR(N)**

The entry \( PRIOR(i) \) holds the priority of process \( P_i \). If the priority of a process is a function of \( P_i \) and/or \( M_i \), then this array is not needed.

**STARVE(N)**

The entry \( STARVE(i) \) holds the number of cancels \( P_k \) received or replies \( P_k \) sent for engaging queries which caused a lower priority query computation initiated by \( P_i \) to be suspended by \( P_k \).
TIMES(N)

This array is the same as in Algorithm II.

TARGET(N)

This array is the same as in Algorithm II.

DEPENDENT(N)

This array is the same as in Algorithm II.

REACHABLES(N)

This array is the same as in Algorithm II.

WAIT(N)

This array is the same as in Algorithm II.

EDGETYPE(N)

This array is the same as in Algorithm II.

LASTREP(N)

The entry LASTREP(i) shows which process from the dependent set last sent a reply to P_k for a query computation initiated by P_i.

LASTTIME

This variable is the same as in Algorithm II.

NEWQRYNUM

This variable is the same as in Algorithm II.

STATE

This variable is the same as in Algorithm II.
DEADLK

This variable is the same as in Algorithm II.

URGENCY

The variable URGENCY may be computed at any time from entries in arrays PRIOR and STARVE. URGENCY is included here for ease of understanding. For some query computation initiated by \( P_i \) with priority \( U \), and being held by \( P_k \), the URGENCY of the held query computation is the sum of \( U \) (found in PRIOR(\( i \))), and the integer quotient of STARVE(\( i \)) divided by some user-chosen constant \( M \). \( M \) normally would be greater than the largest possible number of processes in the system.

In the description of the events for Algorithm III (shown below), and in the code (listed in Appendix C), the one-dimensional array QTL is used just as it was for Algorithm II.

3.8.3. Events for Algorithm III

For Algorithm III, the following events are of interest:

1. An idle process receives a message.

2. A process receives a query.

3. A process receives a reply.

4. A process receives a cancel.

5. A process receives an inform.
(6) A process sends a message.

(7) An executing process changes state to idle.

(8) A process becomes idle for time $T_1$ since last executing or last receiving an inform. This is when the process initiates its own query computation.

(9) A process becomes idle for time $T_2$ (where $T_2 \leq T_1$) since last executing or last receiving an inform. This is when queries being held are restarted.

The actions taken by a process when each of these events occurs are described below. It is assumed, but not shown, that all query traffic received is first checked for validity.

Events in Algorithm III which are the same as those in Algorithm II are noted as such.

The variable $N$ contains the number of processes in the system. The code for Algorithm III is listed in Appendix C.

(1) When an idle process $P_r$ receives a message and begins executing, the actions required are the same as for Algorithm II except that the array $STARVE$ is reset to 0.

(2) When a process $P_r$ receives a query $Q (P_k, P_r, U, T, QTL)$, it takes the following actions:

(a) If $P_r$ is executing and has seen the query computation before ($P_r$ is in the $QTL$), then

   - Discards the query just received.

(b) If $P_r$ is executing and has not seen the query computation before, then

   - Adds itself to the end of the query trace list using sequence number 1.
   - Updates the time field $T$ in the query.
   - Stores a copy of the query.
- Sends an inform to the query initiator.

(c) If \( P_r \) is deadlocked, then

- If \( P_r \) is not in the QTL, adds \( P_r \) and all members of its reachable set which are not already in the QTL to the QTL. The sequence numbers associated with all processes added from the reachable set are 0.
- Sends a reply to process \( P_k \).

(d) If \( P_r \) is idle, and \( P_r \) is in the QTL, then

- If \( P_r \) has been continuously idle since receiving the query computation the first time (\( WAIT(i) \) is TRUE), or if \( P_r \) has a sequence number 0 in the QTL, then sends a reply to \( P_k \). Otherwise the query is discarded during the validity check.

(e) If \( P_r \) is idle and \( P_r \) is not in the QTL, then

- Sets \( WAIT(i) \) to TRUE.
- Adds itself (with sequence number 1) to the QTL.
- If the only process in the dependent set which has not seen the query computation is the engager, sends a reply back to process \( P_k \).
- Otherwise, there is a process in the dependent set which is not the engager and which has not seen the query computation.
  - Stores the query.
  - Sets \( STARVE(i) \) to 0.
  - If \( P_r \) has been idle for \( T_2 \) time since last receiving an inform or executing, and if the URGENCY of the query just received is at least as high as the highest priority of any query currently received, sends a query to the first process \( P_i \) in the dependent set which is not the engager. The query being sent creates either a tree edge (if \( P_i \) is not in the QTL) or a different type of edge (forward, back, or cross edge). Sets \( EDGETYPE(i) \) accordingly.

(3) When a process \( P_r \) receives a reply \( R(P_k, P_r, T, QTL) \), it takes the following actions:

(a) Updates \( LASTREP(i) \) and \( LATEST(i, *) \).
(b) If every process in the dependent set has been queried and if \( P_r \) is the query initiator, then
Declares DEADLOCK for \( P \), and all processes in the QTL.

For each process \( P_i \) appearing in the QTL, sets \( \text{REACHABLES}(j) \) to TRUE.

For each query outstanding, sends a cancel to the target process. Holds the queries.

For each query being held, shortens the query trace list so that \( P_r \) is the last process in the query trace list. Increases the sequence number associated with \( P_r \) by 1.

For each query now being held by \( P_r \), augments the query trace list to include all processes in the reachable set of \( P_r \). The sequence numbers associated with all processes added from the reachable set are 0.

Sends replies to the engager processes.

(c) If \( P_r \) has queried all processes in its dependent set except possibly the engager, and \( P_r \) is not the query initiator, then

- If the query computation has the highest priority of any received, increases \( \text{STARVE}(l) \) by one for each \( l \) where \( P_i \) is the initiator of a query computation currently being held by \( P_r \).

- Sends a reply to the engager process.

(d) If \( P_r \) has been idle \( T_2 \) time since last executing or receiving an inform, then

- Determines the highest priority of any query received. Selects all queries it has received which have an \text{URGENCY} at least this high. For each such query (assume \( P_i \) is the initiator), if the query is being held, sends it to the next process in the dependent set which needs to be queried and sets \( \text{STARVE}(i) \) to 0. \( \text{LASTREP}(i) \) shows the progression through the dependent set. Any queries being sent create either tree edges (if the target processes \( P_i \) are not in the QTL) or different types of edges (forward, back, or cross edges). For each query sent, sets \( \text{EDGETYPE}(i) \) accordingly.

4) When a process \( P_r \) receives a cancel C \((P_k, P_r, \text{QTL})\), it takes the following actions:

(a) If \( P_r \) is executing and the query computation associated with the cancel has the highest priority of any received, increases \( \text{STARVE}(l) \) by one for each \( l \) where \( P_i \) is the initiator of a query computation currently being held by \( P_r \).

(b) Processes the cancel just as for Algorithm II.

(c) For each of the highest urgency queries remaining, if \( P_k \) has been idle for time \( T_2 \) since last executing or receiving an inform, then ensures that the query is not being held, since the cancel could have stopped the highest urgency query.
- Determines the highest priority of any query received.
- Selects all queries it has received which have an URGENCY at least this high. For each such query (assume \( P_i \) is the initiator), if the query is being held, sends it to the next process in the dependent set which needs to be queried and sets STARVE\((i)\) to 0. LASTREP\((i)\) shows the progression through the dependent set. Any queries being sent create either tree edges (if the target processes \( P_i \) are not in the QTL) or different types of edges (forward, back, or cross edges). For each query sent, sets EDGETYPE\((i)\) accordingly.

(5) When a process \( P_r \) receives an inform \( I(P_k, P_r, T) \), the actions required are the same as for Algorithm II.

(6) When a process \( P_k \) sends a message, no query computation action is required.

(7) When an executing process \( P_k \) changes state to idle, it takes the following actions:
   
   (a) Changes its STATE flag to show it is idle.

   (b) Sets the last time that it knew that it was not deadlocked.

   (c) For each query currently being held by \( P_k \), increases by one the sequence number associated with \( P_k \) in the QTL. These queries will be held until \( P_k \) becomes idle for \( T_2 \) time since last executing or receiving an inform.

   (d) If, for any held query, \( P_k \) does not need to query any processes in its dependent set, then sends a reply back to its engager. (This can happen if there is only one process in the dependent set of \( P_k \), and it is its engager).

(8) When a process \( P_i \) becomes idle for time \( T_1 \) since changing state from executing to idle or since receiving the last inform, it initiates a new query computation by building a query and storing it. If the URGENCY of the query just created is as high or higher than the highest priority of any received queries, then sends the new query to the first process in its dependent set. This creates a tree edge. Sets EDGETYPE accordingly.
(9) When a process \( P_i \) becomes idle for time \( T_2 \) (where \( T_2 \leq T_1 \)) since changing state from executing to idle or since receiving the last inform, it takes the following actions:

(a) Determines the highest priority of any query received.

(b) Selects all queries it has received which have an URGENCY at least this high. For each such query (assume \( P_i \) is the initiator), if the query is being held, sends it to the next process in the dependent set which needs to be queried and sets \( \text{STARVE}(i) \) to 0. \( \text{LASTREP}(i) \) shows the progression through the dependent set. Any queries being sent create either tree edges (if the target processes \( P_t \) are not in the QTL) or different types of edges (forward, back, or cross edges). For each query sent, sets \( \text{EDGETYPE}(i) \) accordingly. Lower urgency queries are held.

3.7. Algorithm IV

For the other algorithms, sequence numbers in the query trace lists of two different query computations were independent of each other. The fourth deadlock detection algorithm presented, Algorithm IV, differs from Algorithm III in that a process does not increase its sequence number by 1 when initiating a query computation. Rather, sequence numbers show the number of messages accepted by processes and therefore are no longer tied to query computations [ReKa79]. By using this type of sequence number, more information can be conveyed between processes using the query trace list. When processing a query computation, a process \( P_k \) can forego querying a member of its dependent set \( P_r \) if \( P_k \) can determine that \( P_r \) is idle and that all messages sent from \( P_r \) to \( P_k \) have already arrived. This can sometimes be determined by combining information obtained from previous query computations with that in the query trace list of the current query computation.
3.7.1. Query Traffic Formats for Algorithm IV

Queries have the form

\[ Q(\text{Sender}, \text{Receiver}, U, T, QTL) \]

Each field in a query has the same meaning as in Algorithm III. In the field QTL, each value \( M_i \) shows the number of messages accepted by process \( P_i \).

Replies have the form

\[ R(\text{Sender}, \text{Receiver}, T, QTL) \]

Each field in a reply has the same meaning as in Algorithm III.

Cancels have the form

\[ C(\text{Sender}, \text{Receiver}, QTL) \]

Each field in a cancel has the same meaning as in Algorithm III.

Informs have the form

\[ I(\text{Sender}, \text{Receiver}, M, T) \]

Each field in an inform has the same meaning as in Algorithm III.

3.7.2. Local Variables for Algorithm IV

Each process maintains twelve arrays of local variables and four scalar variables. One of the arrays is two-dimensional, and the other eleven arrays are one-dimensional of length \( N \), where \( N \) is the number of processes in the system. The twelve arrays and four variables, as maintained by process \( P_k \) when processing a query computation initiated by
$P_i$, are described below.

LATEST($N, 2N$)

This array is the same as in Algorithm III.

ENGAGER($N$)

This array is the same as in Algorithm III.

PRIOR($N$)

This array is the same as in Algorithm III.

STARVE($N$)

This array is the same as in Algorithm III.

TIMES($N$)

This array is the same as in Algorithm III.

TARGET($N$)

This array is the same as in Algorithm III.

DEPENDENT($N$)

This array is the same as in Algorithm III.

REACHABLES($N$)

This array is the same as in Algorithm III.

EDGETYPE($N$)

This array is the same as in Algorithm III.

LASTREP($N$)

This array is the same as in Algorithm III.
RECENT(N)

The entry \textit{RECENT}(i) shows the most recent sequence number for process $P_i$ that is known to $P_k$. $P_k$ updates this entry with any available information such as a message received from $P_i$ or any query traffic which has $P_i, M_i$ in the query trace list. This entry does not necessarily reflect the most recent sequence number of $P_i$, although the entry does show a lower bound.

VERIFIED(N)

The entry \textit{VERIFIED}(i) shows the most recent sequence number for process $P_i$ which $P_k$ discovered by receiving either a \textit{query} or \textit{reply} directly from $P_i$. Any message sent from $P_i$ to $P_k$ after the \textit{query} or \textit{reply} must necessarily have been sent after $P_i$ had increased its sequence number, since messages are only sent by executing processes, \textit{queries} and \textit{replies} are sent only by idle processes, and we assumed sequenced message delivery.

LASTTIME

This variable is the same as in Algorithm III.

STATE

This variable is the same as in Algorithm III.

DEADLK

This variable is the same as in Algorithm III.

URGENCY

This variable is the same as in Algorithm III.
In the description of the events for Algorithm IV (shown below), and in the code (listed in Appendix D), the one-dimensional array $QTL$ is used just as it was for Algorithms II and III.

### 3.7.3. Events for Algorithm IV

For Algorithm IV, the following events are of interest:

1. An idle process receives a message.
2. A process receives a *query*.
3. A process receives a *reply*.
4. A process receives a *cancel*.
5. A process receives an *inform*.
6. A process sends a message.
7. An executing process changes state to idle.
8. A process becomes idle for time $T_1$ since last executing or last receiving an *inform*. This is when the process initiates its own query computation.
9. A process becomes idle for time $T_2$ (where $T_2 \leq T_1$) since last executing or last receiving an *inform*. This is when queries being held are restarted.

The actions taken by a process when each of these events occurs are described below. It is assumed, but not shown, that all query traffic received is first checked for validity. Events in Algorithm IV which are the same as those in Algorithm III are noted as such. The variable $N$ contains the number of processes in the system. The pseudo code for
Algorithm IV is listed in Appendix D.

(1) When an idle process $P_r$ receives a message $M(P_k, P_r, M_k, \ldots)$ from $P_k$ and begins executing, it takes the following actions:

(a) Increases its own sequence number by 1. The sequence number is stored in $RECENT(r)$.

(b) Changes $RECENT(k)$ to reflect the sequence number $M_k$.

(c) Performs the same actions as required for Algorithms II and III.

(2) When a process $P_r$ receives a query $Q(P_k, P_r, U, T, QTL)$, it takes the following actions:

(a) For each pair $P_i, M_i$ in the $QTL$, updates the entry $RECENT(l)$ to be $M_i$ if $M_i$ is greater than $RECENT(l)$.

(b) Updates $VERIFIED(k)$ to be $M_k$. (The pair $P_k, M_k$ must be in the $QTL$).

(c) If $P_r$ is executing and has seen the query computation before ($P_r$ is in the $QTL$),

- Discards the query just received.

(d) If $P_r$ is executing and has not seen the query computation before, then

- Adds itself to the end of the query trace list using its current sequence number.
- Updates the time field $T$ in the query.
- Stores a copy of the query.
- Sends an inform to the query initiator.

(e) If $P_r$ is not executing, then checks for any held query computations for which a reply can now be sent to the engager.

(f) If $P_r$ is deadlocked, then

- If $P_r$ is not in the $QTL$, adds $P_r$ and all members of its reachable set which are not already in the $QTL$ to the $QTL$. If process $P_i$ is added from the reachable set, then sequence number $RECENT(i)$ is used. (In this case, $RECENT(i)$ must be the same as $VERIFIED(i)$ so either could be used).
  - Sends a reply to process $P_k$.

(g) If $P_r$ is idle, and $P_r$ is in the $QTL$, then
If $P_r$ has been continuously idle since receiving the query computation the first time ($\text{RECENT}(i)=M_i$), then sends a reply to $P_k$. Otherwise discards the query during the validity check.

(h) If $P_r$ is idle and $P_r$ is not in the QTL, then

- adds itself (with sequence number $\text{RECENT}(r)$) to the QTL.
- If every process $P_i$ in the dependent set is either the engager or appears in the QTL with sequence number $M_i$ which is equal to $\text{VERIFIED}(i)$, then sends a reply back to process $P_k$.
- Otherwise, there is a process $P_i$ in the dependent set which is not the engager and which either has not seen the query computation before ($P_i$ is not in the QTL) or which has sequence number $M_i$ which is greater than $\text{VERIFIED}(i)$.
  - Stores the query.
  - Sets $\text{STARVE}(i)$ to 0.
  - If $P_r$ has been idle for $T_2$ time since last receiving an inform or executing, and if the $\text{URGENCY}$ of the query just received is at least as high as the highest priority of any query currently received, sends a query to the first process $P_i$ in the dependent set which is not the engager and which does not appear in the QTL with sequence number $M_i$ equal to $\text{VERIFIED}(i)$. The query being sent creates either a tree edge (if $P_r$ is not in the QTL) or a different type of edge (forward, back, or cross edge). Sets $\text{EDGETYPE}(i)$ accordingly.

(3) When a process $P_r$ receives a reply $R(P_k, P_r, T, \text{QTL})$, it takes the following actions:

(a) For each pair $P_i, M_i$ in the QTL, updates the entry $\text{RECENT}(i)$ to be $M_i$ if $M_i$ is greater than $\text{RECENT}(i)$.
(b) Updates $\text{VERIFIED}(k)$ to be $M_k$. (The pair $P_k, M_k$ must be in the QTL).
(c) Updates $\text{LASTREP}(i)$ and $\text{LATEST}(i, \ast)$.
(d) If every process $P_i$ in the dependent set appears in the QTL with sequence number $M_i$ equal to $\text{VERIFIED}(i)$, and if $P_r$ is the query initiator, then
  - Declares DEADLOCK for $P_r$ and all processes in the QTL.
  - For each process $P_j$ appearing in the QTL, sets $\text{REACHABLES}(j)$ to TRUE.
- For each query which is either being held, or which is outstanding but did not create a tree edge,

- Shortens the query trace list so that \( P_r \) is the last process in the query trace list.

- For each such query, augments the query trace list to include all processes in the reachable set of \( P_r \). Each process \( P_i \) added from the reachable set uses sequence number \( \text{VERIFIED}(l) \).

- For each such query, sends a reply to the engager process.

(e) If every process \( P_i \) in the dependent set (except possibly the engager) appears in the QTL with sequence number \( M_i \) equal to \( \text{VERIFIED}(l) \), and \( P_r \) is not the query initiator, then

- If the query computation has the highest priority of any received, increases \( \text{STARVE}(l) \) by one for each \( l \) where \( P_i \) is the initiator of a query computation currently being held by \( P_r \).

- Sends a reply to the engager process.

(f) If \( P_r \) is not executing, then checks for any held query computations for which a reply can now be sent to the engager.

(g) If \( P_r \) has been idle \( T_2 \) time since last executing or receiving an inform, then

- Determines the highest priority of any query received. Selects all queries it is has received which have an URGENCY at least this high. For each such query (assume \( P_i \) is the initiator), if the query is being held, sends it to the next process in the dependent set which needs to be queried and sets \( \text{STARVE}(i) \) to 0. A process \( P_i \) in the dependent set which appears in the QTL with sequence number \( M_i \) equal to \( \text{VERIFIED}(l) \) does not need to be queried. Any query being sent creates either a tree edge (if the target process \( P_i \) is not in the QTL) or a different type of edge (forward, back, or cross edge). For each query sent, sets \( \text{EDGETYPE}(i) \) accordingly.

(4) When a process \( P_r \) receives a cancel \( C(P_k, P_r, \text{QTL}) \), it takes the following actions:

(a) If \( P_r \) is executing and the query computation associated with the cancel has the highest priority of any received, increases \( \text{STARVE}(l) \) by one for each \( l \) where \( P_i \) is the initiator of a query computation currently being held by \( P_r \).

