Fluorescence at a Surface

Fluorescence emitted by an atom near a metal surface and the coupling of the surface plasmon field of a dielectric substrate to a molecular electronic transition are studied. Explicit expressions for the atomic and molecular lifetimes are derived. It is shown how the (classical) phase shift of a plane wave upon reflection at the surface is responsible for the alteration of atomic lifetimes. Subsequently, it is demonstrated that the dipole direction of an atom can be fixed by illumination of the system with a polarized light source. For molecular transitions, the surface-plasmon and the surface-roughness contribution to the decay constants are included. In a comparison between the image theory and the energy-transfer theory, it appears that the former can be rather inaccurate for large molecule-surface separations or a highly-conducting substrate.
Abstract

Fluorescence emitted by an atom near a metal surface and the coupling of the surface plasmon field of a dielectric substrate to a molecular electronic transition are studied. Explicit expressions for the atomic and molecular lifetimes are derived. It is shown how the (classical) phase shift of a plane wave upon reflection at the surface is responsible for the alteration of atomic lifetimes. Subsequently, it is demonstrated that the dipole direction of an atom can be fixed by illumination of the system with a polarized light source. For molecular transitions, the surface-plasmon and the surface-roughness contribution to the decay constants are included. In a comparison between the image theory and the energy-transfer theory, it appears that the former can be rather inaccurate for large molecule-surface separations or a highly-conducting substrate.

(Keywords: fluorescence, lifetimes, surface, photon correlations)
I. INTRODUCTION

An atom in empty space decays spontaneously (accompanied by the emission of a fluorescent photon), with a certain lifetime, which is brought about by the coupling of the atomic (transition) dipole moment to the travelling plane wave modes of the electromagnetic vacuum field. Early attempts to comprehend the process of spontaneous emission concentrated on the prediction of the Einstein $A_o$ coefficient, which equals the inverse lifetime of an excited state, and it was one of the first victories of quantum mechanics by Dirac in 1927 to establish unambiguously its value as

$$A_o = \frac{\omega^3}{3\pi\varepsilon_0\hbar c^3} \cdot \frac{|<\phi_m|\mu|\phi_g>|^2}{2j_g + 1}.$$  \hspace{1cm} (1.1)

Here, $<\phi_m|\mu|\phi_g>$ is the reduced matrix element of the atomic dipole operator $\mu$ between an excited level $|\phi_m>$ and the ground level $|\phi_g>$, which have a level separation $\hbar\omega$. Result (1.1) follows from the Golden Rule and is an essentially quantum mechanical expression (because of the appearance of $\hbar$).

Earlier this year$^{1,2}$ it was demonstrated for the first time that it is practically feasible to alter atomic lifetimes for optical transitions through a (semi) confinement of the atom. This was brought about by passing an atomic beam through a set of parallel mirrors or a confocal resonator. In this paper we report recent developments in the theoretical understanding of atomic fluorescence near a metal surface.

Another technique to change the lifetime of an electronic transition pertains to the deposition of a molecular monolayer on a dielectric bulk material. Then the separation between the optically-active compound and the passive substrate can be extremely small, which implies that the lifetime
modification is brought about mainly by coupling to the short-range evanescent plasmon field. Since the decaying system is so close to the surface, it becomes inevitable to take the details of the surface structure (roughness) into consideration.

II. ATOMIC DECAY

The plane $z = 0$ separates the vacuum $z > 0$ from a substrate in $z < 0$, which is assumed to be fairly represented by its dielectric constant $\varepsilon(\omega)$. An atom is positioned on the $z$-axis at $d > 0$. Since every radiation field in the region above the surface can be expanded in plane waves, it should be possible to express any surface effect in an observable quantity in terms of the plane-wave Fresnel reflection coefficients. These are for $s$-polarized waves

$$R_s(\omega, u) = \frac{\sqrt{\varepsilon(\omega) - 1 + u^2} - u}{\sqrt{\varepsilon(\omega) - 1 + u^2} + u} ,$$

