ABSTRACT

A low speed wind tunnel investigation was conducted to examine the aerodynamic characteristics of the flowfield around a three percent scale YF-17 lightweight fighter prototype model at high angles of attack using flow visualization and force and moment measurements. Smoke filaments, injected into the wind tunnel test section, were illuminated by a laser sheet to highlight flow phenomena about the model. Force and moment measurements were made using a precision six-component strain gage balance. The investigation marked the first attempt at qualitative flow analysis using the laser sheet flow visualization system recently installed in the Naval Postgraduate School low speed wind tunnel facility. The investigation was undertaken to specifically identify flow phenomena and/or regions of interest that may have bearing on the design and performance of supermaneuverable aircraft. The data indicate a good correlation between the observed flow phenomena and force and moment measurements at various angles of attack, thus establishing the credibility of such experimental investigations for high angle of attack aerodynamic research.

ACKNOWLEDGMENT

This thesis was funded, in part, by the Naval Air Systems Command in support of the continuing high angle of attack research effort being conducted under the Navy-NASA Joint Institute of Aeronautics and Astronautics.

My gratitude goes to my thesis advisor, Professor S. K. Hebbar, for his guidance and encouragement throughout the months of preparation and data collection required to complete this project. Special acknowledgment is given to, and in memory of, the late Professor Satyanarayana Bodapati who was such a driving force behind the Navy-NASA Joint Institute.

I would also like to thank the many people at the Naval Postgraduate School who provided the services and expertise necessary for this research. In particular:

- Mr. John Moulton, Aeronautics Metal Shop
- Mr. Jack King, Aerolab
- Mr. Andy Sarakon and Mr. Mitch Nichols, Photo Lab

Finally, I acknowledge the sacrifices made by my wife and son in their support of my efforts.
I. INTRODUCTION

A. BACKGROUND

The survivability and tactical effectiveness of a modern fighter aircraft must be evaluated in a great many scenarios ranging from engagements which occur beyond the visual range of the pilots, to close-in, air-to-air combat or "dogfighting". In the close-in engagement, maneuverability becomes one of the most important factors in deciding the outcome of aerial combat [Ref. 1 and 2]. Maneuvering aggressively can rapidly deplete an aircraft's energy and result in rapid deceleration to low speeds and high angles of attack. Flight in this regime often results in exceeding the aircraft performance capabilities producing stalls and loss of control. Expanding the maneuvering envelope boundaries of tactical aircraft to include controlled flight in the low speed, high angle of attack regime is a primary concern of today's aircraft designers. Studies have shown that the ability to perform rapid, transient maneuvers, even into post-stall flight, can greatly enhance an aircraft's air combat capability and significantly improve mission success. These capabilities are highly dependent upon maintaining a high degree of control effectiveness throughout the maneuvering angle of attack range and about all aircraft axes [Ref. 3].
The optimum and maximum angles of attack are highly dependent on the scenario and vary greatly between offensive and defensive maneuvering. Offensive maneuvering requires the pilot to accurately position himself for employment of the specific weapon he has chosen to use in the engagement. This may require absolutely smooth tracking and precise control response in the case of guns or a momentary point and shoot maneuver in the case of IR missiles. Defensive maneuvers, on the other hand, are more commonly carried out at higher angles of attack which are usually past the point of airframe buffet where the concern is not handling accuracy but radical maneuvering to deny the enemy a weapons solution. Defining and expanding the maneuvering envelope at high angles of attack can provide the modern combat pilot the tactical flexibility needed to achieve superiority [Ref. 2].

The drive to obtain supermaneuverability has begun in great earnest. Post-stall (PST) capability up to at least 70 degrees angle of attack and direct force (DFM) control to allow yaw and pitch control independent of flight path have been identified as two related capabilities which hold the greatest promise. PST is seen as a capability required to maneuver the aircraft into an either offensive or defensive position as the situation dictates. DFM would be used primarily to obtain weapons firing solutions once the advantage had been gained [Ref. 4]. In a recent study using numerical optimization techniques it was shown that PST
capability enabled large turn rates and reduced the area required for maneuvering [Ref. 5]. The X-31 aircraft has been designated the first supermaneuverable aircraft and will attempt to exploit these two concepts.