(b) Processes the cancel just as for Algorithms II and III.

(c) For each of the highest urgency queries remaining, if \( P_k \) has been idle for time \( T_2 \) since last executing or receiving an inform, then ensures that the query is not being held, since the cancel could have stopped the highest urgency query computation.
- Determines the highest priority of any query received.
- Selects all queries it has received which have an URGENCY at least this high. For each such query (assume \( P_i \) is the initiator), if the query is being held, it must be sent to the next process in the dependent set which needs to be queried and sets \( \text{STARVE}(i) \) to 0. A process \( P_i \) in the dependent set which appears in the QTL with sequence number \( M_i \) equal to \( \text{VERIFIED}(l) \) does not need to be queried. \( \text{LASTREP}(i) \) shows the progression through the dependent set. Any queries being sent create either tree edges (if the target processes \( P_i \) are not in the QTL) or different types of edges (forward, back, or cross edges). For each query sent, sets \( \text{EDGETYPE}(i) \) accordingly.

5. When a process \( P_r \) receives an inform \( I (P_k, P_r, T) \), the actions required are the same as for Algorithms II and III.

6. When a process \( P_k \) sends a message, no query computation action is required.

7. When an executing process \( P_k \) changes state to idle, it takes the following actions:
   (a) Changes its STATE flag to show it is idle.
   (b) Sets the last time that it knew that it was not deadlocked.
   (c) For each query currently being held by \( P_k \), changes the sequence number associated with \( P_k \) in the QTL to be \( \text{RECENT}(k) \). These queries will be held until \( P_k \) becomes idle for \( T_2 \) time since last executing or receiving an inform.

8. When a process \( P_i \) becomes idle for time \( T_1 \) since changing state from executing to idle or since receiving the last inform, it takes the following actions:
   (a) Initiates a new query computation by building a query and storing it.
   (b) If the URGENCY of the query just created is as high or higher than any received queries, then sends the new query to the first process in its dependent set. This creates a tree edge. Sets \( \text{EDGETYPE} \) accordingly.

9. When a process \( P_i \) becomes idle for time \( T_2 \) (where \( T_2 \geq T_1 \)) since changing state from executing to idle or since receiving the last inform, it takes the following actions:
(a) Determines the highest priority of any query received.

(b) Selects all queries it has received which have an URGENCY at least this high. For each such query (assume $P_i$ is the initiator), if the query is being held, sends it to the next process in the dependent set which needs to be queried and sets $\text{STARVE}(i)$ to 0. A process $P_i$ in the dependent set which appears in the $QTL$ with sequence number $M_i$ equal to $\text{VERIFIED}(i)$ does not need to be queried. $\text{LASTITP}(i)$ shows the progression through the dependent set. Any queries being sent create either tree edges (if the target processes $P_i$ are not in the $QTL$) or different types of edges (forward, back, or cross edges). For each query sent, sets $\text{EDGETYPE}(i)$ accordingly. Lower urgency queries are held.

3.8. Algorithm V

As stated in Section 3.2, one of our goals of a deadlock detection scheme is to make the resolution of deadlock as efficient as possible. In any directed graph, there are one or more strongly connected components [AhHo74, page 189]. If process $A$ is deadlocked, then the entire reachable set of $A$ is also deadlocked. To break all deadlocks in the reachable set of $A$, we need to find all strongly connected components which have the property that the dependent set of any process in any component is also contained in the component. Each such strongly connected component forms what we term a minimal deadlocked set, and deadlock can only be broken by having actions taken by or applied to at least one of the processes in the minimal deadlocked set [Leun83]. Therefore, an efficient deadlock resolution algorithm should operate only on minimal deadlocked sets. Information on the identities of processes in the minimal deadlocked set will be needed to implement such algorithms.

In the example of Figure 3, processes $B$ and $C$ form a strongly connected component, as do processes $E$, $F$, and $G$. Suppose that process $A$, upon becoming idle, first sends an engaging query to $B$ and the following conditions hold:
- $A$ is not in the reachable set of $B$,

- $B$ is deadlocked, and

- No member of the reachable set of $B$ sees the query computation before $B$.

We want to argue that if $B$ replies to its engager, $B$ can discover it is deadlocked and know the identities of all members of its deadlocked set without having to initiate its own query computation. Once the query reaches $B$, $B$ adds itself to the query trace list. Since no member of the reachable set of $B$ has seen the query computation before $B$, it must happen that as long as $B$ has the query computation outstanding, all queries and replies for this query computation occur between members of the reachable set of $B$, and all these processes are added to the query trace list after $B$. Therefore, if $B$ can learn at the time it replies to its engager that this situation has occurred, it can declare deadlock for itself and all succeeding processes in the query trace list. For $B$ to learn this, the query trace list must have a boolean flag for each process saying whether or not that process has a member of its reachable set which precedes it in the query trace list.

![Diagram](image-url)
By some careful manipulation of these boolean flags, it is also possible to discover the minimal deadlocked sets as the query computation progresses. Recall that a minimal deadlocked set is a deadlocked set which is also a strongly connected component. Therefore, the reachable set of any process in a minimal deadlocked set is also in the minimal deadlocked set. Also, if some process A in the minimal deadlocked set receives an engaging query from a process B not in the minimal deadlocked set, it will not reply to its engager until all processes in its reachable set have seen the query computation. All these processes must see the query computation after process A, and therefore will appear in the query trace list after A. Moreover, each of these processes, when querying their dependent sets, will not query a process outside the minimal deadlocked set. Therefore, if A, after querying its dependent set, can determine that

- No process in the reachable set of A occurs before A in the query trace list, and
- There is no minimal deadlocked set in its reachable set which does not include A,

then A can say it is a member of a minimal deadlocked set, and that all processes following it in the query trace list are also members of the minimal deadlocked set. This also says, of course, that B, which is the engager of A, cannot be in any minimal deadlocked set. Process A can then notify other members of the minimal deadlocked set if it wishes, and a deadlock resolution algorithm may be invoked with the identities of all processes in the minimal deadlocked set as input.

3.8.1. Query Traffic Formats for Algorithm V

Queries have the form

\[ Q(\text{Sender}, \text{Receiver}, U, T, QTL) \]
In each query,

(1) Each field except QTL has the same meaning as in Algorithm IV.

(2) QTL is a list of process/boolean flag/sequence number triples $P_i, F_i, M_i, P_j, F_j, M_j, \cdots, P_i, F_i, M_i$ and is referred to as the query trace list. A process $P_i$ which appears in this sequence has been queried during the current query computation and is assumed to be idle by the sender. $F_i$ is a boolean flag used for finding minimal deadlocked sets. $M_i$ is the sequence number associated with process $P_i$.

Replies have the form

$R$ (Sender, Receiver, $T$, QTL)

Each field in a reply has the same meaning as in a query.

Cancels have the form

$C$ (Sender, Receiver, QTL)

Each field in a cancel has the same meaning as in Algorithm IV. The boolean flags are not included in the QTL for a cancel.

Informs have the form

$I$ (Sender, Receiver, $M$, $T$)

Each field in an inform has the same meaning as in Algorithm IV.
3.8.2. Local Variables for Algorithm V

Each process maintains eleven arrays of local variables and five scalar variables. One of the arrays is two-dimensional, and the other ten arrays are one-dimensional of length $N$, where $N$ is the number of processes in the system. The eleven arrays and five variables, as maintained by process $P_k$ when processing a query computation initiated by process $P_i$, are described below.

LATEST$(N,2N)$

This array is the same as in Algorithm IV except that the boolean flag $F_j$ in the query trace list is stored as the sign field of the associated sequence number $M_i$. The array REACHABLES as used in Algorithm IV is insufficient for remembering minimal deadlock sets. Therefore, if a process $P_i$ discovers deadlock, it will store the applicable portion of the query trace list in the array LATEST$(i, *)$ whether or not it initiated the query computation. Once the flag DEADLK is set to true, LATEST$(i, *)$ will not be changed. Note that if a process $P_i$ declares deadlock based on a query computation initiated by another process, then the reachable set of $P_i$ will consist of all processes in the query trace list between $P_i$ and the end of the query trace list, inclusive, at the time $P_i$ replies to its engager.

ENGAGER

This array is the same as in Algorithm IV.

PRIOR

This array is the same as in Algorithm IV.
STARVE(N)
This array is the same as in Algorithm IV.

TIMES(N)
This array is the same as in Algorithm IV.

TARGET(N)
This array is the same as in Algorithm IV.

DEPENDENT(N)
This array is the same as in Algorithm IV.

EDGETYPE(N)
This array is the same as in Algorithm IV.

LASTREP(N)
This array is the same as in Algorithm IV.

RECENT(N)
This array is the same as in Algorithm IV.

VERIFIED(N)
This array is the same as in Algorithm IV.

LASTTIME
This variable is the same as in Algorithm IV.

STATE
This variable is the same as in Algorithm IV.
DEADLK

This variable is the same as in Algorithm IV.

URGENCY

This variable is the same as in Algorithm IV.

In the description of the events for Algorithm V (shown below), and in the pseudo code (listed in Appendix F), the one-dimensional array $QTL$ is used just as it was for Algorithm IV except that $QTL(2k)$ now holds both the boolean flag $F_{i_{t}}$ and the sequence number $M_{i_{t}}$.

3.8.3. Events for Algorithm V

For Algorithm V, the following events are of interest:

(1) An idle process receives a message.

(2) A process receives a query.

(3) A process receives a reply.

(4) A process receives a cancel.

(5) A process receives an inform.

(6) A process sends a message.

(7) An executing process changes state to idle.

(8) A process becomes idle for time $T_{1}$ since last executing. This is when the process initiates its own query computation.
A process becomes idle for time $T_2$ (where $T_2 > T_1$) since last executing. This is when queries being held are restarted.

The actions taken by a process when each of these events occurs are described below. It is assumed, but not shown, that all query traffic received is first checked for validity.

Events in Algorithm V which are the same as those in Algorithm IV are noted as such.

The variable $N$ contains the number of processes in the system. The pseudo code for Algorithm V is listed in Appendix F.

1. When an idle process $P_r$ receives a message $M$ $(P_k, P_r, M_k, \cdots)$ from $P_k$ and begins executing, the actions required are the same as for Algorithm IV.

2. When a process $P_r$ receives a query $Q$ $(P_k, P_r, U, T, QTL)$, it takes the following actions:
   
   (a) If $P_r$ has a query outstanding for an earlier query computation for the same initiator, and the query it sent out earlier created a tree edge, then sends a cancel to stop the earlier query computation.
   
   (b) For each triple $P_i, F_i, M_i$ in the $QTL$, updates the entry RECENT$(i)$ to be $M_i$ if $M_i$ is greater than RECENT$(i)$.
   
   (c) Updates VERIFIED$(k)$ to be $M_k$. (The triple $P_k, F_k, M_k$ must be in the $QTL$).
   
   (d) If $P_r$ is executing and has seen the query computation before ($P_r$ is in the QTL), then discards the query just received.
   
   (e) If $P_r$ is executing and has not seen the query computation before, then
      
      Adds itself to the end of the query trace list using its current sequence number. Sets its boolean flag $F_r$ to FALSE ( ).
      
      Updates the time field $T$ in the query.
      
      Stores a copy of the query.
      
      Sends an inform to the query initiator.
   
   (f) If $P_r$ is not executing, then checks for any held query computations for which a reply can now be sent to the engager.
(g) If \( P \) is deadlocked and \( P \) is a member of a minimal deadlocked set, then

- If \( P \) already has an outstanding query for this query computation, then

  - Adds \( P \) and all members of its reachable set which are not already in the QTL to the QTL using the order in which they appear in \( LATEST(r,^*) \).

  - Finds the first process \( P \) in the QTL which is in the reachable set of \( P \). Does not change the value of flag \( F^* \). For all other flags \( F_i \) in the QTL, if \( P_i \) is in the reachable set of \( P_r \), then sets flag \( F_i \) to be TRUE (+).

- If \( P \) does not already have an outstanding query for this query computation and the engaging process \( P_k \) is in the reachable set of \( P_r \), then

  - Adds \( P \) and all members of its reachable set which are not already in the QTL to the QTL using the order in which they appear in \( LATEST(r,^*) \). The boolean flags are used just as they appear in \( LATEST(r,^*) \).

  - Finds the first process \( P \) in the QTL which is in the reachable set of \( P_r \). Does not change the value of flag \( F^* \). For all other flags \( F_i \) in the QTL, if \( P_i \) is in the reachable set of \( P_r \), then sets flag \( F_i \) to be TRUE (+).

- If \( P \) does not already have an outstanding query for this query computation and the engaging process \( P_k \) is in the reachable set of \( P_r \), then

  - Sets the flag \( F_k \) to TRUE (+).

  - Adds \( P \) and all members of its reachable set which are not already in the QTL to the QTL using the order in which they appear in \( LATEST(r,^*) \). The boolean flags are used just as they appear in \( LATEST(r,^*) \).

  - Sends a reply to process \( P_k \).

(i) If \( P \) knows it is deadlocked and \( P \) is not a member of a minimal deadlocked set, then

  - Sets the flag \( F_k \) is the QTL to TRUE (+).

  - Adds \( P \) and all members of its reachable set which are not already in the QTL to the QTL using the order in which they appear in \( LATEST(r,^*) \). The boolean flags are used just as they appear in \( LATEST(r,^*) \).

  - Sends a reply to process \( P_k \).
(j) If $P_r$ is idle, and $P_r$ is in the QTL, then
   - If $P_r$ has been continuously idle since receiving the query computation the first time ($\text{RECENT}(i) = M_i$), then sends a reply to $P_k$. Otherwise discards the query during the validity check.

(k) If $P_r$ is idle and $P_r$ is not in the QTL, then
   - Adds itself (with sequence number $\text{RECENT}(r)$ and boolean flag $F_r = \text{FALSE} (-)$) to the QTL.
   - If a process in the dependent set of $P_r$ is already in the QTL, then
     - Finds the first process $P_l$ in the QTL which is in the dependent set of $P_r$. Sets all boolean flags between $F_l$ and $F_r$ (non-inclusive) to TRUE (+).
     - Sets the boolean flag $F_r$ to TRUE (+).
   - If every process $P_l$ in the dependent set is either the engager or appears in the QTL with sequence number $M_l$ which is equal to $\text{VERIFIED}(l)$, then
     - If flag $F_r$ is still FALSE (-), then declares DEADLOCK for $P_r$ and all processes occurring after $P_r$ in the QTL. Changes the QTL so that all flags ahead of $F_r$ are set to TRUE (+) and all flags following $F_r$ have the pattern (-----+).
     - Sends a reply back to process $P_k$.
   - Otherwise, there is a process $P_l$ in the dependent set which is not the engager and which either has not seen the query computation before ($P_l$ is not in the QTL) or which has sequence number $M_l$ which is greater than $\text{VERIFIED}(l)$.
     - Stores the query.
     - Sets $\text{STARVE}(i)$ to 0.

(3) When a process $P_r$ receives a reply $R (P_k, P_r, T, \text{QTL})$, it takes the following actions:
(a) For each triple $P_i, F_i, M_i$ in the $QTL$, updates the entry $RECENT(i)$ to be $M_i$ if $M_i$ is greater than $RECENT(i)$.

(b) Updates $VERIFIED(k)$ to be $M_k$. (The triple $P_k, F_k, M_k$ must be in the $QTL$).

(c) Updates $LASTREP(i)$ to be $P_k$.

(d) Adds to $LATEST(i, *)$ any triple $P_i, F_i, M_i$ in the $QTL$, provided $P_i$ is not in $LATEST(i, *)$.

(e) For any triple $P_i, F_i, M_i$ in the $QTL$ which precedes $P_r$, updates the flag $F_i$ in $LATEST(i, *)$ to reflect the value in the $QTL$.

(f) If every process $P_i$ in the dependent set of $P_r$ (except possibly the engager of $P_r$) appears in the $QTL$ with sequence number $M_i$ equal to $VERIFIED(i)$, and if $P_r$ is the query initiator, then

- Declares DEADLOCK for $P_r$ and all processes in the $QTL$. Sets $DEADLK$ to TRUE.

- If $F_r$ is FALSE, $P_r$ knows it is a member of a minimal deadlocked set. Changes $F_r$ and all flags following it in the $QTL$ except the last one to be FALSE. The minimal deadlocked set now has a flag pattern of (-- ---+).

- Updates $LATEST(r, *)$ to reflect the values in the $QTL$.

- For each query which is either being held, or which is outstanding but did not create a tree edge,

- Augments the $QTL$ to include all processes in the reachable set of $P_r$. Each process $P_i$ added from the reachable set uses sequence number $VERIFIED(i)$. These processes in the reachable set of $P_r$ are found in $LATEST(r, *)$ and must be added so as to preserve the identity of all minimal deadlocked sets. Processes not already in the $QTL$ are simply added in the order in which they appear in $LATEST(r, *)$. This ensures that each minimal deadlocked set discovered by $P_r$ is identified by the special pattern of boolean flags (--- --+).

- If $P_r$ is not a member of a minimal deadlocked set, then changes the flag of the engager process to be TRUE (+).

- If $P_r$ is a member of a minimal deadlocked set, and the engager of $P_r$ is not a member of the reachable set of $P_r$, then changes the flag of the engager process to be TRUE (+).

- If $P_r$ is a member of a minimal deadlocked set, and the engager of $P_r$ is in the reachable set of $P_r$ (i.e. also in the same minimal deadlocked set), then finds the first process $P_*$ in the $QTL$ which is in the reachable set of $P_r$. Does not change the value of flag $F_*$ for all other flags $F_i$ in the $QTL$, if $P_i$ is in the reachable set of $P_r$, then sets flag $F_i$ to be TRUE (+). Thus the minimal deadlocked set will have
the flag pattern (++++++) until the reply reaches the first member of the QTL which is a member of the minimal deadlocked set. This process will change the pattern to (-----+).

- For each such query, sends a reply to the engager process.

\( g \)

If every process \( P_i \) in the dependent set (except possibly the engager) appears in the QTL with sequence number \( M_i \) equal to \( \text{VERIFIED}(l) \), and \( P \) is not the query initiator, then

- If the priority of the reply just received is at least as high as the highest priority query computation received, then for each query computation being held, increases its \( \text{STARVE} \) count by 1.

- If \( F_r \) is FALSE (-), then
  
  The engager cannot be a member of the dependent set of \( P_r \). Declares DEADLOCK for \( P_r \) and all processes in the QTL which follow \( P_r \). Stores the rear portion of the QTL beginning with \( P_r \) in \( \text{LATEST}(r, *) \). Changes the flags in \( \text{LATEST}(r, *) \) and in the portion of the QTL starting with \( F_r \) to be the special pattern (------+).
  
  These processes form a minimal deadlocked set. Sets \( \text{DEADLK} \) to TRUE. Sends a reply to the engager.

- For each query which is either being held or which is outstanding but did not create a tree edge,

  For each such query, augments the query trace list to include all processes in the reachable set of \( P_r \). Each process \( P_i \) added from the reachable set uses sequence number \( \text{VERIFIED}(l) \). These processes in the reachable set of \( P_r \) are found in \( \text{LATEST}(r, *) \) and must be added so as to preserve the identity of all minimal deadlocked sets. Processes not already in the QTL are simply added in the order in which they appear in \( \text{LATEST}(r, *) \).

  If the engager of \( P_r \) is not a member of the reachable set of \( P_r \), then changes the flag of the engager process to be TRUE (+). The minimal deadlocked set to which \( P_r \) belongs will be at the end of the QTL with the special pattern of boolean flags (------+).