$$R_p(\omega, u) = \frac{u\varepsilon(\omega) - \sqrt{\varepsilon(\omega) - 1 + u^2}}{u\varepsilon(\omega) + \sqrt{\varepsilon(\omega) - 1 + u^2}} ,$$

where $u$ signifies the cosine of the angle of incidence. Then the mode expansion of the electric field in the region $z > 0$, becomes

$$E(r, t) = \sum_{k_0} \frac{\hbar \omega_{k_0}}{2\varepsilon_0} a_{k_0}(t) F_{-k_0}(r) ,$$

with $F_{k_0}(r)$ the sum of an incident and a reflected wave, and normalized in such a
way that every photon carries an energy $h\omega$. The equation of motion for the density operator of the system reads

$$\frac{i\hbar}{\mathfrak{d}} \frac{\mathfrak{d} \rho}{\mathfrak{d} t} = [H_a + H_r + H_i, \rho],$$

(2.4)

where $a$, $r$ and $i$ indicate atomic, radiation and interaction, respectively.

Transparent interpretations can be obtained if we restrict our attention to (idealized) metals, defined by $\varepsilon(\omega)<0$. From Eqs. (2.1) and (2.2) it then follows that

$$|R_0(\omega,u)| = 1,$$

(2.5)

and hence the metal is perfectly reflecting. Then we can write

$$R_0(\omega,u) = e^{2i\phi_0(\omega,u)},$$

(2.6)

and the real-valued phase shifts $\phi_0$ for $s$ and $p$ waves follow directly from a comparison with Eqs. (2.1) and (2.2). For a perfectly-conducting metal we have $\phi_0 = 0$.

In writing $|j_{m_0}>$ for a magnetic substrate of the upper level, we implicitly refer to a direction in configuration space, e.g., the quantization axis. In our geometry it is most advantageous to take this direction to coincide with the normal to the surface. With this convention the atomic wave functions are unambiguously defined. Then it is a standard procedure\(^4\) to eliminate the explicit occurrence of the radiation field from the equation of motion (2.4), which yields the Einstein coefficients $A_{m_0}$ for the decay of $|j_{m_0}>$. We find
\[ A_{m_e} = A_0 \sum_{m_j} \frac{b_\tau(d)(j_{m_j} | j_{m_e})^2}{m_j^{\tau}} \]  

(2.7)

where \( \tau \) assumes the values -1, 0, 1, corresponding to the three possible helicities of a fluorescent photon. The parameter functions \( b_\tau(d) \) embody the surface modifications to the relaxation constants, and they are explicitly

\[ b_\parallel(d) = b_{\pm1}(d) = 1 - \frac{3}{4} \int_0^1 du \cos(2(\omega du/c + \phi_s(\omega,u))) - \frac{3}{4} \int_0^1 du \, u^2 \cos(2(\omega du/c + \phi_s(\omega,u))) \]  

(2.8)

\[ b_\perp(d) = b_0(d) = 1 - \frac{3}{2} \int_0^1 du \, (1-u^2) \cos(2(\omega du/c + \phi_s(\omega,u))) \]  

(2.9)

Expressions (2.8) and (2.9) are identical to those obtained by Philpott, in a different way.

In the limit \( d \to \infty \), we find \( b_\parallel = b_\perp = 1 \) and \( A_{m_e} = A_0 \), which implies that the atom behaves as an atom in free space (no surface), and that the lifetime of the state \( |j_{m_e} \rangle \) becomes independent of \( m_e \). Conversely, due to the presence of the surface, every excited state has a different relaxation constant \( A_{m_e} \). The relation \( A_{m_e} = A_0 \) for an atom in empty space reflects the isotropy of spontaneous emission, or, the spherical symmetry of the system. In the vicinity of a boundary, this symmetry is destroyed, which gives every state \( |j_{m_e} \rangle \) a different lifetime. From Eq. (2.7) we see that

\[ A_{m_e} = A_{-m_e} \]  

(2.10)
which displays the remaining cylindrical symmetry for rotations about the $z$-axis.\footnote{7}