Though not designed for supermaneuverability, many recently developed aircraft have achieved improved high angle of attack performance by incorporating innovative aerodynamic design features. The Northrop Corporation developed the hybrid wing concept in the late 1960's and applied it to the YF-17 lightweight fighter prototype in 1972 in direct response to the challenge of achieving maximum lift and angle of attack while maintaining positive stability and control. The hybrid wing planform of the YF-17 results from the combining of a conventional wing with moderate sweepback and aspect ratio with a wing root leading edge extension (LEX), also known as a strake. Figure 1 illustrates these two concepts in their combined form. The conventional wing maintains attached flow to moderate angles of attack where the flow separates resulting in buffet and eventual stall. The LEX induces a vortex flow which increases in strength with increasing angles of attack. The stable vortex flow creates an area of high negative pressure on the wing upper surface which increases lift and delays separation of laminar flow on the basic planform. The flight envelope of the aircraft is expanded by the improved stability and control of the aircraft in the high angle of attack regime. [Ref. 6]

Figure 1. Hybrid Wing
As a prelude to engaging in supermaneuverability research at the Naval Postgraduate School, this investigation was undertaken to characterize the flowfield around a fighter aircraft model, specifically, the YF-17. The capabilities of the recently installed laser sheet flow visualization system [Ref. 7] in the low speed wind tunnel facility of the Department of Aeronautics and Astronautics, were adapted for extensive flow visualization of the flowfield about the model. In addition to flow visualization data, measurements were made to obtain force and moment data on the model and the correlation between these two data sets examined to provide insight into areas of aerodynamic interest.

The focus of the current experimental investigation of high angle of attack aerodynamics included:

1. Flow visualization to enhance understanding of the basic aerodynamic phenomena
2. Force and moment measurements at high angles-of-attack and moderate roll and yaw angles
3. Study of the correlation between the observed flow and measured forces and moments

Much of the research to date has been concerned with the effect of isolated aerodynamic mechanisms in an attempt to predict and examine their effect. The intent of this investigation was to gain insight into the high angle of attack behavior of a current fighter aircraft as a whole, not just concentrating on the effect of singular concepts at work
in the design such as the hybrid wing. Once a complete mapping of the flow over the aircraft has been accomplished the interaction of the various lift and drag generating devices can be interpreted and a methodology created to design for enhanced high angle of attack performance. Particular attention has been paid to the effect of forebody generated vortices and their effect on the forces and moments which were measured. A great deal of work has been done on this phenomena, especially in regard to missiles. The results achieved thus far have been far from conclusive and it is hoped this investigation will add to the available literature in a positive manner.

Expected observations include:

1. Increased asymmetrical vortex shedding from the nose section forward of the LEX's as the angle of attack increases. This should be recognizable by an increase in generated side forces.

2. LEX generated vortices should increase in strength through moderate to high angles of attack eventually bursting thus losing their lift enhancing effect.

3. Flow over the wing should remain attached through moderate angles-of attack separating first at the wingtips then moving in gradually with increasing angle of attack. The LEX induced vortices should keep the inboard flow attached until higher angles of attack are
reached where the vortices will burst and lose their effectiveness.

Although the experimental work accomplished in this thesis has been substantial, it is by no means complete. A continuing effort at the Naval Postgraduate School will examine the flowfield characteristics and behavior at high angles of attack using laser Doppler velocimetry (LDV) and hotwire anemometry. This should lead to a thorough investigation and a better understanding of the effects of high angle of attack flight.

B. HIGH ANGLE OF ATTACK AERODYNAMICS

The separation of flow from the body of an aircraft exerts considerable aerodynamic forces that must be understood and controlled if true supermaneuverability is to be realized in our next generation of tactical aircraft. The increasing design complexity of modern aircraft, which includes vortex generating strakes, forward swept wings, canards and leading edge wing snags complicates the flow behavior in ways that are often not understood until well after an aircraft has entered service. This is so, in spite of knowing the high angle of attack characteristics of fighter aircraft are highly configuration dependent [Ref. 3].