  If the engager of \( P_r \) is in the reachable set of \( P_r \) (ie also in the same minimal deadlocked set), then finds the first process \( P_i \) in the QTL which is in the reachable set of \( P_r \). Does not change the value of flag \( F_r \) (it will be FALSE). For all other flags \( F_i \) in the QTL, if \( P_i \) is in the reachable set of \( P_r \), then sets flag \( F_i \) to be TRUE (+). Thus the minimal deadlocked set will have the flag pattern (++++++) until \( P_r \) receives a reply. \( P_r \) will change the pattern to (-----+).
For each such query, sends a reply to the engager process.

(h) If \( P \) has been idle \( T_2 \) time since last executing, then

- Determines the highest priority of any query received. Selects all queries it has received which have an \textit{URGENCY} at least this high. For each such query (assume \( P_i \) is the initiator), if the query is being held, sends it to the next process in the dependent set which needs to be queried and sets \textit{STARVE}(i) to 0. \textit{LASTREP}(i) shows the progression through the dependent set. A process \( P_i \) in the dependent set which appears in the \textit{QTL} with sequence number \( M_i \) equal to \textit{VERIFIED}(i) does not need to be queried. Any query being sent creates either a tree edge (if the target process \( P_i \) is not in the \textit{QTL}) or a different type of edge (forward, back, or cross edge). For each query sent, sets \textit{EDGETYPE}(i) accordingly.

(4) When a process \( P_r \) receives a cancel \( C(P_k, P_r, \textit{QTL}) \), the action required is the same as for Algorithm IV.

(5) When a process \( P_r \) receives an inform \( I(P_k, P_r, T) \), actions required are the same as for Algorithm IV.

(6) When a process \( P_k \) sends a message, no query computation action is required.

(7) When an executing process \( P_k \) changes state to idle, the actions required are the same as for Algorithm IV.

(8) When a process \( P_i \) becomes idle for time \( T_1 \) since changing state from executing to idle, the actions required are the same as for Algorithm IV. The flag \( F_i \) in the \textit{QTL} is set to FALSE.

(9) When a process \( P_i \) becomes idle for time \( T_2 \) (where \( T_2 \leq T_1 \)) since changing state from executing to idle, the actions required are the same as for Algorithm IV.
CHAPTER 4.
Proofs of Correctness

4.1. Introduction

This chapter presents the proofs of the algorithms described in Chapter 3. Theorems 1 and 3 state that all true deadlocks are detected. Theorem 2 says that there are no false detections. Theorems 4, 5, and 6 apply only to Algorithm V; they show that a query computation identifies all minimal deadlocked sets and that at least one process from each minimal deadlocked set discovers deadlock for itself during the course of the query computation. Furthermore, when such a process discovers deadlock, it knows the identities of the other processes in the minimal deadlocked set. Definitions used in these theorems and their proofs are shown in Appendix F. Throughout this chapter, we make the following assumptions:

(1) There are only a finite number of processes in the system,

(2) There is a finite number of priority classes for query computations,

(3) No process is infinitely lazy, and

(4) Messages (and query computations) are delivered in finite amounts of time and in the order sent.

4.2. Theorems and Proofs

Theorem 1, in conjunction with theorem 3, shows that all true deadlocks are detected.
Theorem 1: If the initiator of a query computation is deadlocked when it initiates the computation, it will eventually declare itself "deadlocked".

Proof: For Algorithms I and II: Consider a set $S$ of $N$ processes, including the initiator $P$, which is deadlocked when $P$ initiates a query computation. Processes in $S$ cannot change their dependent sets, and there are no messages in transit between processes in $S$. Hence, after $P$ initiates the query computation, no process in $S$ can become executing. When receiving a query belonging to the query computation for the first time (an engaging query), each process adds itself to the query trace list and queries each process in its dependent set once in turn. Each process, upon receiving a query, either sends the corresponding reply or sends another query. Since each process can have at most $N-1$ processes in its dependent set, there can be at most $N(N-1)$ queries belonging to the query computation initiated by $P$. A reply is sent only when the corresponding query is received for the first time, and for any query received, exactly one reply has been sent. Hence, there can be at most $N(N-1)$ replies for the query computation. Therefore, after some finite amount of time, no more queries will be sent, and the corresponding reply for each query has been sent and received. By this time, the initiator has queried all members of its dependent set, has received the corresponding replies from all of them, and hence, declares itself deadlocked.

For Algorithms III, IV, and V: The above argument holds if no process in the system has a higher priority than $P$, since the highest priority query
computations are never suspended by other query computations. It also holds when all processes with priorities higher than \( P \) are in the set \( S \). In this case, each of the highest priority query computations initiated by processes in \( S \) will finish. Once they do, each of the next highest priority query computations becomes the highest priority query computation. Each of these also finishes, until finally the query computation initiated by \( P \) finishes, and \( P \) detects deadlock.

Suppose, however, that there are exactly \( M \) processes not in \( S \) which have priorities higher than \( P \) and each of which has a reachable set containing \( P \). Let \( H_{\text{max}} \) be the highest priority which may be assigned to a query computation. We will show that the query computation initiated by \( P \) cannot be suspended indefinitely by query computations initiated by these \( M \) processes, causing \( P \) to fail in detecting deadlock. To show that this cannot occur, we show that the highest priority query computation \( QC_0 \) initiated by any process in \( S \) will make progress. More specifically, if the query computation \( QC_0 \) is suspended by a higher priority query computation initiated by one of the \( M \) processes not in \( S \), \( QC_0 \) will eventually increase its urgency by 1. As defined in Chapter 3, urgency is the sum of priority of the query computation and the integer quotient of the starvation count divided by a user-defined finite number \( C \). The starvation count of a suspended query computation is increased by 1 each time the process which suspended the query computation sends a reply or receives a cancel.
We now show that $QC_0$ will raise its starvation count by 1 in finite time. Either $QC_0$ is making progress, in which case the proof is completed, or else it is suspended by an engaging query from a higher priority query computation (say $QC_1$) received by some process $Q$ in $S$ from a process not in $S$. Either $QC_1$ is making progress, or else it is suspended by a higher priority query computation (say $QC_2$) initiated by another process not in $S$. Since there are $M$ processes not in $S$ which have priorities higher than the highest priority process in $S$, there is a query computation $QC_M$ with the highest priority. Note that the priority of $QC_M$ is less than or equal to $H_{max}$. $QC_M$ and all other query computations with this priority, make progress among processes in $S$. Process $Q$ in $S$ which receives an engaging query from any of these highest priority query computations will either eventually reply to its engager, or else receive a cancel for the query computation. Starvation counts of all query computations suspended by $Q$ will be increased by 1. Hence, they make progress. That is, they will eventually finish (replies are sent to engagers) or else they will be terminated with a cancel. In either case, all processes which receive engaging queries belonging to $QC_{M-1}$ will either send a reply or receive a cancel for $QC_{M-1}$. All query computations suspended by these processes thus increase their starvation counts by 1, and hence make progress. Because the number of priority classes is finite, $QC_0$ will eventually increase its starvation count by 1, and hence make progress. By continuing this argument, we can conclude that the starvation count of $QC_0$ will eventually reach the level $C$, causing its urgency to increase by 1. Similarly, the
urgency of $QC_0$ eventually will reach a level sufficient to ensure its progress. In particular, since the priority of any query computation is bounded by $H_{\text{max}}$, $QC_0$ begins to make progress whenever its urgency is as high or higher than the priority of the query computation which caused process $Q$ to suspend $QC_0$.

Theorem 2 states that a process does not detect a false deadlock. It will be proven by contradiction using Lemma 1.

**Lemma 1:** Suppose that a process $P_k$ sends a reply to its engager and subsequently becomes executing at some time $T_a$ during a query computation. Then there exists a process $P_r$ in the dependent set of $P_k$ which receives a query for that query computation and subsequently becomes executing at some time $T_b < T_a$.

**Proof:** Suppose that a process $P_e$ sends process $P_k$ an engaging query at some time $T_c$. Thus, $P_e$ is the engager of $P_k$. Suppose that $P_k$ receives this query at some time $T_d > T_c$ and sends a reply to $P_e$ at some time $T_e > T_d$. $P_k$ was idle. It can only become executing if it receives a message from some process $P_r$ in its dependent set. Suppose that $P_k$ receives a message from $P_r$ and becomes executing at some time $T_a > T_e$. The relationships between $T_a$, $T_e$, $T_d$, and $T_c$ are as shown below. There are two cases: either $P_r$ is $P_e$, or $P_r$ is not $P_e$.

```
T_e  T_d  T_e  T_a
```
Case 1: Suppose that \( P_r \) is \( P_e \).

Since message delays are finite, \( P_r \) sent the message at some time \( T_b < T_a \).

Also, since sequenced message delivery is assumed, the query was sent by \( P_r \) to \( P_k \) before the message. Hence, \( T_e < T_b \) as shown below.

\[
\begin{align*}
T_c & \quad T_b & \quad T_d & \quad T_e & \quad T_a
\end{align*}
\]

Queries are sent only by idle processes, and messages are sent only by executing processes. Hence \( P_r \) was idle at time \( T_c \), received the query (or initiated it), and subsequently became executing at time \( T_b < T_a \).

Case 2: Suppose that \( P_r \) is not \( P_e \).

For Algorithms I, II, and III, \( P_k \) does not send a reply to \( P_r \) until it has queried and received replies from every process in its dependent set (except possibly the engager). Therefore, \( P_r \) received a query from \( P_k \) at some time \( T_h > T_d \) and sent a reply to \( P_k \) at some time \( T_i \), where \( T_h < T_i < T_e \) as shown below. Since \( P_k \) received a message from \( P_r \) after receiving a reply from \( P_r \), the message from \( P_r \) was sent at some time \( T_b \) where \( T_i < T_b < T_a \) as shown.

\[
\begin{align*}
T_c & \quad T_d & \quad T_h & \quad T_i & \quad T_e & \quad T_b & \quad T_a
\end{align*}
\]

Hence, \( P_r \) was idle, received the query (or initiated it), and subsequently was executing at time \( T_b < T_a \).

For Algorithms IV and V, \( P_k \) does not send a reply to \( P_e \) unless every process in its dependent set appears in the query trace list and the sequence
number \( N_i \) matches the most recent sequence number \( M_i \) of some query or
reply sent from \( P_i \) to \( P_k \) for every process id/sequence number pair \( P_i N_i \)
appearing in the query trace list. Therefore, when \( P_k \) sends a reply to \( P_r \) at
time \( T_e \), process \( P_r \) and its associated sequence number \( N_r \) are in the query
trace list. \( P_k \) knows from some query or reply it received from \( P_r \) that any
message subsequently received from \( P_r \) carries a sequence number greater
than \( N_r \). Therefore, the message received by \( P_k \) at time \( T_a \) carries a
sequence number greater than \( N_r \). Since \( P_i \) inserted itself with sequence
number \( N_i \) in the query trace list, this implies that \( P_r \) became executing at
some time \( T_b < T_a \) after receiving the query computation.

Theorem 2 states that a process does not detect a false deadlock, and that whenever
it detects a deadlock, it knows all the processes in its reachable set.

**Theorem 2:** If the initiator \( P \) of a query computation declares itself "deadlocked", then
it belongs to a deadlocked set \( \hat{S} \) containing itself and all the processes in its
reachable set. Moreover, all the processes in the reachable set of \( P \) are
known to \( P \) when deadlock is declared.

**Proof:** Let \( S \) be the set of processes which receive queries during the query
computation. As described in Chapter 3, a process \( Q \) in \( S \) adds itself to the
query trace list when it receives an engaging query. Every process replies to
its engager only after it receives a reply for every query that it sent. After
the initiator receives a reply for every query that it sent, it declares itself
deadlocked. Therefore, when the initiator \( P \) declares itself deadlocked,
every process in $S$ has replied to its engager in the query computation.

We now show by contradiction that no process in $S$ can become executing after sending a reply to its engager. In other words, processes in $S$ are indeed deadlocked when $P$ declares itself deadlocked. Suppose some processes in $S$ become executing after replying to their engagers. Let $Q$ be the first such process. From Lemma 1, if process $Q$ becomes executing at time $t_Q$ after replying to its engager, then there is a process $R$ in the dependent set of $Q$ which becomes executing at time $t_R$ after receiving a query, and $t_R > t_Q$. $Q$ cannot be the engager of $R$, since $Q$ being the engager of $R$ means that $R$ replied to $Q$ before $Q$ replied to its engager. If this happens, then $Q$ is not the first process to execute after replying to its engager as it is supposed to be. Two possibilities remain: either $R$ is in the engager chain of $Q$, or it is not. If it is not, then $R$ must have received an engaging query from some other process and replied to that process before $Q$ received its engaging query. Again, $Q$ is not the first process to execute after replying to its engager if this happens. The only other possibility is that $R$ is in the engager chain of $Q$. $Q$ being the first process to execute after replying to its engager means that $R$ has not replied to its engager at time $t_R$. Therefore, $R$ still has an outstanding query at time $t_R$. When $R$ executes at time $t_R$, it cancels its outstanding query. For Algorithm I, the query computation is halted, and for Algorithms II, III, IV, and V process $R$ increases its sequence number in the query trace list. Thus, the reply which $Q$ sent no longer belongs to the current query computation. It follows that no process in $S$ becomes executing after sending a reply to its engager.
For Algorithms III, IV, and V, when a process that has already declared deadlock receives an engaging query, it adds the members of its reachable set to the query trace list and sends a reply to its engager without querying its dependent set. This means that the set $S$ of processes may be a proper subset of the reachable set of $P$. To complete the proof, we need to show closure over the dependent set relationships for the deadlocked set declared by $P$. To do this, we first suppose that $P$ is the first process in $S$ to declare deadlock. We can conclude that the dependent set of every process in $S$ is also in $S$, since every process in the dependent set of some process $Q$ in $S$ sees the query computation before $Q$ replies to its engager. In this case, $S$ is a deadlocked set. Every process in the reachable set of $P$ receives an engaging query and adds itself to the query trace list. We can further conclude that the initiator $P$ knows the identity of every process in its reachable set upon receiving the last reply. That is, the set $\hat{S}$ is the set $S$.

Suppose that $P$ is not the first process in $S$ to declare deadlock. We prove by induction that the set $\hat{S}$ containing $P$ and its reachable set is a deadlocked set, and that $P$ knows the identities of all processes in its reachable set. Let $V$ be the first process to declare deadlock. By the argument above, $V$ and its reachable set is a deadlocked set, and $V$ knows the identities if all processes in its reachable set. Consider the set of processes $S'$ which is the union of $S$ and the reachable sets of those processes in $S$ which have already declared deadlock. Suppose that the reachable set of any process $W$ in $S$ that declared deadlock before $P$ is a deadlocked set and that $W$ knows the identities of all processes in its
reachable set. We first show that $S'$ is also a deadlocked set. We have already shown that no member of $S$ can become executing after sending a reply to its engager. None of the processes added to $S$ to form $S'$ can become executing either, since they are members of deadlocked sets. Therefore, $S'$ is a deadlocked set. We now show that $P$ learns the identities of all processes in its reachable set. Each process in $S'$ is in the reachable set of $P$. Suppose there is a process $U$ which is in the reachable set of $P$ which is not in $S'$. There is a chain of processes $P, Q_1, Q_2, ..., U$ such that each process is in the dependent set of its predecessor. Each process either receives an engaging query from its predecessor, or else some ancestor in the chain has already declared deadlock. If no process in the chain has declared deadlock, then $U$ receives a query, and hence $U$ is a member of $S$. If some process in the chain has declared deadlock, then let $Q_0$ be the first one (in the chain order). $Q_0$ receives a query and sends a reply after including in the query trace list all members of its reachable set. Therefore, $U$ will be in $S'$. This says every process in the reachable set of $P$ is in $S'$. Therefore, the reachable set of $P$ is $S'$. This also says that $S'$ is $S$. Because each process in $S$ adds itself to the query trace list, and any process which already declared deadlock adds its reachable set to the query trace list, all processes in $S'$ will appear in the query trace list when $P$ declares deadlock. Thus, $P$ knows the identities of all processes in its reachable set.

Theorem 3 is used in conjunction with theorem 1 to show that all true deadlocks are detected.
**Theorem 3:** (for Algorithm I)

If every process initiates a new query computation after it becomes idle or receives an inform, then every process in every deadlocked set will report "deadlocked".

**Proof:** Suppose a process $P$, upon becoming idle, initiates a query computation. Since all messages are delivered in finite time, $P$ will eventually declare deadlock if the query computation is not halted. Hence, we need to consider only the case when the query computation initiated by $P$ is halted. The query computation may be halted in one of three ways:

1) An idle process with an outstanding query receives a message and starts executing;
2) An executing process receives a query; or
3) An idle process receives a nonengaging query and the process has not been continuously idle since seeing the engaging query.

Consider cases 1 and 2. When some process $Q$ halts a query computation, it sends an inform to $P$. Once the inform arrives, $P$ will initiate a new query computation.

Now consider case 3. Let $Q$ be the first process to halt the query computation. Suppose that $Q$ receives the nonengaging query from a process $W$, where $W$ is not necessarily different from $P$. If process $Q$ is in the engager chain of $W$, then we have case 1. That is, $P$ will receive an inform from $Q$. If $Q$ is not in the engager chain of $W$ when $Q$ begins
executing at some time $T_Q$, then $Q$ received an engaging query, sent a reply to its engager, received a message and became executing, and then received the nonengaging query from $W$. By Lemma 1, some process $R$ in the dependent set of $Q$ received an engaging query and subsequently became executing at some time $T_R < T_Q$. Process $R$ cannot have an outstanding query at time $T_R$, since it would have stopped the query computation when it began executing. Therefore, $R$ replied to its engager before time $T_R$. This leads to a contradiction to the supposition that $Q$ is the first process to stop the query computation.

**Theorem 3:** (for Algorithms II, III, IV, and V)

If every process initiates a new query computation whenever it becomes idle, then every process in every deadlocked set will report "deadlocked".

**Proof:** From theorem 1, the last process to become idle in a deadlocked set will detect deadlock. We now show that when all processes in a deadlocked set become idle, the query computations initiated by the processes other than the last process to become idle in the deadlocked set will run to completion. When they complete, their initiators will each declare deadlock. To show this, we note that query computations can be halted only by the initiator when it executes. When a process $Q$ in the engager chain of a query computation executes, it suspends the query computation (and sends a cancel if needed). Then $Q$ shortens the engager chain so that it is the last process on the engager chain. Once $Q$ becomes idle, it resumes the query computation by querying its dependent set.
Theorems 4, 5, and 6 only apply to Algorithm V. These theorems establish that a
deadlocked process will recognize all minimal deadlocked sets in its reachable set. Lemma
2 is used in the proof for theorem 5.

Lemma 2: If a process $P$ replies to its engager, then all processes in the reachable set
of $P$ appear in the query trace list of the reply.

Proof: Suppose a process $P$ replies to its engager, and $Q$ is in the reachable set of
$P$ but not in the query trace list of the reply sent from $P$ to its engager.
There is a path from $P$ to $Q$ such that each process in the path is in the
dependent set of its predecessor. Let $R$ be the first process on this path
which is not in the query trace list. We note that no process between $P$ and
$R$ has declared deadlock, since if there were a process between $P$ and $R$
which had declared deadlock, it would have added itself and all members of
its reachable set to the query trace list. That is, $R$ would be in the query
trace list. Let $V$ be the predecessor of $R$ in the path from $P$ to $Q$. Since
$V$ is in the query trace list, it will have seen the query computation and
added itself to the query trace list. In other words, $V$ has queried each each
member of its dependent set which is not already in the query trace list
before replying to its engager. Therefore, $V$ has queried $R$. This is a
contradiction, since this implies $R$ added itself to the query trace list before
relying to $V$.