By summing Eq. (2.7) over the magnetic quantum numbers $m_e$, we obtain the sum rule

$$\frac{1}{2j_e+1} \sum_{m_e} A_{m_e} = \frac{1}{3} A_{\perp} + \frac{2}{3} A_{\parallel} ,$$

(2.11)

with $A_{\perp} = A_0 b_{\perp}$ and $A_{\parallel} = A_0 b_{\parallel}$. Here, the left-hand side is the average value of $A_{m_e}$ over the different substates, because there are $2j_e + 1$ excited states $|j_e m_e>$ for a given $j_e$. If the population of the excited state is randomly distributed over the various substates, with no coherence between the states, then the atom will effectively decay with the average of $A_{m_e}$. In this respect the result (2.11) is a quantum mechanical justification for a randomization of the dipole direction, which is commonly applied in semiclassical theories of relaxation near an interface. For excitation with a polarized light source this procedure is not correct, as we shall show in due course.

Another interesting feature is the dependence of the lifetimes on the distance $d$ between atom and surface. From Eqs. (2.8) and (2.9) we see that $b_{\parallel}(d)$ and $b_{\perp}(d)$ are determined by a superposition of waves with a different value of $u$, where $u$ is the cosine of the angle of incidence. Properties of the reflecting medium are accounted for by the phase shifts $\phi_0(\omega, u)$. From this interpretation it follows that the $d$ dependence of $A_{m_e}$ is brought about by simple interference of plane waves, which is a pure classical effect. The relevance of the phase shift is most easily demonstrated by considering the limit $d \to 0$. In the case of a perfect conductor we then find

$$b_{\parallel}(0) = 0 , \quad b_{\perp}(0) = 2 ,$$

(2.12)
whereas the limit $\varepsilon \to 0$ yields

$$b_{\|}(0) = 1, \quad b_{\perp}(0) = 0 .$$  \hspace{1cm} (2.13)

For a perfectly-conducting solid the inverse lifetime of a parallel dipole is zero, but if the conductivity becomes smaller, it is the inverse lifetime of a perpendicular dipole which vanishes. This reversal of behavior of parallel and perpendicular dipoles as a function of the conductivity illustrates the dramatic effect that a phase change upon reflection of a plane wave can have on the optical properties of an atom, which experiences these plane-wave fields. Figure 1 gives more details of the $\varepsilon$ dependence of $b_{\|}(0)$ and $b_{\perp}(0)$.

III. FLUORESCENCE

Dynamical behavior of an atom in a radiation field can be studied experimentally by observation of the fluorescence. Information on various details, like lifetimes, is reflected in the different statistical properties of the emitted radiation. Therefore, we consider the (quantum) radiation field in more detail. In Eq. (2.3) we gave the general expression for the electric field $E(r,t)$, and we notice that its time dependence only enters through the time dependence of the annihilation operator $a_{k0}(t)$. By definition, this Heisenberg operator obeys the time-evolution equation

$$i\hbar \frac{d}{dt} a_{k0}(t) = [a_{k0}(t) , H_a + H_r + H_i] .$$  \hspace{1cm} (3.1)

If we work out the commutator, differentiate the equation with respect to time and substitute the result in the second time derivative of Eq. (2.3), then it
follows that $E(r,t)$ obeys the wave equation, with the dipole moment as source term. We can solve this equation and make an asymptotic expansion for $r = |r| + \infty$, which finally yields the expression for the electric field in the radiation zone

$$E(r,t) = \frac{\omega^2}{4\pi\varepsilon_0 rc^2} \int_0^\infty \left( \epsilon_{\|} - \epsilon_{\perp} \right) \left( \frac{\mu(t-r/c)e^{-i\omega t/c}}{\epsilon_{\|} - \epsilon_{\perp}} \right) e^{i(\omega t/c + 2\phi_0(\omega, u))} + \mu'(t-r/c)e^{i\omega t/c} \right) d\omega + \text{h.c.} + \text{free field} \quad (3.2)$$

Here, the polarization vectors $\epsilon_{\|}$ correspond to the plane waves which travel in the direction of observation $\bar{r}$, and $u$ is now the cosine of the angle of observation (angle between $\bar{r}$ and the $z$-axis). The mirror dipole moment $\mu'$ is defined as $\mu' = \mu_\perp - \mu_\|$ in terms of the separation $\mu = \mu_\perp + \mu_\|$ for the atomic dipole. Result (3.2) encompasses all spectral, temporal and polarization properties of the emitted photons, including their angular distribution. We notice that the surface-conductivity effect is incorporated by the phase shift $\phi_0$ of the component with source $\mu'$, which originates from the mirror dipole in $\bar{r} = -d_{\text{z}}$ below the surface.