Conventional aircraft controls have limited capability at high angles of attack. The yaw control provided by a conventional rudder decreases with increasing angle of attack as the tail becomes blanketed by the stalled flow from the
wing. Previous studies show that improvement of rudder effectiveness may not be possible. Reduced maneuvering capability results from inadequate yaw control just when maximum effectiveness is required. The long, slender nose of the modern fighter aircraft also contributes to the problem by producing powerful vortex flowfields at high angles of attack. The side forces generated by the asymmetric shedding of these vortices coupled with the long moment arm from the nose to the aircraft's center of gravity present a control problem of significant proportion. [Ref. 3 and 8]

The aerodynamics of vortex generation from slender bodies is well documented [Ref. 9, 10 and 11]. Reding and Ericsson [Ref. 11] describe the phenomena as consisting of four regions in which characteristic vortices induce angle of attack dependent forces and moments. At very low angles of attack the flow is vortex free. As the angle of attack increases symmetric vortices are formed at the nose which gain strength as the angle of attack gets higher and higher. Eventually the angle of attack reaches a point at which the vortices become asymmetric which create side forces on the body. These vortices are relatively steady but can alternate positions near the point of maximum side force generation. Finally, the angle of attack increases to the value where the flow separation becomes unsteady. The side forces decrease to zero while the normal force becomes nearly constant [Ref. 12]. Figure 2, reproduced from [Ref. 13], illustrates the
various regimes as they affect a slender body of rotation with an ogive nose. Forebody vortex management has been suggested as a means of yaw control for aircraft operating at high angles of attack. Strakes, conformally attached in the nose section, would deploy to generate asymmetric vortex shedding thus providing controlled yaw [Ref. 14].

The lifting surfaces of an aircraft influence the actual effect shedding vortices have. Flow around the sharp leading edge of a delta wing forms vortices which increase in strength with increasing angle of attack (see Figure 3). LEX's, discussed previously, are merely highly swept delta wings purposely designed to take advantage of the increased lift generated by these vortices. The body vortices also interact with the LEX's up to certain angles of attack to improve the lift performance of the basic planform. [Ref. 13]

C. FLOW VISUALIZATION

Flow visualization has been an important tool in the understanding of fluid dynamics for many years. As early as 1883, when Osborne Reynolds used dye in water to visualize flow through a glass tube, scientists have realized the value of visual cues in unraveling the physical mysteries of fluid mechanics [Ref. 15]. There are numerous techniques by which flow is made visible. Flow visualization by laser sheet and water tunnel dye injection are two of the most recent developments which are proving most valuable in high angle of attack research. Sophisticated water tunnels with dye
Figure 3. Vortex Flow about a Delta Wing

jecting models provide the researcher with a three dimensional view of flow phenomenon. Observation of the flow as it reacts to aircraft movement, offers the capability to understand the dynamics of flow around the entire body of an aircraft. The vortex dominated flows typically generated by the new missile and aircraft designs of the early 1970's were responsible for the increasing use of water tunnels because wind tunnels lacked the capability to provide the required definition [Ref 16].

Figures 4 and 5 illustrate the details of complex flowfields available through water tunnel flow visualization. The vortices generated by the forebody of the aircraft are
Figure 4. Pitch = 50°

Figure 5. Pitch = 70°
clearly visible as are the differences between the flow patterns at the two angles of attack. These are typical water tunnel flow visualization results achieved in the Naval Postgraduate School water tunnel flow visualization facility with a 1/48 scale model of an F/A-18 aircraft.

Flow visualization by laser sheet combines a tracer material in the flow with a thin sheet of laser light to provide a two dimensional representation of local flow behavior. Laser light has been a proven method of illumination for years and continues to be used in various capacities for flow research [Ref. 17]. This was the flow visualization method employed in this investigation and will be discussed in detail in the following section.

A recent study by Malcolm and Nelson [Ref. 18] addressed the relationship between the results obtained in testing in both wind tunnels and water tunnels. Using identical models and operating both tunnels at the same Reynolds number, the results showed the vortex characteristics to be almost identical. The study goes on to compare results with both tunnels running at different Reynolds number. For low speeds, vortex behavior exhibited only minor differences between the two mediums. It is concluded that both techniques are eminently suitable for the study of vortex flowfields.

Detailed study of the flowfield cross sections, accomplished for specified flight regimes in this
experimental investigation, is the first step toward understanding the physics of the phenomena and ultimately achieving true supermaneuverability in combat aircraft. Controlled flight at high angles of attack will require the designer to be innovative and resourceful to fully utilize the ever changing flowfield about the aircraft. True supermaneuverability will, no doubt, involve a combination of vectored thrust and active aerodynamic controls.
II. EQUIPMENT AND PROCEDURE

A. APPARATUS

Major equipment required to complete the experimental portion of this thesis included:

1. A low-speed wind tunnel
2. A fighter aircraft model and necessary support structures
3. A flow visualization system
4. A six-component strain gage balance
5. Data acquisition hardware/software

Information concerning the specifications, construction and configuration of all equipment used is provided in this section.