Theorem 4: If a process $P$ in a minimal deadlocked set initiates a query computation, it
will declare deadlock for itself and all members of its reachable set.
Moreover, $P$ recognizes that its reachable set is a minimal deadlocked set.
Proof: From theorem 1, the initiator $P$ eventually declares deadlock. From theorem 2, $P$ knows the identity of every process in its reachable set. We now show that $P$ recognizes its reachable set as a minimal deadlocked set. Every process in the reachable set of $P$ is in the same strongly connected component as $P$. $P$ initializes its boolean flag $F_p$ in the query trace list to FALSE. $P$ recognizes its reachable set as a minimal deadlocked set if and only if the boolean flag $F_p$ in the last reply received by $P$ is FALSE. The only way in which the boolean flag $F_p$ in the query trace list can be set to TRUE is if some process $Q$ in the reachable set of $P$ recognizes that $Q$ is in a minimal deadlocked set, and that the engager of $Q$ is not. To show that this cannot happen, we suppose some process $Q$ in the reachable set of $P$ recognizes that $Q$ is in a minimal deadlocked set. When $Q$ replies to its engager, the boolean flag $F_Q$ is FALSE. All processes in the dependent set of $Q$ appear after $Q$ in the query trace list, since otherwise $Q$ would have set $F_Q$ to TRUE. Also, for a process $R$ appearing after $Q$ in the query trace list, all processes in the dependent set of $R$ appear after $Q$ in the query trace list. This says there is no directed path from $Q$ to $P$. This is a contradiction, since $P$ and $Q$ are in the same strongly connected component. Therefore, our supposition is not true; $P$ recognizes it is in a minimal deadlocked set and that all processes following $P$ in the query trace list are also members of the minimal deadlocked set.

**Theorem 5:** If a process $P$ in a minimal deadlocked set receives an engaging query from a process $Q$ that is not in the minimal deadlocked set and subsequently replies to $Q$, then $P$ will declare deadlock for itself and all members of its
reachable set. Furthermore, \( P \) recognizes that its reachable set forms a minimal deadlocked set. When \( Q \) receives the reply from \( P \), \( Q \) knows that \( Q \) itself is not in a minimal deadlocked set, and that the reachable set of \( P \) does comprise a minimal deadlocked set.

Proof: The proof for theorem 5 is similar to that for theorem 4.

Theorem 6: If a process \( P \) declares deadlock, it knows the identities of all members of every minimal deadlocked set in its reachable set. For each of these minimal deadlocked sets, there is a process \( Q \) belonging to the minimal deadlocked set such that \( Q \) knows the identity of the reachable set of \( Q \), and that the reachable set of \( Q \) forms a minimal deadlocked set.

Proof: The proof for theorem 6 is similar to that for theorem 4.
CHAPTER 5.
Simulation Studies

5.1. Introduction

The CMH Algorithm and the five new algorithms proposed in this thesis were simulated to compare their performance and efficiencies. In these studies, the efficiency of an algorithm is measured in terms of the number and length of messages sent on the communication network, the additional storage required of each process, and the time required by the algorithms to detect deadlock once deadlock exists.

5.2. Design

The algorithms were simulated using six Pascal programs, with each program implementing one of the deadlock detection algorithms. The simulation is event-driven and uses an events list which holds events to occur in the future. As an event is forecast, it is added to the events list after all events already scheduled to occur earlier or at the same time. Events in the events list are processed one at a time. The simulation ends when the events list expires, or when a termination event is encountered.

5.3. Simulation Model of Communicating Processes

In the simulation model of communicating processes, an idle process begins to execute upon receiving a message from any process in its dependent set. An executing process may send a message to another process.

The time $t$ between the instant at which a process $P$ last became executing to the instant at which it will either send a message or become idle is exponentially distributed
with mean $1/\lambda$. Let $\pi$ be the probability that the process will send a message rather than becoming idle. After sending a message, an executing process will continue to execute for a period of time, after which it will become idle or send another message and continue executing. Let $t_k$ be the length of time between the instant at which a process sends the $(k-1)$th message after it last became executing to the instant at which it will either become idle or send the $k$th message. We assume that the $t_k$'s are statistically independent, identically distributed with average $1/\lambda$. When the probability $\pi_k$ that the process will send the $k$th message is $\pi$ independent of $k$, the length of time between the instant at which a process last became executing to the instant at which it will become idle is exponentially distributed with average $1/(\lambda \pi)$.

An executing process enqueues all messages it receives while executing. Upon becoming idle, it checks the queue for messages it may have received from processes in its dependent set. These messages are considered to be acceptable in that the process may accept one and begin executing again. Messages received by a process but not yet accepted for processing remain in the queue. If no acceptable messages have arrived, the process remains idle waiting for a message from any process in its dependent set. As an option of the simulation programs, however, messages may be discarded if they cannot be accepted immediately.

The model described here allows us to simulate direct communicating processes as well as a resource allocation system where a resource manager process is waiting to receive a message from a process releasing one of its resources held by that process. While the resource manager is waiting to regain control of its resources, other processes can request its resources by sending request messages to it. These messages are simply enqueued since the manager process does not have the requesting processes in its
5.4. Connection Topology

The processes form several clusters as shown in the schematic diagram in Figure 4. Such a model can be used to simulate a wide-area network, with each cluster in the model simulating a site or a local-area network within the wide-area network. The model can also be used to simulate a local-area network with different hosts. Communication between any two processes in the same cluster is subject only to an intra-cluster delay. Communication between two processes in different clusters is subject to an inter-cluster delay. For the cases simulated in this thesis, we measured the communication delays in terms of the number of hops required. This assumes that message and query traffic delays are constant and therefore are not affected by such factors as volume of network traffic and capacity of transmission channels. The assumption of constant network delays was made to allow all deadlock detection algorithms to be simulated in an identical environment. Such an assumption may not be valid, especially for the CMH Algorithm (Ref ShSi85). The effects these two factors may have on the algorithms simulated are discussed later in this chapter.

Figure 4
Clusters of Processes
5.5. Input Parameters

The following parameters are used to initialize the system.

(1) Number of clusters in the system.

(2) For each cluster, the number of processes in that cluster.

(3) For each cluster, the message delay time between two processes in that cluster.

(4) For each cluster, the message delay times to every other cluster.

(5) For each process, four parameters governing dependent set selection — When a process becomes idle, its new dependent set is formed and consists of some processes selected from within the same cluster and some processes selected from the other clusters in the network. The four parameters are the minimum and maximum number of processes in the dependent set which may come from the same cluster and the minimum and maximum number of processes in the dependent set which may come from all the other clusters. The new dependent set is chosen randomly by picking \( N_1 \) processes from the other clusters and \( N_2 \) processes from the same cluster. The numbers \( N_1 \) and \( N_2 \) are uniformly distributed between their respective minima and maxima (inclusive).

(6) Probability \( \pi \) that the next event of an executing process is to send another message and continue executing instead of becoming idle. This is a parameter which has associated with it two constraints. The first is a minimum number of processes which remain executing, and the second is a maximum number of processes which should be allowed to execute. If there are \( N \) processes in the system and the two constraints are 0 and \( N \), then the constraints have no effect on the simulation. If,
however, the lower constraint is greater than 0, then a minimum number of processes will always be executing (that is, a process is not allowed to become idle if the minimum number of executing processes is not maintained).

(7) Average time $1/\lambda$ an executing process executes until its next event occurs.

(8) Number of messages used to initialize the system. The simulation is started with each process having just become idle and having generated a new dependent set. Messages are introduced into the system as though they had been sent at time 0, but not yet received. Processes will begin executing once they receive these messages.

5.6. Statistics Collected

Each query, reply, cancel, and inform contains the initiator identifier of the query computation and a sequence number. For Algorithms II, III, IV, and V, this sequence number is the sequence number associated with the query computation initiator. Each process has two categories of query computations associated with it: those that fail to detect deadlock, and one (or less) which succeeds in detecting deadlock. Queries, replies, cancels, and informs are tallied according to the query computation initiator and sequence number, with all old query computations for a given initiator lumped together. If deadlock is discovered, the contents of all counters are recorded. These counts show how much effort has been spent to that point.

In addition to the statistics mentioned above, the numbers of queries, replies, cancels, informs, and messages sent and accepted, both until the first deadlock is discovered and over the duration of the simulation, are recorded. The number of messages sent does not always equal the number of messages accepted, since a message is not be accepted by a process unless its intended receiver is idle and the sender
is in the receiver's dependent set.

The total number of data fields required to be sent is also recorded. For the new algorithms which use a variable-length format, it is assumed that one extra field is required to indicate the length of the query, reply, cancel, or inform. Header information was not added to the number of data fields required.

Associated with each process is a variable showing when that process last changed state from executing to idle. Since our algorithms identify all processes in the deadlocked set, it is possible to determine the time at which the deadlock first developed. This information is then used in determining how long the algorithms require to detect deadlock.

Two additional statistics collected are the average number of idle processes and the average size of dependent sets. The average size of dependent sets ($\hat{D}$) is a time-weighted average which takes into account the durations of dependent sets. Thus, if during the course of the simulation of duration $T$, there are $m$ dependent sets generated for all processes, and dependent set $i$ has size $S_i$ and duration $t_i$, then

$$
\hat{D} = \frac{\sum_{i=1}^{m} (t_i \cdot S_i)}{\sum_{i=1}^{m} t_i}
$$

The average number of idle processes ($\hat{N}$) in the system is also a time-weighted average which takes into account the amount of time a process is idle.

$$
\hat{N} = \frac{\sum_{i=1}^{m} t_i}{T}
$$

The average number of dependency relationships ($\hat{C}$) is the product of the average size of
a dependent set \((\hat{D})\) and the average number of idle processes in the system \((\hat{N})\).

\[
\hat{C} = \hat{D} \times \hat{N}
\]  

(3)

5.7. Results and Analysis

The first case study is carried out to determine in which order an idle process should query the processes in its dependent set. Case studies 2 and 3 are done in order to fix the values of \(T_1\) and \(T_2\) for the remaining case studies. In case studies 4 through 7, the performance of the algorithms are evaluated.

5.7.1. Case Study 1

The first case study of communicating processes demonstrates that, for Algorithms III, IV, and V, processes in a dependent set should be queried in the order of highest priority first, rather than lowest priority first. Table 1 shows the input parameters used in this case study. Each test configuration was run 75 times. The first test configuration was designed so that all 75 runs resulted in detection of deadlock, and an average of 64 messages were sent during each run. The second test configuration was designed so that at least 2 processes were executing at any one time, and deadlock was never detected in all 75 runs. Each run executed for 5000 time units, and an average of 1481 messages were sent during each run. The means and the 90% confidence intervals for the two test configurations are shown in Tables 2 and 3.

Tables 2 and 3 show that it is important that processes be queried in the order of highest priority first, especially when deadlock is likely to occur. For the remainder of the simulation studies, processes in a dependent set are queried in order of highest priority first for Algorithms III, IV, and V.

5.7.2. Case Study 2

\(T_1\) is the time a process waits after becoming idle before initiating a query computation. \(T_2\) is the minimum time after a process becomes idle before it sends to a process in its dependent set a query in a query computation initiated by another process.

The result of this case study shows the efficiency of each algorithm is very sensitive to the parameter \(T_1\) for any given set of input parameters. Table 4 lists the different parameter values used in the first three test configurations, each of which contains a single large cluster of processes. Table 5 lists the parameter values for three more test configurations containing five small clusters of processes. For this case study, \(T_2\) was taken to be 0.9 \(T_1\). Different values of \(T_2\) are used in case study 3. The results are shown in Figures 5 through 10 for the first three test configurations, and in Figures 11 through 16 for the second three test configurations. Each line on the graphs shows the total amount of query traffic (queries, replies, and cancels). Because the simulation may be halted with the events list still containing future events, an error is introduced into the
measured result. The size of this error is dependent on $T_1$ and $T_2$. For example, if $T_1 = 500$, and the duration of the simulation is 5000, then any process becoming idle after 4500 does not affect the amount of query traffic passed before the simulation halts, since the query computation for that process will not start until after the simulation halts. In this case, the duration of the simulation (5000) is long enough to ensure that the error introduced in this manner is less than approximately 10%. For the value $T_1 = 800$, the simulation was run for 10,000 time units, with the volume of query traffic being divided by 2. Thus, the shape of the curve approximately reflects the amount of query traffic which will never detect deadlock. For Algorithms CMH, I, and II, each test configuration was simulated enough times so that we can say that the expected mean lies within 10% of the sample mean with an 80% level of confidence. For Algorithms III, IV, and V, the same can be said with a 90% level of confidence.

</table>

As $T_1$ becomes smaller, an idle process initiates a query computation sooner, and therefore has a greater chance of initiating a query computation which encounters an executing process. There is also a greater chance that the initiator will become executing after initiating the query computation. Plots in Figures 5 through 16 show what happens as the average size of the dependent sets increases. For Algorithm CMH, the volume of query traffic increases due to the multiplying effect caused by the breadth-first approach. For the depth-first algorithms, however, just the opposite occurs. The results of our simulation show that as the average size of the dependent sets increases, the average number of idle processes encountered by queries in a query computation actually
decreases. Hence, a query computation using the depth-first approach tends to encounter an executing process sooner, and the average volume of query traffic is less.

With the exception of case study 3, the rest of our results were obtained with the value of $T_1$ chosen to be 500. This value of $T_1$ is chosen because for values less than 500, the CMH Algorithm requires significantly more query traffic. For our algorithms, increasing $T_1$ from 500 to 800 resulted in no significant decrease in query traffic. For the second set of plots in which the processes are in five small clusters, we observed similar results showing the CMH Algorithm requiring significantly more query traffic for values of $T_1$ less than 500, and no significant improvement for our algorithms when increasing $T_1$ from 500 to 800. We observe that the performance of the algorithms does not depend significantly on whether the processes form one or more than one cluster when the inter-
cluster delay times are not too much greater than the intra-cluster delay times.

5.7.3. Case Study 3

This case study shows that the performance of Algorithms III, IV, and V is sensitive to the parameter \( T_2 \) for any given set of other input parameters. Test configurations 1, 2, 3, and 5 from case study 2 were selected, and \( T_2 \) was assigned the values 0.9 \( T_1 \), 0.5 \( T_1 \), and 0.1 \( T_1 \). Table 6 shows the different parameter values used in this simulation. Figures 17 through 22 show the results for the three test configurations containing a single large cluster, and Figures 23 through 24 show the results for the test configuration with five small clusters. Since the data for Algorithms IV and V were the same, their plots were combined. Each line on the graphs shows the total amount of query traffic (queries, replies, and cancels) averaged over 50 trials. As in case study 2, we have an 80% level of confidence that the expected mean lies within 10% of the sample mean. For Algorithms III, IV, and V, the same can be said with a 90% level of confidence.

$T_2$ is the minimum time a process waits after becoming idle before it sends to a process in its dependent set a query in a query computation initiated by another process. The plots in Figures 17 through 24 show that as $T_2$ increases from 0.1 $T_1$ to 0.9 $T_1$, the volume of query traffic is approximately cut in half. For values of $T_1$ greater than 200, very little is gained by increasing $T_2$ from 0.5 $T_1$ to 0.9 $T_1$. Since in case study 2 we...
chose $T_1$ to be 500, any choice of $T_2$ greater than $0.5 T_1$ does not significantly affect the volume of query traffic. As $T_2$ increases, the time to detect deadlock tends to increase, since the last process to become idle waits longer before processing any query computations. We choose $T_2 = 0.9 T_1$ for the remaining case studies primarily to minimize the volume of query traffic.

5.7.4. Case Study 4

The fourth case study evaluates the time required to detect deadlock once deadlock exists and the load placed on the network during deadlock detection. The input parameters for the two test configurations used in this example are shown in Table 7. The values of $T_1$ and $T_2$ are chosen to be 500 and 450 and are based on the results from case studies 2 and 3. Each test configuration was simulated to obtain 25 times when deadlock existed. This was sufficient to establish that, with an 80% level of confidence, the expected mean differs from the sample mean by no more than 15% of the sample mean.

The performance characteristics for the algorithms when deadlock exists are shown in Figures 25 and 26. For each run $R_i$, the time when the last process in the deadlocked became permanently idle is $\psi_i$. That is, deadlock first existed at time $\psi_i$. The time scales for each run were normalized with respect to the largest $\psi_i$, which was 439. The statistics were collected in buckets, with each bucket collecting data from all 20 processes for 50 units of time. The results were averaged over the 25 trials.

For Test Configuration 1, the first process became permanently idle at time 300, and the number of permanently idle processes increased until at time 439, all processes had become permanently idle. Since $T_1 = 500$, any query computation begun after time 939 will result in detection of deadlock. For the CMH Algorithm curve, the portion between time 800 and time 950 represents mostly query computation traffic for which deadlock is not detected.

The CMH Algorithm exhibits a large surge of query computation traffic since it employs a breadth-first method. Assuming the system can handle this surge with no increase in message delivery time, the CMH Algorithm will complete faster than the other

algorithms. However, the assumption of constant message and query traffic delays may not be valid, especially for the CMH Algorithm |Ref ShSi85|. Most communication networks cannot handle the initial surge without increasing message delivery time; effectively there is a ceiling on the network throughput which in turn limits the volume of query traffic on the network at any one time. For example, if the maximum throughput of the network for Test Configuration 1 is placed at 300 messages per time unit, then the CMH Algorithm requires approximately 1700 time units to detect deadlock, and Algorithms I and II are unaffected in Figure 25.

Algorithm II requires a greater volume of query computation traffic than Algorithm I because the query computations initiated before time 939 do not terminate when they encounter an executing process. Hence, there are always 20 query computations which
Figure 25
Time to Detection of Deadlock and System Load, Test Configuration 1
With Five Small Clusters and Small to Medium Size Dependent Sets
Figure 26
Time to Detection of Deadlock and System Load, Test Configuration 2
With Five Small Clusters and Medium to Large Size Dependent Sets
detect deadlock. The heights of the curves for Algorithms I and II are dependent on the number of query computations and the message delay times, since for each query computation, there is only one query or reply in transit at any given time.

For Algorithms III, IV, and V in Test Configuration 1, deadlock is first detected around time 1750. The curves for Algorithms III, IV, and V show that the priority system is very effective in reducing query traffic for all but the highest priority query computation. The curves for Algorithms IV and V also show that using information from other query computations is very effective in reducing the volume of query traffic, especially when the highest priority query computation has completed. This result is explained further in case study 5. The slight surge in the volume of query traffic for Algorithm III after time 1750 shows the effect of other query computations processing once they are not blocked by higher priority ones.

The curves for Test Configuration 2 are similar in shape to those for Test Configuration 1. The average size of dependent sets for Test Configuration 2 is almost three times as large as for Test Configuration 1. Figures 25 and 26 show that the height of the CMH Algorithm curve is about 2.5 times as high, although not much wider. For the CMH Algorithm, the width of the curve (that is, the time to detect deadlock) is primarily determined by the height of the search tree and the message delay times. The deadlocks detected in this case study produced relatively short tree heights for the CMH Algorithm.

As in Test Configuration 1, the heights of the curves for Algorithms I and II are determined by the number of query computations in the system and the message delay times. Hence, the heights of these curves are approximately the same for both test
configurations. The heights of the curves for Algorithms III, IV, and V are also approximately the same for both test configurations. The areas under the curves are greater, though, showing that as the number of dependency relationships increases, the time required for the depth-first approach to detect deadlock also increases.