IV. PHOTON CORRELATIONS

Recently, we advocated that in designing an experiment for the observation of surface-modified optical properties of atoms, one can greatly benefit from the polarization properties of the fluorescence, which are induced by the presence of the substrate. Especially the combination with state-selective excitation by an intense polarized laser beam, propagating in a well-defined direction, allows the construction of a geometrical configuration for which only a specific combination
of $\alpha_\perp$ and $\alpha_\parallel$ determines the statistical properties of the fluorescence. In order to illustrate the idea, we consider a $j_\ell = 1 \rightarrow j_g = 0$ transition. If we take the incident cw laser field to be linearly polarized and travelling in a direction parallel to the surface, then it follows from the dipole selection rules that only the state $|1,0\rangle$ will be populated. Alternatively, we can assume a circularly-polarized beam which is incident normal to the surface. In this case only one of the substates $|1,t\rangle$ will be occupied. Since $|1,0\rangle$ and $|1,t\rangle$ decay with an inverse lifetime equal to $\alpha_\perp$ and $\alpha_\parallel$ respectively, we can simply fix the dipole direction with our choice of external field.

Driving an atomic transition with a cw laser results in a time-independent fluorescent intensity $I$, and consequently the information contained in this quantity is minimal. Therefore, we consider the stationary two-photon correlation function $f(t)$, which has the significance of the probability for the detection of a photon at time $t \geq 0$, after the detection of a photon at time zero, and irrespective of possible detections at other times (for instance in $[0,t]$). In general the function $f(t)$ acquires the form

$$f(t) = \langle E^(-)(0)E^-(t)E^+(t)E^+(0) \rangle,$$  \hspace{1cm} (4.1)

where $E^+(t)$ is the projection of $E^+(r,t)$ on the polarization direction of a polarizer. Evaluation of this expression is quite involved,\(^7\) so here we shall merely quote the result. We find

$$f(t) = I(1-e^{-3\alpha t/4}(\cos(\Omega t)+3A\sin(\Omega t)/4\Omega))$$ \hspace{1cm} (4.2)

for a strong laser exactly on resonance with the transition frequency $\omega$. Here, $\Omega$ denotes the Rabi frequency ($\Omega^2 = \text{laser power}$). Surface-induced effects are
entirely incorporated in the Einstein coefficient $A$, which equals $A_\perp$ for the linearly-polarized case ($\Delta m = 0$), and $A_\parallel$ for a circularly-polarized laser ($\Delta m = \pm 1$). The advantage of a laser-driven atom and observation of the photon correlations is that the desired relaxation constant can simply be selected by an appropriate choice of external field.

V. MOLECULAR DECAY AT ROUGH SURFACES

In the previous sections perfect flatness of the surface has been assumed. However, there are many experiments with large admolecules (e.g., pyrazine) in which roughness of the surface unavoidably exists. Hence, in this section we shall summarize some of our recent work on molecular decay rates at rough metallic surfaces, where surface plasmon excitation has been found to play a dominant role.