5.6.5 Case Study 5

The fifth case study evaluates the volume of query traffic used by each process during deadlock detection. The input parameters for the two tests used are the same as for case study 4. Figures 27 and 28 show that the CMH Algorithm requires a larger volume of query traffic than Algorithms I and II. This happens because, in the CMH Algorithm, a process queries each member of its dependent set, whereas for Algorithms I and II, a process does not need to query its engager. This modification could be implemented very easily in the CMH Algorithm. The results for Algorithm III show most of the work being done by the highest priority query computation. For the fourth and successive query computations, the level of work required is approximately that required by the initiator to query each member of its dependent set and hence is related to the size of the dependent sets. For Algorithms IV and V, the highest priority query computation requires less query traffic than for Algorithm III because for Algorithms IV and V, it uses information from other query computations. Lower priority query computations in Algorithms IV and V require very little query traffic because they use information from previous query computations, and in particular, from the highest priority query computation. The volume of query traffic required by the lower priority query computations does not appear to depend on the size of the dependent sets or the number of processes in the system. On the average, the query computations initiated by processes 3 through 20 only require one query and one reply to determine they are deadlocked.

With Five Small Clusters and Small to Medium Size Dependent Sets
Figure 28

Volume of Query Traffic for Test Configuration 2

With Five Small Clusters and Medium to Large Size Dependent Sets
5.7.6. Case Study 6

The sixth case study evaluates the average number of data fields transmitted by all 20 processes during a single simulation run. We assume that all fields in the query traffic (except the bit flags used in Algorithm V) are the same length, and that each query, reply, and cancel requires one header field, also of that same length. We also assume that the bit flags used in Algorithm V add 1 bit for each 16 bits (2 fields) used in the query trace list. This implicitly assumes that each data field is 8 bits long. The input parameters for the four test configurations are shown in Table 8. The results in Tables 9 through 12 show that the new algorithms always require less query traffic than the CMH Algorithm.

The results from Test Configurations 1 and 2 show that the CMH Algorithm requires significantly fewer data fields to be transmitted than Algorithms I and II when deadlock exists because the CMH Algorithm uses fixed length queries and replies. Algorithms IV and V require fewer data fields to be transmitted than the CMH Algorithm in all four test configurations. The ratios of data fields transmitted to query traffic communications sent show that, when deadlock exists, most queries and replies for the new algorithms have fairly long query trace lists.

The results from Test Configurations 3 and 4 show that Algorithms I, III, IV, and V all require significantly fewer data fields to be transmitted than the CMH Algorithm when deadlock does not exist. The results from Test Configuration 4 also show that for larger sized dependent sets, Algorithm II also requires fewer data fields to be transmitted than the CMH Algorithm. The ratios show that, when deadlock does not exist, most queries and replies for the new algorithms have relatively short query trace lists. For Algorithms
III, IV, and V, the priority system ensures that most query computations are suspended due to higher priority query computations, and hence their query trace lists are kept short.

5.7.7. Case Study 7

The seventh case study compares the volume of query traffic as a function of the time-weighted average number of dependency relationships defined by equation (1). The input parameters for the three test configurations are shown in Table 13. During a simulation run, the size of the dependent sets was held constant. Each test configuration was simulated 50 times for each size of dependent set. Results of simulations with a dependent set size of 4 are not shown for Test Configurations 2 and 3 due to difficulty in obtaining deadlock-free simulations without changing other input parameters such as the probability a process sends a message for its next event or the minimum number of processes to be kept executing. The smaller values of $T_1$ and $T_2$ in Test Configuration 3 show more clearly that all the algorithms are very sensitive both to the number of dependency relationships and the values of $T_1$ and $T_2$. Figure 29 shows that as the dependent set size increases, the average number of idle processes decreases. This happens because the probability that an idle process will accept a new message increases as the dependent set size increases. We tried to minimize this effect by requiring the following preference scheme be used when any process $H$ sends any message. The destination
process $A$ is chosen in the following order of decreasing preference:

1. $A$ is an idle process which has $B$ in its dependent set.
2. $A$ is an executing process.
3. $A$ is an idle process which does not have $B$ in its dependent set.

Figure 30 shows that as the dependent set size increases, the average number of dependency relationships increases linearly.

The results of the comparison between the volume of query traffic and the number of dependency relationships are shown in Figures 31 through 45. The data are the same for Algorithms IV and V, so they are plotted together.

Query Traffic for Algorithms IV and V, Test Configuration 1 With Deadlock

Figure 44
Query Traffic for Algorithms IV and V, Test Configuration 2 Without Deadlock
To detect deadlock, each query computation in the CMH Algorithm requires one query and one reply for each dependency relationship. As expected, Figure 31 shows that the volume of query traffic increases linearly with respect to the average number of dependency relationships when the number of processes is held constant. Figures 32 and 33 show similar results when deadlock does not exist. Algorithms I and II also exhibit similar behavior when deadlock exists. When deadlock does not exist, the volume of query traffic for all the new algorithms decreases as the number of dependency relationships increases. This can also be observed in the results from Case Study 2. This happens because the average number of idle processes also decreases as shown in Figure 29. As the number of executing processes increases, the probability that a query computation will encounter one of these executing processes also increases. With the depth-first approach of the new algorithms, when any executing process is encountered, the entire query computation is either halted or suspended. This is not the case for the
Figure 43 seems to suggest that, when deadlock exists for Algorithms IV and V, the volume of query traffic grows sub-linearly with the number of dependency relationships when the number of processes in the system is held constant. Let $A \rightarrow B$ denote the relationship of $B$ being in the dependent set of $A$. In this simulation, as the number of dependency relationships increased, the number of dependency relationships $A \rightarrow B$ for which no message was sent from $B$ to $A$ during the course of the simulation also increased. The curve may be straightened by running the simulation until, for every pair of processes $(A,B)$, $A$ has sent at least one message to $B$. 
CHAPTER 6.
Conclusions and Recommendations

6.1. Introduction

Five algorithms which use variable-length queries and replies to detect deadlock have been presented. Instead of using timeout to indicate an absence of deadlock, these algorithms use explicit messages called informs to convey the absence of deadlock to the initiator of a query computation. Algorithm I detects a deadlock if it existed when the query computation was initiated. The other algorithms also detect deadlock if deadlock conditions develop after the query computation is initiated. Proofs of correctness have been provided for the algorithms. A simulation study was conducted to compare their performance with that of the CMH Algorithm.

6.2. Conclusions

For distributed deadlock detection among communicating processes, the use of informs, cancels, and the depth-first approach has been shown to significantly reduce both the volume of query computation traffic and the number of data fields transmitted. The use of informs to notify processes directly when they are not deadlocked allows processes to discover they are not deadlocked much sooner. Our simulation results show that the average length of the query trace list was found to be very short when deadlock does not exist. In general, only a few queries were sent for a query computation, followed by an inform. Thus, the initiator learned it was not deadlocked only a few message delays after initiating the query computation. The CMH Algorithm always requires a wait at least as long as $2N$ message delays. The depth-first algorithms are also less
sensitive than the CMH Algorithm to the amount of time a process waits before initiating a query computation. By adding a priority scheme, using information from previous query computations, and using extra bit flags in the query trace list, a process can learn the identity of all minimal deadlocked sets in its reachable set with a minimum of query traffic.

For the CMH Algorithm and Algorithms I and II, query computations operate independently of each other. Each process, after becoming idle, initiates a query computation. Each query computation uses one query and one reply for each dependency relationship between processes in the reachable set of the initiator. Thus, for a system with \( N \) processes, the CMH Algorithm and Algorithms I and II may require \( O(N^2) \) queries and replies for each query computation, or a total of \( O(N^3) \) queries and replies. Algorithms III, IV and V, however, only require \( O(N^2) \) queries and replies for the highest priority query computation. Our simulation results show that for Algorithm III, the other lower priority query computations only require \( O(N) \) queries and replies. For Algorithms IV and V, the other lower priority query computations only require a constant number of queries and replies. Thus, Algorithms III, IV, and V require a total of \( O(N^2) \) queries and replies. This assumes, of course, that each process has a unique priority.

With the CMH Algorithm, it is assumed that any process which detects deadlock simply breaks the deadlock in some manner. However, some processes which detect deadlock may not be in a minimal deadlocked set. For them to try to break a deadlock is futile. Also, more than one process in a minimal deadlocked set may try to break the deadlock. This may be wasteful, especially if they are processes which must undo a relatively large amount of work. Algorithm V identifies all the minimal deadlocked sets in
the reachable set of the initiator. Therefore, only processes in minimal deadlocked sets will participate in a scheme to break the deadlock. Since the minimal deadlocked set is fully identified, an efficient method of breaking the deadlock is more likely to be found.

The CMH Algorithm requires a process which sends out $M$ queries to receive $M$ replies before sending a reply to its engager. Duplicate replies render this approach impractical and prone to false deadlock detection, although Chandy, Misra, and Haas circumvent this by assuming a completely reliable message delivery system. By requiring the new algorithms to match a reply with the corresponding query, the new algorithms are not affected by the problem of duplicate queries and replies. Lost query traffic and network partitioning remain a problem, of course.

The CMH Algorithm and Algorithm I both use storage proportional to $N$ for each process, whereas Algorithms II through V use storage proportional to $N^2$ for each process. This extra storage is required so that processes can suspend and later resume query computations. This is a requirement of the priority scheme first introduced in Algorithm III.

6.3. Recommendations

Three modifications should be incorporated into the CMH Algorithm. First, the inform should be used. This modification would require that executing processes be able to be interrupted so that they can process query computations. This would allow a process to discover it is not deadlocked quickly instead of requiring it to assume so after a lengthy wait. Second, a process which detects deadlock should initiate a second phase of deadlock detection which involves notifying all members of its reachable set. This also would be a breadth-first approach, with the notification message that deadlock was
detected being sent first to processes in the dependent set of the initiator, and then having
them pass the information along to their dependent sets, and so forth. This may prevent
some of the processes from initiating their own query computations. It would also be a
first step toward breaking deadlocks more efficiently. Third, when a process receives an
engaging query, it does not need to query its engager if its engager is a member of its
dependent set.

The algorithms proposed in this thesis should also incorporate a provision for having
the initiator notify processes in its reachable set that they form a deadlocked set. For
systems with a reliable broadcast capability, this could be a one-step process, since the
query trace list identifies all such processes.

The algorithms proposed in this thesis need to be sensitive to the network structure
when processes are clustered. That is, if inter-cluster delay times are significantly larger
than intra-cluster delay times, then the number of inter-cluster queries and replies
should be kept to an absolute minimum. Also, inter-cluster querying should be
postponed as long as possible. To accomplish this, processes would have to know the
identities of the processes in each cluster. A process could then query the processes in its
dependent set which are in the same cluster before querying processes belonging to other
clusters. Work by Goldman [Gold77], Obermarck [Ober80], and Tsai [Tsai82] may also
offer suggestions in this area.

Appendix A.

Code for Algorithm I

In the code shown below, $QTL$ represents the query trace list of the current query computation. It is assumed that the $QTL$ is variable in length and is as short as possible.

The following subprograms are used in the code shown below for Algorithm I.

**COMBIN** Procedure **COMBIN** accepts a query trace list ($QTL$) and adds to it any processes which are in the reachable set of the deadlocked calling process.

**NXTQRY** Procedure **NXTQRY** determines the next process in the dependent set which must be queried for a given query computation. It returns in its fourth argument $P_s$ a value of zero if no more processes in the dependent set need to be queried, or else the process number of the next process to receive the query.

Following is the pseudo-code for Algorithm I.

(1) When an idle process $P_r$ receives a message and begins executing, the following occurs:

\[
T := \text{clocktime};
\]
\[
\text{STATE} := \text{TRUE};
\]
\[
\text{for } F := 1 \text{ to } N \text{ do begin}
\]
\[
\text{WAIT}(F) := \text{FALSE};
\]
\[
\text{if } \text{TARGET}(F) \neq 0 \text{ then begin}
\]
\[
\text{(* Find all outstanding queries *)}
\]
\[
\text{(* Send inform to query initiator *)}
\]
\[
\text{(* Cancel all outstanding queries *)}
\]
\[
\text{(* which created tree edges when sent *)}
\]
\[
\text{if } \text{EDGETYPE}(F) \text{ then send } \text{cancel} \ C(P_r, \text{TARGET}(F), \text{LATEST}(F), P_F);\]
TARGET(F) := 0;
end;
endif

(* Remove all traces of queries received *)

ENGAGER(F) := 0;
end;

(2) When a process $P_r$ receives a query $Q(P_k, P_r, M, P_i, ..., P_j)$, the following occurs:

$T := \text{clocktime}$;  
if $(M \not> \text{LATEST}(i))$  
then begin  
$\text{LATEST}(i) := M$;  
if $\text{STATE}$  
then send $\text{inform}$ $I(P_r, P_i, M, T)$  
else begin  
if $\text{DEADLK}$  
then begin  
$\text{WAIT}(i) := \text{TRUE}$;  
(* Combine the query trace list $QTL$ *)  
(* with the reachable set of $P_r$ *)  
$\text{COMBIN}(QTL, P_r)$;  
(* Send the reply using the *)  
(* augmented query trace list *)  
send $\text{reply}$ $R(P_r, P_k, M, QTL)$;  
end  
else begin  
if $P_r$ is in the query trace list  
then begin  
if $\text{WAIT}(i)$  
then send $\text{reply}$ $R(P_r, P_k, M, P_i, ..., P_r, ..., P_j)$  
else send $\text{inform}$ $I(P_r, P_i, M, T)$;  
end  
else begin  
$\text{WAIT}(i) := \text{TRUE}$;  
(* find the next process to send a query to *)  
$\text{NXTQRY}(P_r, 0, P_k, P_s)$;  
(* if all members of the dependent set have *)  
(* been queried by $P_r$, then send a reply *)  
(* to the process which sent the query *)  
if $P_s = 0$  
then begin  
send $\text{reply}$ $R(P_r, P_k, M, P_i, ..., P_j, P_r)$;  
$\text{ENGAGER}(i) := 0$;  
end  
else begin
(* else send a query to the first process *)

(* in the dependent set *)

send query \( Q(P_r, P_s, M, P_i, ..., P_j) \); if \( P_s \) is in the query trace list then \( \text{EDGETYPE}(i) := \text{FALSE} \) else \( \text{EDGETYPE}(i) := \text{TRUE} \);

\( \text{TARGET}(i) := P_s \); \( \text{ENGAGER}(i) := P_k \); end; endif; end; endif;
end; endif;
end; endif;
endif;
endif;
endif;
end; endif;
end; endif;
end; endif;
endif;
end; endif;

(3) When a process \( P_r \), receives a reply \( R(P_k, P_r, M, P_i, ..., P_j) \), the following occurs:

if \((\text{ENGAGER}(i) = 0) \) OR \((M \neq \text{LATEST}(i)) \) OR \((\text{STATE}) \)

(* check for process not being continuously idle, *)

(* or the reply not being current *)

then null action
else begin
  if \( \text{DEADLK} \)
  then begin
      \( \text{COMBIN}(QTL, P_r) \);
      send reply \( R(P_r, \text{ENGAGER}(i), M, P_i, ..., P_j) \);
      \( \text{TARGET}(i) := 0 \);
      \( \text{ENGAGER}(i) := 0 \);
  end
  else begin
    (* find the first member of the dependent set *)
    (* which has not been queried *)

    \( \text{NXTQRY}(P_r, P_k, \text{ENGAGER}(i), P_s) \);

    if \( P_s = 0 \)

    (* \( P_r \) has already queried all *)
    (* members of its dependent set *)

    then begin
      if \( P_r = P_i \)

      (* \( P_r \) is the query initiator, so declare deadlock *)

      then DECLARE DEADLOCK for all processes \( P_i, ..., P_j \)

      else begin
        (* send a reply to the process *)
        (* which originally sent the query *)

        send reply \( R(P_r, \text{ENGAGER}(i), M, P_i, ..., P_j) \);
TARGET(i) := 0;
ENGAGER(i) := 0;
end;
endif
end
else begin
(* query next process in the dependent set *)
(* which needs to be queried *)
send query Q(P_r, P_s, M, P_i, ..., P_j);
if P_s is in the query trace list
then EDGETYPE(i) := FALSE
else EDGETYPE(i) := TRUE;
TARGET(i) := P_s;
end;
dendif
end;
dendif
end;
dendif

(4) When a process P_r receives a cancel C(P_k, P_r, M, P_i), the following occurs:

if (TARGET(i) ≠ 0) AND (M = LATEST(i))
(* if an outstanding query exists with *)
(* the same initiator and matching *)
(* sequence number, and the query created *)
(* a tree edge when it was sent, then *)
(* send the cancel on *)
then begin
send cancel C(P_r, TARGET(i), M, P_i);
(* delete references to the query being cancelled *)
TARGET(i) := 0;
ENGAGER(i) := 0
end
endif

(5) When a process P_r receives an inform I(P_k, P_r, T), the following occurs:

(* The process knows it isn't deadlocked yet, *)
(* so it should use the timestamp field T *)
(* in the inform to update the time used in *)
(* determining when to initiate another query. *)

if T ≤ LASTTIME
then LASTTIME := T
endif

(6) When a process sends a message, no query traffic action is required.
(7) When an executing process $P_k$ changes state to idle, the following occurs:

\[
STATE := FALSE \\
LASTTIME := \text{clocktime}
\]

(* array \textit{DEPENDENT} shows which processes *)

(* are in the dependent set of $P_k$ *)

(8) When a process $P_i$ becomes idle for time $T_1$ since becoming idle or since last receiving an \textit{inform}, the following occurs:

\[
\text{WAIT}(i) := \text{TRUE}; \\
\text{LATEST}(i) := \text{LATEST}(i) + 1;
\]

(* find first process in the dependent set *)

\[
\text{NXTQRY}(P_i, 0, 0, P_s);
\]

if $P_s = 0$

(* check for an empty dependent set *)

then \text{TERMINATE THE PROCESS}

else begin

(* Initiate a new query computation *)

(* Send a query to the first process *)

(* $P_s$ in the dependent set *)

send \textit{query} $Q(P_i, P_s, \text{LATEST}(i), P_i)$;

\[
\text{TARGET}(i) := P_s; \\
\text{ENGAGER}(i) := P_i; \\
\text{EDGETYPE}(i) := \text{TRUE};
\]

end;
endif
Appendix B.

Code for Algorithm II

In the code shown below, $QTL$ represents the query trace list of the current query computation. It is assumed that the $QTL$ is variable in length and is always as short as possible. The following subprograms are used in the code shown below for Algorithm II.

COMBIN Procedure **COMBIN** accepts a query trace list ($QTL$) and adds to it any process and its sequence number which is in the reachable set of the deadlocked calling process.

NXTQRY Procedure **NXTQRY** determines the next process in the dependent set which must be queried for a given query computation. It returns in its fourth argument $P_S$ a value of zero if no more processes in the dependent set need to be queried, or else the process number of the next process to receive the query.

SEQCHK Procedure **SEQCHK** accepts a query trace list and a process id. It returns the sequence number associated with the process id. The value zero is returned if the process is not in the query trace list or if it actually has a sequence number of zero. A process appears in a query trace list with a sequence number of zero if it was added by procedure **COMBIN** as a member of some deadlocked set.

SIG Procedure **SIG** accepts a one-dimensional array which holds a query trace list. **SIG** returns as a query trace list the portion of the array which is non-zero (i.e., the significant portion).
**CHP**

Procedure CHP accepts a query trace list and returns a query trace list which has been shortened so that the calling process is the last process in the query trace list.

**LNG**

Procedure LNG accepts a query trace list and returns its length. Each process id/sequence number pair counts as length 2.

Following is the pseudo-code for Algorithm II.

(1) When an idle process $P_r$ receives a message from process $P_k$ and begins executing, the following occurs:

\[
T := \text{clocktime};
\]

\[
STATE := \text{TRUE};
\]

for $F := 1$ to $N$ do

\[
WAIT(F) := \text{FALSE};
\]

if $TARGET(r) \neq 0$

then begin

if $EDGETYPE(r)$

then begin

send $\text{cancel C}(P_r, TARGET(r), \text{SIG (LATEST}(r, *))$;

(* delete the query initiated by $P_r$ *)

\[
EDGETYPE(r) := \text{FALSE};
\]

end;

endif

$TARGET(r) := 0$;

$LATEST(r, *) := 0$;

$ENGAGER(r) := 0$;

$TIMES(r) := 0$;

end;

endif

for $F := 1$ to $N$ do

begin

(" for all queries remaining, send an inform ")

(" to the query initiator ")

(" and cancel any outstanding queries ")

if $ENGAGER(F) \neq 0$

then begin

$TIMES(F) := T$;

send $\text{inform I}(P_r, P_F, LATEST(F, *))$;

(* chop off the query trace list *)

(* so $P_r$ is the last process *)
\( LATEST(F, *) := CHP \ (LATEST(F, *)) \)
if \( TARGET(F) \neq 0 \)
then begin
if \( EDGETYPE(F) \)
then begin
send cancel \( C(P_r, TARGET(F), SIG \ (LATEST(F, *)) \));
\( EDGETYPE(F) := \) FALSE;
end;
endif
\( TARGET(F) := 0; \)
end;
endif
\( end; \)
end;
endif
\( end; \)
endif
\( end; \)
\( end; \)
\( end; \)

(2) When a process \( P_r \) receives a query \( Q(P_k, P_r, T, P_i, M_i, ..., P_j, M_j) \), the following occurs:

\(*\) ensure the query is valid \(*\)

\( FLAG := 0; \)
if \( ENGAGER(i) = 0 \)
then \( FLAG := 2; \)
endif
\( v := LNG \ (QTL); \)
\( vv := LNG \ (SIG \ (LATEST(i, *)); \)
\( l := 0; \)
while \((FLAG \neq 0) \) AND \((l \cdot v) \) AND \((l \cdot vv) \) do
begin
\( l := l+2; \)
if \( QTL(l) > LATEST(i, l) \)
then \( FLAG := 1 \)
else if \( QTL(l) \cdot LATEST(i, l) \)
then \( FLAG := -1; \)
endif
end;
if \( FLAG \neq 0 \)
then begin
if \( STATE \)
then begin
if \( P_r \) is already in the \( QTL \)
then discard the \( query \)
else begin
\(*\) store a copy of the \( query \) \(*\)
\(*\) with \( P_r \) added to the query trace list \(*\)
\( LATEST(i, *) := QTL; \)
\( LATEST(i, v+1) := P_r; \)
end;
\[ LATEST(i, v+2) := 1; \]
\[ ENGAGER(i) := P_k; \]
\[ T := \text{clocktime}; \]
\[ TIMES(i) := T; \]

(* since \( P_r \) is executing, send an inform *)
(* to the query computation initiator *)

send inform \( I(P_r, P_i, LATEST(i,2), T) \);

else begin
endif
end

endif else begin
if \( DEADLK \)
then begin
(* if \( P_r \) is deadlocked, combine the reachable set *)
(* with the query trace list and send a reply *)

if \( P_r \) is not in the \( QTL \)
then \( \text{COMBIN}(QTL, P_r) \);
endif

send reply \( R(P_r, P_k, T, QTL) \);
end
else begin

Appendix C.

Code for Algorithm III

In the code shown below, QTL represents the query trace list of the current query computation. It is assumed that the QTL is variable in length and is always as short as possible. The following subprograms are used in the code shown below for Algorithm III.

**COMBIN** Procedure COMBIN accepts a query trace list (QTL) and adds to it any process and its sequence number which is in the reachable set of the deadlocked calling process.

**NXTQRY** Procedure NXTQRY determines the next process in the dependent set which must be queried for a given query computation. It returns in its fourth argument $P_S$ a value of zero if no more processes in the dependent set need to be queried, or else the process number of the next process to receive the query.

**SEQCHK** Procedure SEQCHK accepts a query trace list and a process id. It returns the sequence number associated with the process id. The value zero is returned if the process is not in the query trace list or if it actually has a sequence number of zero. A process appears in a query trace list with a sequence number of zero if it was added by procedure COMBIN as a member of some deadlocked set.

**URGENT** Function URGENT determines the urgency of a query based on its priority and the number of replies and cancels received by the process holding the query since the query was received.
SIG  Procedure SIG accepts a one-dimensional array which holds a query trace list. SIG returns as a query trace list the portion of the array which is non-zero (ie the significant portion).

CHP  Procedure CHP accepts a query trace list and returns a query trace list which has been shortened so that the calling process is the last process in the query trace list.

LNG  Procedure LNG accepts a query trace list and returns its length. Each process id/sequence number pair counts as length 2.

Following is the pseudo-code for Algorithm III.

(1) When an idle process \( P_r \) receives a message from process \( P_k \) and begins executing, the following occurs:

\[
T := \text{clocktime};  \quad \text{(* process changes state to executing *)}
\]

\[
STATE := \text{TRUE};
\]

for \( F := 1 \) to \( N \) do

begin

\[
\text{WAIT}(F) := \text{FALSE};
\]

\[
\text{STARVE}(F) := 0;
\]

end;

if \( \text{ENGAGER}(r) \neq 0 \)
then begin

if \( \text{TARGET}(r) \neq 0 \)
then begin

if \( \text{EDGETYPE}(r) \)
then begin

send \text{cancel C}(P_r, \text{TARGET}(r), \text{SIG} \{\text{LATEST}(r, *)\});

\( \text{EDGETYPE}(r) := \text{FALSE}; \)

end;

endif

\( \text{TARGET}(r) := 0; \)

end;

endif

\( \text{LATEST}(r, *) := 0; \)

\( \text{ENGAGER}(r) := 0; \)
TIMES(r) := 0;
PRIOR(r) := 0;
LASTREP(r) := 0;
end;
endif
for F := 1 to N do
begin
(* for all queries remaining, send an inform *)
(* to the query initiator, *)
(* and cancel any outstanding queries *)
if ENGAGER(F) \neq 0
then begin

TIMES(F) := T;
LASTREP(F) := 0;
ifr \neq F
then send inform l(P_r, P_F, LATEST(F,2), T);
endif
(* chop off the query trace list *)
(* so P_r is the last process *)
LATEST(F, *) := CHP (LATEST(F, *));
if TARGET(F) \neq 0
then begin
if EDGETYPE(F)
then begin
send cancel C(P_r, TARGET(F), SIG (LATEST(F, *)));
EDGETYPE(F) := FALSE;
end;
endif
TARGET(F) := 0;
end;
endif
end;
end;
end;

(2) When a process \(P_r\) receives a query \(Q(P_k, P_r, U, T, P_i, M_i, \ldots, P_j, M_j)\), the following occurs:

(* ensure the query is valid *)

FLAG := 0;
if ENGAGER(i) = 0
then FLAG := 2;
endif
v := LNG (QTL);
wv := LNG (SIG (LATEST(i, *)));
l := 0;
while (FLAG = 0) AND (l < v) AND (l < wv) do
begin
\[ l := l + 2; \]
if \( QTL(l) > LATEST(i, l) \)
then \( FLAG := 1 \)
else if \( QTL(l) < LATEST(i, l) \)
then \( FLAG := -1; \)
endif
endif
end;
if \( FLAG = 1 \)
then begin
\( (*) \text{ send a cancel first to stop the old query } (*) \)
if \( TARGET(i) \neq 0 \)
then begin
if \( EDGETYPE(i) \)
then begin
send cancel \( C(P, TARGET(i), CHP \ (LATEST(i, *)) \));
\( EDGETYPE := \text{FALSE}; \)
end;
endif
\( TARGET(i) := 0; \)
end;
endif
\( (*) \text{ wipe out the old query } (*) \)
\( LATEST(i, *) := 0; \)

        else EDGETYPE($F$) := TRUE;
      end;
    endif
  end;
end;
Appendix D.

Code for Algorithm IV

In the code shown below, \( QTL \) represents the query trace list of the current query computation. It is assumed that the \( QTL \) is variable in length and is always as short as possible. The following subprograms are used in the code shown below for Algorithm IV.

**COMBIN** Procedure COMBIN accepts a query trace list \( (QTL) \) and adds to it any process and its sequence number which is in the reachable set of the deadlocked calling process.

**NXTQRY** Procedure NXTQRY determines the next process in the dependent set which must be queried for a given query computation. It returns in its fourth argument \( P_S \) a value of zero if no more processes in the dependent set need to be queried, or else the process number of the next process to receive the query.

**SEQCHK** Procedure SEQCHK accepts a query trace list and a process id. It returns the sequence number associated with the process id. The value zero is returned if the process is not in the query trace list.

**URGENT** Function URGENT determines the urgency of a query based on its priority and the number of replies and cancels received by the process holding the query since the query was received.

**UPDATR** Function UPDATR updates the arrays \( \text{VERIFIED} \) and \( \text{RECENT} \) whenever a query or reply is received. The inputs to UPDATR are a query trace list, the calling process (which just received the query or reply).
and the identity of the process which sent the query or reply.

**CHKRPY** Procedure **CHKRPY** is called by a process to check to see if a reply can be sent for any held query computations. It is possible that information learned from another query computation can change the status of a held query computation so that the processes in the dependent set remaining to be queried no longer need to be queried, and hence a reply can be sent. **CHKRPY** takes care of sending the reply.

**SIG** Procedure **SIG** accepts a one-dimensional array which holds a query trace list. **SIG** returns as a query trace list the portion of the array which is non-zero (i.e., the significant portion).

**CHP** Procedure **CHP** accepts a query trace list and returns a query trace list which has been shortened so that the calling process is the last process in the query trace list.

**LNG** Procedure **LNG** accepts a query trace list and returns its length. Each process id/sequence number pair counts as length 2.

Following is the pseudo-code for Algorithm IV.

(1) When an idle process \(P_i\) receives a message from process \(P_k\) and begins executing, the following occurs:

\[
\begin{align*}

Appendix E.

Code for Algorithm V

In the code shown below, \( QTl \) represents the query trace list of the current query computation. It is assumed that the \( QTl \) is variable in length and is always as short as possible. The following subprograms are used in the code shown below for Algorithm V.

COMBIN  Procedure COMBIN accepts a query trace list (\( QTl \)) and adds to it any process (together with its sequence number and boolean flag) which is in the reachable set of the deadlocked calling process.

NXTQRY  Procedure NXTQRY determines the next process in the dependent set which must be queried for a given query computation. It returns in its fourth argument \( P_5 \) a value of zero if no more processes in the dependent set need to be queried, or else the process number of the next process to receive the query.

SEQCHK  Procedure SEQCHK accepts a query trace list and a process id. It returns the sequence number associated with the process id. The value zero is returned if the process is not in the query trace list.

URGENT  Function URGENT determines the urgency of a query based on its priority and the number of replies and cancels received by the process holding the query since the query was received.

UPDATR  Function UPDATR updates the arrays VERIFIED and RECENT whenever a query or reply is received. The inputs to UPDATR are a query trace list, the calling process (which just received the query or reply).
and the identity of the process which sent the query or reply.

**REPUPD** Procedure **REPUPD**, when called by $P_r$, updates the array $LATEST(r, *)$ with information from the query trace list of a reply received by $P_r$. The flags of any process up to and including $P_r$ are changed to reflect the way they are in the query trace list. The flag of any process which appears after $P_r$ is not changed. Any process which appears in the query trace list but not in the array $LATEST(r, *)$ is added, together with its sequence number and flag as they appear in the query trace list.

**CHKRPY** Procedure **CHKRPY** is called by a process to check to see if a reply can be sent for any held query computations. It is possible that information learned from another query computation can change the status of a held query computation so that the processes in the dependent set remaining to be queried no longer need to be queried, and hence a reply can be sent. **CHKRPY** takes care of sending the reply.

**FGFIXR** Procedure **FGFIXR** accepts as input a query trace list, the calling process $P_r$, and the array $LATEST(r, *)$. It is called by a process which knows it is deadlocked and is preparing a reply to send to its engager. The deadlocked process first calls **COMBIN** to add the processes in its reachable set to the query trace list, and then it calls **FGFIXR** to set the flags correctly in the query trace list. **FGFIXR** finds the first process in the query trace list which is also in the reachable set of $P_r$. The boolean flags for all processes occurring after this process in the query trace list are set to TRUE.
**FGCHKR** Procedure **FGCHKR** accepts as input a query trace list, the calling process $P_r$, and the array $DEPENDENT$ belonging to $P_r$. It is called by a process which has just received an engaging query. The process $P_r$ calls **FGCHKR** to set the flags correctly in the query trace list. **FGCHKR** finds the first process in the query trace list which is also in the dependent set of $P_r$. The boolean flags for all processes occurring after this process in the query trace list are set to TRUE.

**CHKMDS** Procedure **CHKMDS** accepts as input a query trace list and the calling process $P_r$. It is called by $P_r$ when it has just received its last reply. The process $P_r$ calls **CHKMDS** to set the flags correctly in the query trace list and to check for membership in a minimal deadlocked set. **CHKMDS** first finds the process $P_r$ in the query trace list. If its boolean flag is FALSE (−), then $P_r$ is a member of a minimal deadlocked set. If so, then all boolean flags preceding the one for process $P_r$ are set to TRUE (+), and the ones following it are set to show the pattern (−−−+).

**SIG** Procedure **SIG** accepts a one-dimensional array which holds a query trace list. **SIG** returns as a query trace list the portion of the array which is non-zero (ie the significant portion).

**CHP** Procedure **CHP** accepts a query trace list and returns a query trace list which has been shortened so that the calling process is the last process in the query trace list.

**LNG** Procedure **LNG** accepts a query trace list and returns its length. Each process id/sequence number pair counts as length 2.
Procedure ABS is just the standard function for absolute value.

Following is the pseudo-code for Algorithm V.

1. When an idle process $P_r$ receives a message from process $P_k$ and begins executing, the following occurs:

   $T := \text{clocktime}$; 
   (* process changes state to executing *)

   $STATE := \text{TRUE}$;
   for $F := 1$ to $N$ do
      $\text{STARVE}(F) := 0$;
      $RECENT(r) := \text{RECENT}(r) + 1$;
      $\text{VERIFIED}(r) := \text{RECENT}(r)$;
      if $\text{ENGAGER}(r) \neq 0$
         then begin
            if $\text{TARGET}(r) \neq 0$
               (* delete the query initiated by $P_r$ *)
               then begin
                  if $\text{EDGETYPE}(r)$
                     then begin
                        send $\text{cancel } \text{C}(P_r, \text{TARGET}(r), \text{SIG}(\text{LATEST}(r,*)))$;
                        (* trailing zeros were truncated *)
                        $\text{EDGETYPE}(r) := \text{FALSE}$;
                        end;
                     endif
               endif
               $\text{TARGET}(r) := 0$;
            endif
         endif
   end;
   for $F := 1$ to $N$ do
      begin
         (* for all queries remaining, send an inform *)
         (* to the query initiator, *)
         (* and cancel any outstanding queries *)
         if $\text{ENGAGER}(F) \neq 0$
            then begin
               $\text{TIMES}(F) := T$;
               $\text{LASTREP}(F) := 0$;
               if $r \neq F$
                  then send $\text{inform } l(P_r, P_F, \text{LATEST}(F,2), T)$;
            endif
(*) chop off the query trace list *)

(* so Pr is the last process *)

\[\text{LATEST}(F, *) := \text{CHP} (\text{LATEST}(F, *))\];
\[v := \text{LNG} (\text{SIG} (\text{LATEST}(F, *))\];
\[\text{LATEST}(F, v) := -\text{ABS} (\text{LATEST}(F, v))\];
if \(\text{TARGET}(F) \neq 0\)
then begin
  if \(\text{EDGETYPE}(F)\)
  then begin

endif

(9) When a process $P_i$ becomes idle for time $T_2$ (where $T_2 < T_1$) since changing state from executing to idle, the following occurs:

**CHKRPY:**

$W := 0$;

for $F := 1$ to $N$ do
    if ($ENGAGER(F) \neq 0$ AND ($PRIOR(F) \neq W$))
        then $W := PRIOR(F)$;
    endif
for $F := 1$ to $N$ do
    begin
        if $ENGAGER(F) \neq 0$
            then begin
                if ($URGENT(F) \leq W$) AND ($TARGET(F) = 0$)
                    then begin
                        $NXTQRY(P, LASTREP(F), ENGAGER(F), P_S)$;
                        $QTL := LATEST(F, *)$;
                        $T := TIMES(F)$;
                        send query Q(P, PS, PRIOR(F), T, QTL);
                        $TARGET(F) := PS$;
                        if $P_S$ is already in the $QTL$
                            then $EDGETYPE(F) := FALSE$
                        else $EDGETYPE(F) := TRUE$
                    end;
                endif
            end;
        endif
    end;
end;
Appendix F.

Definitions

Deadlock: A nonempty set of processes $S$ is *deadlocked* if and only if

1) All processes in $S$ are idle;
2) The dependent set of every process in $S$ is a subset of $S$; and
3) There are no messages in transit between processes in $S$.

A process is *deadlocked* if and only if it belongs to some deadlocked set.

Minimal deadlocked set

A minimal deadlocked set is a deadlocked set which is either strongly connected or which is a strongly connected component [AhHo74, page 189].

Engaging query and Engager:

When a process $P_j$ receives a query from a process $P_i$ belonging to a query computation that $P_j$ has not seen before (i.e. $P_j$ is not in the QTL), then the query is called an *engaging query*, and process $P_i$ is called the *engager*.

Engager chain:

For a particular query computation, the *engager chain* consists of the query computation initiator and all processes $P_k$ such that the following conditions hold:

1) $P_k$ is in the dependent set of some process $P_j$,
2) $P_j$ is in the engager chain,
3) $P_j$ sent an engaging query to $P_k$,

4) $P_j$ has not executed since sending the query to $P_k$, and

5) $P_k$ has received, but not yet replied to the engaging query.

Each query computation has only one engager chain. If, for a particular query computation, process $P$ is a member of the engager chain, then the engager chain of $P$ consists of the query computation initiator and all processes in the engager chain up to but not including $P$.

Current query computation:

A query sent from process $P$ to process $Q$ belongs to the current query computation if and only if

1) $P$ was a member of the engager chain for that query computation when it sent the query, and

2) Neither $P$ nor any process on the engager chain of $P$ has executed since $P$ sent the query.

A reply sent from process $Q$ to process $P$ belongs to the current query computation if and only if the corresponding query sent from $P$ to $Q$ belongs to the query computation.

Target process: When a process $P_j$ receives a query (not necessarily an engaging query) from a process $P_i$, then process $P_j$ is the target process for that query.

Reachable set: Consider a directed graph in which nodes represent processes. A directed edge from $A$ to $B$ means that process $A$ is waiting to
receive a message from process B, and therefore B is in the dependent set of A. If, for some process C, there is a directed path from A to C, then C is said to be reachable from A, and C is in the reachable set of A.

Observation 1 If P is in the reachable set of Q, and Q is in the reachable set of R, then P is in the reachable set of R.

Observation 2 If P is in the reachable set of Q, then the size of the reachable set of Q is greater than or equal to the size of the reachable set of P.
Appendix G.