To simplify the problem, we shall follow a classical phenomenological approach based on Maxwell's theory, which has been found to be adequate for molecule-surface distances ($d$) greater than a few Angstroms. Then the "quantum spreads" of both the surface and the molecule can be neglected. Within this approach, the molecule is modeled as a point dipole ($\mu$), satisfying the damped-oscillator equation of motion, driven by the surface field ($E$). The induced decay rate obtained in this model can be expressed as

$$\begin{align*}
A_F &= A_0 (1 + \frac{3}{2} \frac{q}{k^3} \text{Im} G_F), \\
A_R &= A_0 [1 + \frac{3}{2} \frac{q}{k^3} \text{Im}(G_F + G_R)],
\end{align*}$$

(5.1) (5.2)

where $q$ is the quantum yield of the emitting state, $k = \omega/c$ equals the emission wave number, and the sub(super)scripts $R$, $F$ and $o$ stand for cases with a rough
surface, flat surface and free molecule respectively. The $G$-functions in Eqs. (5.1) and (5.2) are defined as the surface field acting on the molecule per unit dipole moment and as a function of the emission frequency

$$G(\omega) = \frac{E(\omega)}{\mu}.$$ 

Note that in writing Eq. (5.2) we have followed an approach which distinguishes between the contributions to the surface-induced decay rates from the flat boundary and from the roughness, respectively.\textsuperscript{13,14}

The remaining task in this approach is to calculate the $G(\omega)$-functions. In general, there are two ways of doing this, namely, the image method and the energy-transfer theory. In the image theory (IT), one regards the surface field $E(\omega)$ as given by the image field, induced by the molecular dipole, which is obtained from solving the electrostatic Poisson equation. For example, in the case of a flat surface and $\mu$ located at $(0,0,d)$, oriented perpendicular to the surface, one obtains\textsuperscript{14}

$$G_{IT}(\omega) = \frac{k^3}{4\varepsilon c^{\varepsilon-1} d^{\varepsilon+1}} ,$$ 

where $d = kd$ is the reduced distance and $\varepsilon(\omega) = \varepsilon_1(\omega) + i\varepsilon_2(\omega)$ is the complex bulk dielectric constant of the substrate material.

The other approach, energy-transfer theory (ET), is a more exact electrodynamical treatment in which one has to solve the full set of Maxwell's equations (or the Helmholtz wave equation) by regarding the dipole emission as the source (incident) field, and by matching boundary conditions at the surface. Then $E(\omega)$ will be given by the reflected field from the surface, evaluated at the
molecular site. For the case of a flat surface, this problem has been solved by Chance, Prock and Silbey\cite{12} (CPS) by applying the Sommerfeld theory for a radiating dipole antenna above the earth's surface. Thus for the above example the CPS theory gives

\[ G_{ET}(\omega) = -k^3 \int_0^\infty R_p(\omega, \text{l}_1) e^{-2i \text{l}_1 \frac{\omega}{\text{u}}^3} \text{l}_1, \]  

where \( \text{l}_1 = -i(1-u^2)^\frac{1}{2} \).

It is obvious from the above examples that IT is in general an approximate but much simpler approach than ET. It has been a wide belief\cite{15} that in the short-distance or long-wavelength limit (\( \text{d} << 1 \)), which holds for most experimental conditions (\( \text{d} \leq 10^2 \text{ A} \) and \( \lambda - 10^3 \text{ A} \)\),\cite{16} IT should be accurate enough to describe the phenomenon. Moreover, although both IT and ET are available for the case of flat surfaces, only IT is available so far in the literature when surface roughness cannot be neglected.\cite{13,14}

In a recent analysis of the limit of IT, however, it was pointed out that the condition \( \text{d} << \lambda \) is not sufficient to ensure IT to be valid.\cite{17} The additional condition found for IT to hold is \( \text{d} << \delta \), with \( \delta \) being the skin depth of the substrate. In particular, for a highly-conducting substrate such as silver and for the above example, IT has been found to break down appreciably for \( \text{d} >> 0.01\lambda \). Roughly speaking, the physical origin for such a failure of IT stems from the fact that the Helmholtz wave equation in a conducting medium does not reduce to the static Poisson equation in the limit \( \lambda \rightarrow \infty \), if the conductivity of the medium becomes infinite.

It is therefore necessary to develop a dynamical theory (ET) for a complete description of the decay rates of admolecules at rough surfaces. Recently, an attempt\cite{18} in this direction was made by combining the CPS theory\cite{12} and the
integral-equation formalism of Maxwell's equations for rough boundaries, established chiefly by Maradudin and Mills (MM) and Agarwal. Let us describe the roughness by a profile function $\zeta(x,y)$. The main idea of the MM theory is to regard $\zeta$ as a source for the homogeneous Helmholtz equation in the case of a perfectly-flat boundary. One is then able to obtain perturbative solutions in orders of $\zeta$ for the reflected field $E(\omega)$, which is the relevant surface field for the calculation of the $G(\omega)$-functions. Then $E(\omega)$ is expressible as a combination of the contributions from the flat boundary and the roughness as

$$E = E^F + E^R,$$  \hspace{1cm} (5.6)

and to order $\zeta$ one obtains for the $\mu$-th component of $E^R$  

$$E^R_{\mu}(r;\omega) = -\frac{k^2}{16\pi^3} d^{-1} \left[ \varepsilon(\omega) - 1 \right] \int d^2k_\parallel e^{ik_\parallel \cdot r} \zeta(k_\parallel - k_\parallel^{(0)})$$

$$\times \int dz' \, d_{\mu\nu}(k_\parallel^{(0)}zz') \delta(z') \, E^{(0)}_\nu(k_\parallel^{(0)}z'z') \hspace{1cm} (5.7)$$  

Here, $E^{(0)}$ is the total field for a perfectly flat boundary, and $\zeta$ and $d_{\mu\nu}$ are the Fourier transforms of the profile function and the Green tensors, respectively, as given in Ref. 19. The evaluation of the $\delta$ functions for discontinuous fields across a boundary is understood to follow MM together with Agarwal's prescription.  

To illustrate this dynamical theory, we consider the simple case of a perpendicular dipole located at $(0,0,d)$ above a shallow sinusoidal grating. After application of the CPS theory for the calculation of $E^{(0)}$, we obtain to lowest order in $\zeta$
\[ E_R^z(d; \omega) = -iuk^3 \frac{(\varepsilon - 1)}{4\pi^2} \int d^2k_\parallel \xi(k_\parallel) \frac{k_\parallel^2 e^{ik_2d}}{k_1 - ck_2} \int_0^\infty du (1-R_p) \frac{u^3}{k_1} e^{-\frac{1}{2}u} , \quad (5.8) \]

where

\[ k_1 = -[\varepsilon(\omega)k^2 - k_\parallel^2]^{1/2}, \]

\[ k_2 = \begin{cases} (k^2 - k_\parallel^2)^{1/2}, & k^2 > k_\parallel^2 \\ i(k^2 - k_\parallel^2)^{1/2}, & k^2 < k_\parallel^2 \end{cases} \quad (5.9) \]

For \( \xi(x,y) = \xi_o e^{iQx} \) we obtain

\[ \xi(k_\parallel) = (2\pi)^2 \xi_o \delta(Q - k_\parallel), \quad (5.10) \]

where

\[ Q = Q_o \quad (5.11) \]

Equation (5.8) finally yields

\[ G_{ET} = \frac{E_R}{\mu} = -ik^3 \xi_o (\varepsilon - 1) \frac{Q^2 e^{ik_2d}}{k_1 - ck_2} \int_0^\infty du (1-R_p) \frac{u^3}{k_1} e^{-\frac{1}{2}u} , \quad (5.12) \]

where \( k_1 \) and \( k_2 \) are now defined as in Eq. (5.9) with \( k_\parallel \) replaced by \( Q \).
Previously, we have also solved the same problem by the image method through the application of the image theory for a rough boundary, established by Rahman and Maradudin. The result thus obtained can be expressed as

\[ \varphi_{\text{IT}}^R = \frac{4\varepsilon_0}{v} \frac{\varepsilon-1}{(\varepsilon+1)^2} \int_0^\infty \int_0^\infty dv (\varepsilon f + h) \exp[-(f+g)d] , \]  

(5.13)

where \( f, g \) and \( h \) are functions of \( u \) and \( v \), given by

\[ f(u,v) = \left( (u+\frac{Q}{2})^2 + v^2 \right)^{\frac{1}{2}} , \]

\[ g(u,v) = \left( (u-\frac{Q}{2})^2 + v^2 \right)^{\frac{1}{2}} , \]