Examples for Deadlock Detection Algorithms

This appendix contains examples showing how the five new algorithms and the CMH algorithm detect deadlock. The first example shows the primary differences between the algorithms, although it does not show the use of the cancel. The second example shows in greater detail the way in which Algorithm V detects the minimal deadlocked sets.

Example 1

The first example shows how the different algorithms work when encountering an executing process and how they then go on to detect deadlock once it exists. The initial state of the system is shown in Figure 46. Process D is executing and is in the dependent sets of processes B and E. The primary events will occur in the following order:

1. Process A will initiate a query computation.
2. Process B will initiate a query computation.
3. Process D will become idle and wait for processes B and E (see Figure 47).
4. Process D will initiate a query computation.

A plausible sequence of events showing how the deadlock detection algorithms work within this scenario is shown for each algorithm.

![Figure 46](image)

Initial Configuration without Deadlock
Algorithm CMH

The CMH Algorithm is shown first so the new algorithms may be compared to it.

Time   Action
(1)   A initiates a query computation
      A sends Q(A,1,A,B) to B
      A sets its NUM(A) to 1
(2)   B receives Q(A,1,A,B) and is idle, so
      B sends Q(A,1,B,C) to C
      B sends Q(A,1,B,D) to D
      B sends Q(A,1,B,E) to E
      B sets its NUM(A) to 3
(3)   C receives Q(A,1,B,C) and is idle, so
      C sends Q(A,1,C,B) to B
      C sets its NUM(A) to 1
(4)   D receives Q(A,1,B,D) and is executing, so
      D discards the query
(5)   E receives Q(A,1,B,E) and is idle, so
      E sends Q(A,1,E,B) to B
      E sends Q(A,1,E,D) to D
      E sets its NUM(A) to 2
(6)   B receives Q(A,1,C,B) and is still idle, so
      B sends R(A,1,B,C) to C
(7)   B receives Q(A,1,E,B) and is still idle, so
      B sends R(A,1,B,E) to E
(8)   D receives Q(A,1,E,D) and is executing, so
      D discards the query
(9) C receives R (A,1,B,C)
   C decrements its NUM(A) by 1
   C's NUM(A) is now 0, so
   C sends R (A,1,C,B) to B

(10) E receives R (A,1,B,E) and is still idle, so
     E decrements its NUM(A) by 1
     E's NUM(A) is now 1, so E waits for another reply

(11) B receives R (A,1,C,B) and is still idle, so
     B decrements its NUM(A) by 1
     B's NUM(A) is now 2, so B waits for two more replies

(12) B initiates a query computation
     B sends Q (B,1,B,C) to C
     B sends Q (B,1,B,D) to D
     B sends Q (B,1,B,E) to E
     B sets its NUM(B) to 3

(13) C receives Q (B,1,B,C) and is idle, so
     C sends Q (B,1,C,B) to B
     C sets its NUM(B) to 1

(14) D receives Q (B,1,B,D) and is executing, so
     D discards the query

(15) E receives Q (B,1,B,E) and is idle, so
     E sends Q (B,1,E,B) to B
     E sends Q (B,1,E,D) to D
     E sets its NUM(B) to 2

(16) B receives Q (B,1,C,B) and is still idle, so
     B sends R (B,1,B,C) to C

(17) B receives Q (B,1,E,B) and is still idle, so
     B sends R (B,1,B,E) to E

(18) D receives Q (B,1,E,D) and is executing, so
     D discards the query

(19) C receives R (B,1,B,C)
     C decrements its NUM(B) by 1
     C's NUM(B) is now 0, so
     C sends R (B,1,C,B) to B

(20) E receives R (B,1,B,E) and is still idle, so
     E decrements its NUM(B) by 1
     E's NUM(B) is now 1, so E waits for another reply

(21) B receives R (B,1,C,B) and is still idle, so
     B decrements its NUM(B) by 1
B’s $NUM(B)$ is now 2, so B waits for two more replies

(22) D becomes idle and waits for processes B and E (see Figure 47)

(23) D initiates a query computation
    D sends $Q(D,1,D,B)$ to B
    D sends $Q(D,1,D,E)$ to E
    D sets its $NUM(D)$ to 2

(24) B receives $Q(D,1,D,B)$ and is idle, so
    B sends $Q(D,1,B,C)$ to C
    B sends $Q(D,1,B,D)$ to D
    B sends $Q(D,1,B,E)$ to E
    B sets its $NUM(D)$ to 3

(25) E receives $Q(D,1,D,E)$
    E sends $Q(D,1,E,B)$ to B
    E sends $Q(D,1,E,D)$ to D
    E sets its $NUM(D)$ to 2

(26) C receives $Q(D,1,B,C)$
    C sends $Q(D,1,C,B)$ to B
    C sets its $NUM(D)$ to 1

(27) D receives $Q(D,1,B,D)$ and is still idle, so
    D sends $R(D,1,D,B)$ to B

(28) E receives $Q(D,1,B,E)$ and is still idle, so
    E sends $R(D,1,E,B)$ to B

(29) B receives $Q(D,1,E,B)$ and is still idle, so
    B sends $R(D,1,B,E)$ to E

(30) D receives $Q(D,1,E,D)$ and is still idle, so
    D sends $R(D,1,D,E)$ to E

(31) B receives $Q(D,1,C,B)$ and is still idle, so
    B sends $R(D,1,B,C)$ to C

(32) B receives $R(D,1,D,B)$ and is still idle, so
    B decrements its $NUM(D)$ by 1
    B’s $NUM(D)$ is now 2, so B waits for 2 more replies

(33) B receives $R(D,1,E,B)$ and is still idle, so
    B decrements its $NUM(D)$ by 1
    B’s $NUM(D)$ is now 1, so B waits for 1 more reply

(34) E receives $R(D,1,B,E)$ and is still idle, so
    E decrements its $NUM(D)$ by 1
    E’s $NUM(D)$ is now 1, so E waits for 1 more reply
(35) E receives R (D,1,D,E) and is still idle, so
E decrements its NUM(D) by 1
E's NUM(D) is now 0, so
E sends R (D,1,E,D) to D

(36) C receives R (D,1,B,C) and is still idle, so
C decrements its NUM(D) by 1
C's NUM(D) is now 0, so
C sends R (D,1,C,B) to B

(37) D receives R (D,1,E,D) and is still idle, so
D decrements its NUM(D) by 1
D's NUM(D) is now 1, so D waits for 1 more reply

(38) B receives R (D,1,C,B) and is still idle, so
B decrements its NUM(D) by 1
B's NUM(D) is now 0, so
B sends R (D,1,B,D) to D

(39) D receives R (D,1,B,D) and is still idle, so
D decrements its NUM(D) by 1
D's NUM(D) is now 0, so
D now declares DEADLOCK

Algorithm I

Algorithm I introduces the concept of depth-first querying, cancels, and informs. A query computation terminates when encountering an executing process. The query trace list shows the processes in the reachable set of the initiator of the query computation.

Time Action
(1) A initiates a query computation
A sends Q (A,B,1,A) to B

(2) B receives Q (A,B,1,A) and is idle, so
B sends Q (B,C,1,A,B) to C

(3) C receives Q (B,C,1,A,B) and is idle, so
C sends R (C,B,1,A,B,C) to B

(4) B receives R (C,B,1,A,B,C) and is still idle, so
B sends Q (B,D,1,A,B,C) to D
(5) D receives \(Q(B,D,1,A,B,C)\) and is executing, so
D sends \(I(D,A,1,\text{timestamp})\) to A
D discards the query

(6) B initiates a query computation
B sends \(Q(B,C,1,B)\) to C

(7) C receives \(Q(B,C,1,B)\) and is idle, so
C sends \(R(C,B,1,B,C)\) to B

(8) B receives \(R(C,B,1,B,C)\) and is still idle, so
B sends \(Q(B,D,1,B,C)\) to D

(9) D receives \(Q(B,D,1,B,C)\) and is executing, so
D sends \(I(D,B,1,\text{timestamp})\) to B
D discards the query

(10) D becomes idle and waits for processes B and E (see Figure 47)

(11) D initiates a query computation
D sends \(Q(D,B,1,D)\) to B

(12) B receives \(Q(D,B,1,D)\) and is idle, so
B sends \(Q(B,C,1,D,B)\) to C

(13) C receives \(Q(B,C,1,D,B)\) and is idle, so
C sends \(R(C,B,1,D,B,C)\) to B

(14) B receives \(R(C,B,1,D,B,C)\) and is still idle, so
B sends \(Q(B,E,1,D,B,C)\) to E

(15) E receives \(Q(B,E,1,D,B,C)\) and is idle, so
E sends \(Q(E,D,1,D,B,C,E)\) to D

(16) D receives \(Q(E,D,1,D,B,C,E)\) and is still idle, so
D sends \(R(D,E,1,D,B,C,E)\) to E

(17) E receives \(R(D,E,1,D,B,C,E)\) and is still idle, so
E sends \(R(E,B,1,D,B,C,E)\) to B

(18) B receives \(R(E,B,1,D,B,C,E)\) and is still idle, so
B sends \(R(B,D,1,D,B,C,E)\) to D

(19) D receives \(R(B,D,1,D,B,C,E)\) and is still idle, so
D sends \(Q(D,E,1,D,B,C,E)\) to E

(20) E receives \(Q(D,E,1,D,B,C,E)\) and is still idle, so
E sends \(R(E,D,1,D,B,C,E)\) to D

(21) D receives \(R(E,D,1,D,B,C,E)\) and is still idle, so
D declares DEADLOCK for processes D, B, C, and E
Algorithm II

Algorithm II introduces the concept of allowing an executing process to hold a query computation and then restart it once the process becomes idle. Each process in the query trace list has its own sequence number.

<table>
<thead>
<tr>
<th>Time</th>
<th>Action</th>
</tr>
</thead>
</table>
| 1   | A initiates a query computation  
    | A sends Q(A,B,t,A,1) to B |
| 2   | B receives Q(A,B,t,A,1) and is idle, so  
    | B sends Q(B,C,t,A,1,B,1) to C |
| 3   | C receives Q(B,C,t,A,1,B,1) and is idle, so  
    | C sends R(C,B,t,A,1,B,1,C,1) to B |
| 4   | B receives R(C,B,t,A,1,B,1,C,1) and is still idle, so  
    | B sends Q(B,D,t,A,1,B,1,C,1) to D |
| 5   | D receives Q(B,D,t,A,1,B,1,C,1) and is executing, so  
    | D sends I(D,A,1,timestamp) to A  
    | D holds the query computation |
| 6   | B initiates a query computation  
    | B sends Q(B,C,t,B,1) to C |
| 7   | C receives Q(B,C,t,B,1) and is idle, so  
    | C sends R(C,B,t,B,1,C,1) to B |
| 8   | B receives R(C,B,t,B,1,C,1) and is still idle, so  
    | B sends Q(B,D,t,B,1,C,1) to D |
| 9   | D receives Q(B,D,t,B,1,C,1) and is executing, so  
    | D sends I(D,B,1,timestamp) to B  
    | D holds the query computation |
| 10  | D becomes idle and waits for processes B and E (see Figure 47)  
    | D is holding two query computations  
    | D sends Q(D,E,t,A,1,B,1,C,1,D,2) to E  
    | D sends Q(D,E,t,B,1,C,1,D,2) to E |
| 11  | E receives Q(D,E,t,A,1,B,1,C,1,D,2) and is idle, so  
    | E sends Q(E,B,t,A,1,B,1,C,1,D,2,E,1) to B |
| 12  | E receives Q(D,E,t,B,1,C,1,D,2) and is idle, so  
    | E sends Q(E,B,t,B,1,C,1,D,2,E,1) to B |
(13) B receives Q \((E,B,t,A,1,B,1,C,1,D,2,E,1)\) and is still idle, so B sends R \((B,E,t,A,1,B,1,C,1,D,2,E,1)\) to E

(14) B receives Q \((E,B,t,B,1,C,1,D,2,E,1)\) and is still idle, so B sends R \((B,E,t,B,1,C,1,D,2,E,1)\) to E

(15) E receives R \((B,E,t,A,1,B,1,C,1,D,2,E,1)\) and is still idle, so E sends R \((E,D,t,A,1,B,1,C,1,D,2,E,1)\) to D

(16) E receives R \((B,E,t,B,1,C,1,D,2,E,1)\) and is still idle, so E sends R \((E,D,t,B,1,C,1,D,2,E,1)\) to D

(17) D receives R \((E,D,t,A,1,B,1,C,1,D,2,E,1)\) and is still idle, so D sends R \((D,B,t,A,1,B,1,C,1,D,2,E,1)\) to B

(18) D receives R \((E,D,t,B,1,C,1,D,2,E,1)\) and is still idle, so D sends R \((D,B,t,B,1,C,1,D,2,E,1)\) to B

(19) B receives R \((D,B,t,A,1,B,1,C,1,D,2,E,1)\) and is still idle, so B sends Q \((B,E,t,A,1,B,1,C,1,D,2,E,1)\) to E

(20) B receives R \((D,B,t,B,1,C,1,D,2,E,1)\) and is still idle, so B sends Q \((B,E,t,B,1,C,1,D,2,E,1)\) to E

(21) E receives Q \((B,E,t,A,1,B,1,C,1,D,2,E,1)\) and is still idle, so E sends R \((E,B,t,A,1,B,1,C,1,D,2,E,1)\) to B

(22) E receives Q \((B,E,t,B,1,C,1,D,2,E,1)\) and is still idle, so E sends R \((E,B,t,B,1,C,1,D,2,E,1)\) to B

(23) B receives R \((E,B,t,A,1,B,1,C,1,D,2,E,1)\) and is still idle, so B sends R \((B,A,t,A,1,B,1,C,1,D,2,E,1)\) to A

(24) B receives R \((E,B,t,B,1,C,1,D,2,E,1)\) and is still idle, so B declares DEADLOCK for processes B, C, D, and E

(25) A receives R \((B,A,t,A,1,B,1,C,1,D,2,E,1)\) and is still idle, so A declares DEADLOCK for processes A, B, C, D, and E

(26) D initiates a query computation
    D sends Q \((D,B,t,D,1)\) to B

(27) B receives Q \((D,B,t,D,1)\) and is idle, so B sends Q \((B,C,t,D,1,B,1)\) to C

(28) C receives Q \((B,C,t,D,1,B,1)\) and is idle, so C sends R \((C,B,t,D,1,B,1,C,1)\) to B

(29) B receives R \((C,B,t,D,1,B,1,C,1)\) and is still idle, so B sends Q \((B,E,t,D,1,B,1,C,1)\) to E

(30) E receives Q \((B,E,t,D,1,B,1,C,1)\) and is idle, so E sends Q \((E,D,t,D,1,B,1,C,1,E,1)\) to D
Algorithm III

Algorithm III introduces the concept of a priority scheme to reduce the amount of query traffic. Also, if a deadlocked process receives a query, then it will add all members of its reachable set to the query trace list using a zero sequence number. Just as for Algorithm II, each process in the query trace list has its own sequence number.

Time Action

(1) A initiates a query computation
   A sends Q (A,B,1,t,A,1) to B

(2) B receives Q (A,B,1,t,A,1) and is idle, so
   B sends Q (B,C,1,t,A,1,B,1) to C

(3) C receives Q (B,C,1,t,A,1,B,1) and is idle, so
   C sends R (C,B,1,t,A,1,B,1,C,1) to B

(4) B receives R (C,B,1,t,A,1,B,1,C,1) and is still idle, so
   B sends Q (B,D,1,t,A,1,B,1,C,1) to D

(5) D receives Q (B,D,1,t,A,1,B,1,C,1) and is executing, so
   D sends I (D,A,1,timestamp) to A
   D holds the query computation

(6) B initiates a query computation
   B has a higher priority query outstanding, so
   B sends Q (B,D,1,t,A,1,B,1,C,1) to A
   A receives Q (B,D,1,t,A,1,B,1,C,1) and is still idle, so
   A sends R (A,B,1,t,A,1,B,1,C,1) to B

(7) E initiates a query computation
   E has a higher priority query outstanding, so
   E sends Q (E,B,1,t,B,1) to B

(8) B receives Q (E,B,1,t,B,1) and is still idle, so
   B sends Q (B,C,1,t,B,1,C,1) to C

(9) C receives Q (B,C,1,t,B,1,C,1) and is still idle, so
   C sends R (C,B,1,t,B,1,C,1) to B

(10) B receives R (C,B,1,t,B,1,C,1) and is still idle, so
    B sends Q (B,D,1,t,B,1,C,1) to D

(11) D receives Q (B,D,1,t,B,1,C,1) and is still idle, so
    D sends R (D,B,1,t,B,1,C,1) to E

(12) E receives R (D,B,1,t,B,1,C,1) and is still idle, so
     E sends R (E,C,1,t,B,1,C,1) to C

(13) C receives R (E,C,1,t,B,1,C,1) and is still idle, so
     C sends R (C,E,1,t,B,1,C,1) to E

(14) E receives R (C,E,1,t,B,1,C,1) and is still idle, so
     E sends R (E,B,1,t,B,1,C,1) to B

(15) B receives R (E,B,1,t,B,1,C,1) and is still idle, so
    B sends Q (B,C,1,t,B,1,C,1) to C

(16) C receives Q (B,C,1,t,B,1,C,1) and is still idle, so
    C sends R (C,B,1,t,B,1,C,1) to B

(17) B receives R (C,B,1,t,B,1,C,1) and is still idle, so
     B sends Q (B,D,1,t,B,1,C,1) to D

(18) D receives Q (B,D,1,t,B,1,C,1) and is still idle, so
    D sends R (D,B,1,t,B,1,C,1) to E

(19) E receives R (D,B,1,t,B,1,C,1) and is still idle, so
     E sends R (E,C,1,t,B,1,C,1) to C

(20) C receives R (E,C,1,t,B,1,C,1) and is still idle, so
     C sends R (C,E,1,t,B,1,C,1) to E

(21) E receives R (C,E,1,t,B,1,C,1) and is still idle, so
     E sends R (E,B,1,t,B,1,C,1) to B

(22) B receives R (E,B,1,t,B,1,C,1) and is still idle, so
    B sends Q (B,C,1,t,B,1,C,1) to C

(23) C receives Q (B,C,1,t,B,1,C,1) and is still idle, so
    C sends R (C,B,1,t,B,1,C,1) to B

(24) B receives R (C,B,1,t,B,1,C,1) and is still idle, so
    B sends Q (B,D,1,t,B,1,C,1) to D

(25) D receives Q (B,D,1,t,B,1,C,1) and is still idle, so
    D sends R (D,B,1,t,B,1,C,1) to E

(26) E receives R (D,B,1,t,B,1,C,1) and is still idle, so
     E sends R (E,C,1,t,B,1,C,1) to C

(27) C receives R (E,C,1,t,B,1,C,1) and is still idle, so
     C sends R (C,E,1,t,B,1,C,1) to E

(28) E receives R (C,E,1,t,B,1,C,1) and is still idle, so
     E sends R (E,B,1,t,B,1,C,1) to B

(29) B receives R (E,B,1,t,B,1,C,1) and is still idle, so
    B sends Q (B,C,1,t,B,1,C,1) to C

(30) C receives Q (B,C,1,t,B,1,C,1) and is still idle, so
    C sends R (C,B,1,t,B,1,C,1) to B

(31) D receives Q (D,E,1,t,D,1,B,1,C,1,E,1) and is still idle, so
    D sends R (D,E,1,t,D,1,B,1,C,1,E,1) to E

(32) E receives R (D,E,1,t,D,1,B,1,C,1,E,1) and is still idle, so
    E sends R (E,B,1,t,D,1,B,1,C,1,E,1) to B