(5.14)

\[ h(u,v) = u^2 + v^2 - \frac{Q^2}{4} . \]

Hence for this problem, according to Eq. (5.6), Eqs. (5.4) and (5.13) provide a complete description of \( A \) within IT, whereas Eqs. (5.5) and (5.12) provide a complete dynamical theory (ET) for \( A \). We have carried out detailed numerical studies of these results for different metal substrates such as Ag, Au, Cu and Ni, where both \( \omega \) and \( d \) were varied. For illustrative purposes, we have reproduced some results in Fig. 2. In general, we arrive at the following conclusions: \( ^{14,17,18} \) (i) IT can be very inaccurate for both flat and rough surfaces in the case of a highly-conducting substrate or for large molecule-surface distances; (ii) the surface-plasmon effect can cause serious damping when \( \omega \) is close to the resonance frequency; (iii) surface roughness can either enhance or diminish the flat-surface value for this induced decay, depending on \( \omega, d \) and the orientation of the admolecule.
Although we have most of the time considered the sinusoidal grating as a prototype of rough surfaces, other kinds of roughness have also been considered in the literature. As an example, Arias, Aravind and Metiu\textsuperscript{13} have constructed an IT for admolecules at surfaces with randomly-distributed (Gaussian) roughness. To extend ET to this case, one has to include contributions to $E(\omega)$ which are second order in $\zeta$,\textsuperscript{18} since the first-order contribution will vanish in this case. Nevertheless, we expect that similar comparisons will be obtained as in Fig. 2.

VI. CONCLUSIONS

In this paper, we have summarized some of our recent results on the spectroscopic properties for atoms as well as molecules in the vicinity of a dielectric surface. For the case of adatoms near a flat surface, a fully quantum electrodynamical (QED) treatment has been followed where the atomic lifetimes, polarization of the atomic dipole and photon correlation phenomena have been analyzed. For the case of a molecular dipole in the vicinity of a rough metallic surface, a simpler classical phenomenological approach has been followed to establish a dynamical theory of the surface-induced decay rates. It is found that the hitherto available static (image) theory has very limited validity. Future directions in this research may involve a more exact QED treatment for the case of rough surfaces (along the same lines as we did for flat surfaces), as well as possible nonlinear surface spectroscopy due to a high-intensity laser field or special surface properties. To this later aspect, we have recently looked into the possibility of applying the technique of optical phase conjugation by a surface\textsuperscript{22} to study possible novel spectroscopic phenomena for a system of molecules in the vicinity of such surfaces.

FIGURE CAPTIONS

Fig. 1. Plot of the parallel (curve a) and perpendicular (curve b) inverse lifetimes as a function of the relative permittivity $\varepsilon$, and in the limit of a zero atom-surface distance. For $\varepsilon \rightarrow \infty$ the curves approach the values $b_\parallel(0) = 0$ and $b_\perp(0) = 2$, corresponding to a perfect conductor. We notice that $b_\parallel(0)$ is almost independent of $\varepsilon$ and approximately equal to zero over the entire $\varepsilon$ range. Only for $\varepsilon \rightarrow 0$ does it attain a finite value. From curve b we see that $b_\perp(0)$ gradually changes as a function of $\varepsilon$, and that it never reaches its perfect-conductor limit for any reasonable value of $\varepsilon$.

Fig. 2. Comparison between the energy transfer theory (ET, solid curves) and the image theory (IT, dotted curves) for decay rates of admolecules. Curves a and b are the values of $\text{Im}G^R$ for an Ag grating substrate ($\zeta_0 = 0.7\text{Å}, Q = 0.01 \text{Å}^{-1}$) at $\omega = 2.5 \text{eV}$, and curves c and d are the values of $\text{Im}G^F$ for a flat Ni surface at $\omega = 3.3 \text{eV}$. The unit of G is $\text{Å}^{-3}$. The role of the substrate conductivity is evident from these graphs.