(33) B receives R (E,B,1,t,D,1,B,1,C,1,E,1) and is still idle, so
    B sends R (B,D,1,t,D,1,B,1,C,1,E,1) to D

(34) D receives R (B,D,1,t,D,1,B,1,C,1,E,1) and is still idle, so
    D sends Q (D,E,1,t,D,1,B,1,C,1,E,1) to E

(35) E receives Q (D,E,1,t,D,1,B,1,C,1,E,1) and is still idle, so
    E sends R (E,D,1,t,D,1,B,1,C,1,E,1) to D

(36) D receives R (E,D,1,t,D,1,B,1,C,1,E,1) and is still idle, so
    D declares DEADLOCK for processes D, B, C, and E
B holds Q (B,C,2,t,B,1)

(7) D becomes idle and waits for processes B and E (see Figure 47)
D is holding one query computation
D sends Q (D,E,1,t,A,1,B,1,C,1,D,2) to E

(8) E receives Q (D,E,1,t,A,1,B,1,C,1,D,2) and is idle, so
E sends Q (E,B,1,t,A,1,B,1,C,1,D,2,E,1) to B

(9) B receives Q (E,B,1,t,A,1,B,1,C,1,D,2,E,1) and is still idle, so
B sends R (B,E,1,t,A,1,B,1,C,1,D,2,E,1) to E

(10) E receives R (B,E,1,t,A,1,B,1,C,1,D,2,E,1) and is still idle, so
E sends R (E,D,1,t,A,1,B,1,C,1,D,2,E,1) to D

(11) D receives R (E,D,1,t,A,1,B,1,C,1,D,2,E,1) and is still idle, so
D sends R (D,B,1,t,A,1,B,1,C,1,D,2,E,1) to B

(12) B receives R (D,B,1,t,A,1,B,1,C,1,D,2,E,1) and is still idle, so
B sends Q (B,E,1,t,A,1,B,1,C,1,D,2,E,1) to E

(13) E receives Q (B,E,1,t,A,1,B,1,C,1,D,2,E,1) and is still idle, so
E sends R (E,B,1,t,A,1,B,1,C,1,D,2,E,1) to B

(14) B receives R (E,B,1,t,A,1,B,1,C,1,D,2,E,1) and is still idle, so
B sends R (B,A,1,t,A,1,B,1,C,1,D,2,E,1) to A
B sends Q (B,C,2,t,B,1) to C

(15) A receives R (B,A,1,t,A,1,B,1,C,1,D,2,E,1) and is still idle, so
A declares DEADLOCK for processes A, B, C, D, and E

(16) C receives Q (B,C,2,t,B,1) and is idle, so
C sends R (C,B,2,t,B,1,C,1) to B

(17) B receives R (C,B,2,t,B,1,C,1) and is still idle, so
B sends Q (B,D,2,t,B,1,C,1) to D

(18) D receives Q (B,D,2,t,B,1,C,1) and is idle, so
D sends Q (D,E,2,t,B,1,C,1,D,2) to E

(19) E receives Q (D,E,2,t,B,1,C,1,D,2) and is idle, so
E sends Q (E,B,2,t,B,1,C,1,D,2,E,1) to B

(20) B receives Q (E,B,2,t,B,1,C,1,D,2,E,1) and is still idle, so
B sends R (B,E,2,t,B,1,C,1,D,2,E,1) to E

(21) E receives R (B,E,2,t,B,1,C,1,D,2,E,1) and is still idle, so
E sends R (E,D,2,t,B,1,C,1,D,2,E,1) to D

(22) D receives R (E,D,2,t,B,1,C,1,D,2,E,1) and is still idle, so
D sends R (D,B,2,t,B,1,C,1,D,2,E,1) to B
Algorithm IV

Algorithm IV introduces the concept of using information obtained from previous query computations. Also, if a deadlocked process receives a query, then it will add all members of its reachable set to the query trace list, but it will not use sequence numbers of 0. With this algorithm, sequence numbers reflect the number of times processes have accepted messages and executed.

Time Action

(1) A initiates a query computation
A sends Q (A,B,1,t,A,1) to B

(2) B receives Q (A,B,1,t,A,1) and is idle, so
B sends Q (B,C,1,t,A,1,B,1) to C

(3) C receives Q (B,C,1,t,A,1,B,1) and is idle, so
C sends R (C,B,1,t,A,1,B,1,C,1) to B

(23) B receives R (D,B,2,t,B,1,C,1,D,2,E,1) and is still idle, so
B sends Q (B,E,2,t,B,1,C,1,D,2,E,1) to E

(24) E receives Q (B,E,2,t,B,1,C,1,D,2,E,1) and is still idle, so
E sends R (E,B,2,t,B,1,C,1,D,2,E,1) to B

(25) B receives R (E,B,2,t,B,1,C,1,D,2,E,1) and is still idle, so
B declares DEADLOCK for processes B, C, D, and E

(26) D initiates a query computation
D sends Q (D,B,4,t,D,1) to B

(27) B receives Q (D,B,4,t,D,1) and is deadlocked, so
B sends R (B,D,4,t,D,1,B,2,C,0,E,0) to D

(28) D receives R (B,D,4,t,D,1,B,2,C,0,E,0) and is still idle, so
D sends Q (D,E,4,t,D,1,B,2,C,0,E,0) to E

(29) E receives Q (D,E,4,t,D,1,B,2,C,0,E,0) and sees its sequence number is 0, so
E sends R (E,D,4,t,D,1,B,2,C,0,E,0) to D

(30) D receives R (E,D,4,t,D,1,B,2,C,0,E,0) and is still idle, so
D declares DEADLOCK for processes D, B, C, and E
(4) B receives R (C,B,1,t,A,1,B,1,C,1) and is still idle, so
B sends Q (B,D,1,t,A,1,B,1,C,1) to D

(5) D receives Q (B,D,1,t,A,1,B,1,C,1) and is executing, so
D sends I (D,A,1,timestamp) to A
D holds the query computation

(6) B initiates a query computation
B has a higher priority query outstanding, so
B holds Q (B,C,2,t,B,1)

(7) D becomes idle and waits for processes B and E (see Figure 47)
D is holding one query computation
D sends Q (D,E,1,t,A,1,B,1,C,1,D,2) to E

(8) E receives Q (D,E,1,t,A,1,B,1,C,1,D,2) and is idle, so
E sends Q (E,B,1,t,A,1,B,1,C,1,D,2,E,1) to B

(9) B receives Q (E,B,1,t,A,1,B,1,C,1,D,2,E,1) and is still idle, so
B sends R (B,E,1,t,A,1,B,1,C,1,D,2,E,1) to E
B learns that any messages sent to B by E when E was executing with
sequence number 1 have arrived.

(10) E receives R (B,E,1,t,A,1,B,1,C,1,D,2,E,1) and is still idle, so
E sends R (E,D,1,t,A,1,B,1,C,1,D,2,E,1) to D

(11) D receives R (E,D,1,t,A,1,B,1,C,1,D,2,E,1) and is still idle, so
D sends R (D,B,1,t,A,1,B,1,C,1,D,2,E,1) to B

(12) B receives R (D,B,1,t,A,1,B,1,C,1,D,2,E,1) and is still idle
B knows all messages sent to it by E when E was executing with
sequence number 1 have arrived, so
B sends R (B,A,1,t,A,1,B,1,C,1,D,2,E,1) to A
B was holding a query computation it initiated, so
B sends Q (B,C,2,t,B,1) to C

(13) A receives R (B,A,1,t,A,1,B,1,C,1,D,2,E,1) and is still idle, so
A declares DEADLOCK for processes A, B, C, D, and E

(14) C receives Q (B,C,2,t,B,1) and is idle, so
C sends R (C,B,2,t,B,1,C,1) to B

(15) B receives R (C,B,2,t,B,1,C,1) and is still idle, so
B sends Q (B,D,2,t,B,1,C,1) to D

(16) D receives Q (B,D,2,t,B,1,C,1) and is idle, so
D sends Q (D,E,2,t,B,1,C,1,D,2) to E

(17) E receives Q (D,E,2,t,B,1,C,1,D,2) and is idle
E knows all messages sent to it by B when B was executing with
sequence number 1 have arrived, so
E sends R (E,D,2,t,B,1,C,1,D,2,E,1) to D
Algorithm V

Algorithm V introduces the concept of using information obtained during the current query computation to detect all minimal deadlocked sets. Boolean flags are used to carry this information from process to process, and they will be represented as a sign preceeding the sequence number.

<table>
<thead>
<tr>
<th>Time</th>
<th>Action</th>
</tr>
</thead>
</table>
| (1)  | A initiates a query computation  
      | A sends Q (A,B,1,t,A,1) to B |
| (2)  | B receives Q (A,B,1,t,A,1) and is idle, so  
      | B sends Q (B,C,1,t,A,1,B,1) to C |
| (3)  | C receives Q (B,C,1,t,A,1,B,1) and is idle, so  
      | C sends R (C,B,1,t,A,1,B,1,C,1) to B |
| (4)  | B receives R (C,B,1,t,A,1,B,1,C,1) and is still idle, so  
      | B sends Q (B,D,1,t,A,1,B,1,C,1) to D |
| (5)  | D receives Q (B,D,1,t,A,1,B,1,C,1) and is executing, so  
      | D sends I (D,A,1,timestamp) to A  
      | D holds the query computation |
| (6)  | B initiates a query computation  
      | B has a higher priority query outstanding, so  
      | B holds Q (B,C,2,t,B,1) |
(7) D becomes idle and waits for processes B and E (see Figure 47)
D is holding one query computation
D sends $Q(D,E,1,t,A,-1,B,-1,C,+1,D,+2)$ to B

(8) E receives $Q(D,E,1,t,A,-1,B,-1,C,+1,D,+2)$ and is idle, so
E sends $Q(E,B,1,t,A,-1,B,-1,C,+1,D,+2,E,+1)$ to B

(9) B receives $Q(E,B,1,t,A,-1,B,-1,C,+1,D,+2,E,+1)$ and is idle, so
B sends $R(B,E,1,t,A,-1,B,-1,C,+1,D,+2,E,+1)$ to E
B learns that any messages sent to B by E when E was executing with
sequence number 1 have arrived.

(10) E receives $R(B,E,1,t,A,-1,B,-1,C,+1,D,+2,E,+1)$ and is idle, so
E sends $R(E,D,1,t,A,-1,B,-1,C,+1,D,+2,E,+1)$ to D

(11) D receives $R(E,D,1,t,A,-1,B,-1,C,+1,D,+2,E,+1)$ and is idle, so
D sends $R(D,B,1,t,A,-1,B,-1,C,+1,D,+2,E,+1)$ to B

(12) B receives $R(D,B,1,t,A,-1,B,-1,C,+1,D,+2,E,+1)$ and is idle
B knows all messages sent to it by E when E was executing with
sequence number 1 have arrived, so
B knows it is a member of a deadlocked set consisting of B, C, D, and E, so
B declares DEADLOCK for processes B, C, D, and E.
B sends $R(B,A,1,t,A,+1,B,-1,C,-1,D,-2,E,+1)$ to A
The query trace list identifies the minimal deadlocked set to A.
B was holding a query computation it initiated, but this is not needed, so
B discards $Q(B,C,2,t,B,-1)$ as unnecessary.

(13) A receives $R(B,A,1,t,A,+1,B,-1,C,-1,D,-2,E,+1)$ and is idle, so
A declares DEADLOCK for processes A, B, C, D, and E.
A recognizes the minimal deadlocked set consisting of processes B, C, D, and E,
and that A is not a member of the minimal deadlocked set.

(14) D initiates a query computation
D sends $Q(D,B,4,t,D,-2)$ to B

(15) B receives $Q(D,B,4,t,D,-2)$ and is deadlocked, so
B sends $R(B,D,4,t,D,-2,B,+1,C,+1,E,+1)$ to D

(16) D receives $R(B,D,4,t,D,-2,B,+1,C,+1,E,+1)$ and is idle, so
D declares DEADLOCK for processes D, B, C, and E.
D recognizes it is a member of a minimal deadlocked set
consisting of D, B, C, and E.
Example 2

The following example shows in greater detail how the minimal deadlocked sets are determined by Algorithm V. In this example, suppose that all the processes are idle, and that there are no messages in transit. The system is shown in Figure 48. The query computation initiated by process A is shown.

![Figure 48: Final Configuration with Deadlock](image)

<table>
<thead>
<tr>
<th>Time</th>
<th>Action</th>
</tr>
</thead>
</table>
| (1)  | A initiates a query computation  
A sends $Q(A,B,1,t,A,-1)$ to B |
| (2)  | B receives $Q(A,B,1,t,A,-1)$  
B sends $Q(B,C,1,t,A,-1,B,-1)$ to C |
| (3)  | C receives $Q(B,C,1,t,A,-1,B,-1)$  
C sends $R(C,B,1,t,A,-1,B,-1,C,+1)$ to B |
| (4)  | B receives $R(C,B,1,t,A,-1,B,-1,C,+1)$  
B recognizes it is a member of a minimal deadlocked set consisting of B and all processes in the query trace list following B (namely C).  
B declares DEADLOCK for processes B and C.  
B turns the flag off for A. since A cannot be in the minimal deadlocked set.  
B sends $R(B,A,1,t,A,+1,B,-1,C,+1)$ to A |
| (5)  | A receives $R(B,A,1,t,A,+1,B,-1,C,+1)$  
A sends $Q(A,D,1,t,A,+1,B,-1,C,+1)$ to D |
(6) D receives Q(A,D,1,t,A,+,1,B,+,1,C,+,1) Since A is in the dependent set of D, D turns off the flags for all processes between A and D in the query trace list.
D sends Q(D,B,1,t,A,+,1,B,+,1,C,+,1) to B

(7) B receives Q(D,B,1,t,A,+,1,B,+,1,C,+,1) B sends R(B,D,1,t,A,+,1,B,+,1,C,+,1) to D

(8) D receives R(B,D,1,t,A,+,1,B,+,1,C,+,1) D sends Q(D,E,1,t,A,+,1,B,+,1,C,+,1) to E

(9) E receives Q(D,E,1,t,A,+,1,B,+,1,C,+,1) E sends Q(E,F,1,t,A,+,1,B,+,1,C,+,1) to F

(10) F receives Q(E,F,1,t,A,+,1,B,+,1,C,+,1) F sends Q(F,G,1,t,A,+,1,B,+,1,C,+,1) to G

(11) G receives Q(F,G,1,t,A,+,1,B,+,1,C,+,1) G sends Q(G,E,1,t,A,+,1,B,+,1,C,+,1) to E

(12) E receives Q(G,E,1,t,A,+,1,B,+,1,C,+,1) E sends R(E,G,1,t,A,+,1,B,+,1,C,+,1) to G

(13) G receives R(E,G,1,t,A,+,1,B,+,1,C,+,1) G sends R(G,F,1,t,A,+,1,B,+,1,C,+,1) to F

(14) F receives R(G,F,1,t,A,+,1,B,+,1,C,+,1) F sends R(F,E,1,t,A,+,1,B,+,1,C,+,1) to E

(15) E receives R(F,E,1,t,A,+,1,B,+,1,C,+,1) E recognizes it is a member of a minimal deadlocked set, along with processes F and G.
E declares DEADLOCK for processes E, F, and G.
E changes the flag pattern in the minimal deadlocked set to be (--- + +).
E sends R(E,D,1,t,A,+,1,B,+,1,C,+,1,D,+,1,E,+,1,F,+,1,G,+,1) to D

(16) D receives R(E,D,1,t,A,+,1,B,+,1,C,+,1,D,+,1,E,+,1,F,+,1,G,+,1) D sends Q(D,H,1,t,A,+,1,B,+,1,C,+,1,D,+,1,E,+,1,F,+,1,G,+,1) to H

(17) H receives Q(D,H,1,t,A,+,1,B,+,1,C,+,1,D,+,1,E,+,1,F,+,1,G,+,1) H sends Q(H,B,1,t,A,+,1,B,+,1,C,+,1,D,+,1,E,+,1,F,+,1,G,+,1,H,+,1) to B

(18) B receives Q(H,B,1,t,A,+,1,B,+,1,C,+,1,D,+,1,E,+,1,F,+,1,G,+,1,H,+,1) B sends R(B,H,1,t,A,+,1,B,+,1,C,+,1,D,+,1,E,+,1,F,+,1,G,+,1,H,+,1) to H

(19) H receives R(B,H,1,t,A,+,1,B,+,1,C,+,1,D,+,1,E,+,1,F,+,1,G,+,1,H,+,1) H sends Q(H,F,1,t,A,+,1,B,+,1,C,+,1,D,+,1,E,+,1,F,+,1,G,+,1,H,+,1) to F

(20) F receives Q(H,F,1,t,A,+,1,B,+,1,C,+,1,D,+,1,E,+,1,F,+,1,G,+,1,H,+,1) F knows from previous queries and replies that the sequence numbers for E and G in the query trace list are the latest ones.
F sends R(F,H,1,t,A,+,1,B,+,1,C,+,1,D,+,1,E,+,1,F,+,1,G,+,1,H,+,1) to H
(21) H receives \( R(F, H, 1, t, A, +1, B, +1, C, +1, D, +1, E, +1, F, +1, G, +1, H, +1) \)
H sends \( Q(H, D, 1, t, A, +1, B, +1, C, +1, D, +1, E, +1, F, +1, G, +1, H, +1) \) to D

(22) D receives \( R(H, D, 1, t, A, +1, B, +1, C, +1, D, +1, E, +1, F, +1, G, +1, H, +1) \)
D only updates the information about \((H, +1)\) from the query trace list
D sends \( R(D, A, 1, t, A, +1, B, +1, C, +1, D, +1, E, -1, F, -1, G, +1, H, +1) \) to A

(23) A receives \( R(B, H, 1, t, A, +1, B, +1, C, +1, D, +1, E, -1, F, -1, G, +1, H, +1) \)
A only updates the information about \((D, +1, E, -1, F, -1, G, +1, H, +1)\) from the query trace list.
A now has a query trace list which shows
\((A, -1, B, -1, C, +1, D, +1, E, -1, F, -1, G, +1, H, +1)\)
A is finished querying its dependent set, so
A declares DEADLOCK for processes \(A, B, C, D, E, F, G, \) and \(H\).
A looks for patterns of \((- - - +)\) in the query trace list to find all the minimal deadlocked sets.
These patterns occur for \((B, -1, C, +1)\) and \((E, -1, F, -1, G, +1)\), which means these form minimal deadlocked sets.
Notice that processes \(B\) and \(E\) were also able to detect deadlock during this query computation.
Richard Arthur Adams, the son of Ralph W. Adams and (the late) Constance J. Adams, was born in New Hampton, Iowa on 12 December 1951, and raised on a farm near Waucoma, Iowa. After graduating from Turkey Valley Community School in 1970, he attended Iowa State University in Ames, Iowa, receiving a Bachelor of Science degree in Mathematics and Computer Science and a commission in the USAF through the AFROTC program. He entered active duty as a Second Lieutenant and was stationed at Offutt Air Force Base for three years as a computer systems analyst. From August 1977 to March 1979, he attended the School of Engineering, Air Force Institute of Technology, and received a Master of Science degree in Computer Systems. He then was stationed in Stuttgart, West Germany for four years and while there he earned a Bachelor of Arts degree in German from the University of Maryland, European Division. In June 1983, he entered the University of Illinois to begin graduate studies in Computer Science, and on 1 February 1986 was promoted to his present rank of major. He is a member of the honor societies of Tau Beta Pi, Pi Mu Epsilon, and Phi Kappa Phi. Richard is married to the former Heather M. Olds and they have two children.