1. Wind Tunnel

Experimental investigations were carried out at the Naval Postgraduate School wind tunnel test facility. The tunnel is a horizontal flow low-speed design from the Aerolab Development Company of Pasadena, California, installed in the mid-1950's. It is a single return tunnel which measures 64 feet in length and varies between 21.5 and 25.5 feet in width (see Figure 6). The wind tunnel is powered by a 100 horsepower electric motor which drives a three-blade variable pitch fan through a four-speed transmission. Turning vanes located in all four corners and a set of stator blades directly downstream of the fan straighten and smooth the
Figure 6. Low Speed Wind Tunnel
airflow. Two fine-mesh wire screens immediately prior to the settling chamber breakdown any remaining turbulent fluctuations. The contraction ratio between the settling chamber and the test section is approximately 10:1. A heavy wire mesh screen at the end of the test section diffuser guards against foreign object damage to the fan blades. [Ref. 19]

The test section of the tunnel operates at atmospheric pressure and measures 45 inches wide by 32 inches high, with corner fillets that contain the test section lighting and alleviate boundary layer effects at the wall intersections. The walls of the test section also diverge slightly to compensate for contraction effects due to boundary layer growth. Breather slots located immediately downstream of the test section allow air to enter the tunnel circuit to make up for losses due to leakage and ensure the test section pressure remains uniform. Available test section height is reduced to 28 inches by a horizontal reflection plane located in the middle of the test section floor. A remotely controlled turntable in the center of the reflection plane allows for model mounting and variable pitch angles. Access to the test section is through hinged windows located on either side or through a removable plexiglass insert on top. [Ref. 19]

Flow measurement components integral to the wind tunnel are a dial thermometer, a water manometer and a test
section pitot static tube. The dial thermometer measures temperature in the settling chamber. The water-filled manometer is used to measure the static pressure difference between the test section and the settling chamber. Each section has four static pressure taps, one on each wall, connected to a common manifold. The manifolds feed into the manometer where the pressure difference in centimeters of water gives the test section dynamic pressure. The taps in the test section are located at the entrance to preclude any induced errors from model interference. Actual test section velocity is determined by the following equation: [Ref. 19]

\[
U_m = \left(\frac{2 \times 2.046 \times \text{cm } H_2O}{0.93 \times \rho}\right)^{0.5}
\]

where:

- \(U_m\) = measured velocity (ft/sec)
- 2.046 = conversion factor
- \( \text{cm } H_2O\) = manometer reading in cm of \(H_2O\)
- 0.93 = settling chamber total pressure correction
- \(\rho\) = air density (lbm/ft\(^3\))

A digital readout of the test section dynamic pressure is provided through a pressure transducer circuit connected to the manometer. Greater accuracy is available with the digital readout once it has been calibrated. The test section pitot tube system provides only approximate velocity readings through an airspeed indicator starting at 40 knots.
2. Fighter Model

The fighter model is a three percent scale model of the Northrop Corporation's YF-17 lightweight fighter prototype (see Figure 7 and 8). The model was fabricated by the company's Aero Sciences branch in the early 1970's from steel and aluminum and has provisions for variable flap settings and wingtip missiles. The balance block section of the model accommodates a one-inch precision balance and contains the balance attachment and locating pin.

The YF-17 was the prototype aircraft from which the McDonnell Douglas F/A-18 evolved. The model was utilized by Northrop for extensive subsonic and supersonic wind tunnel testing of the hybrid wing concept discussed earlier. Key dimensions of the model are listed below: [Ref. 20]

1. Total length = 19.125 in.
2. Wing span = 12.60 in.
3. Wing area = 45.36 in.²
4. Wing MAC = 3.88 in.
5. Frontal area = 2.88 in.²
6. Planform area = 89.28 in.²
7. Side area = 53.42 in.²

The longitudinal axis scaling in Figure 7 is included to provide a visual reference for discussion of the flow visualization results.
Figure 7. YF-17 Scaled Planform View (TOP)

Figure 8. YF-17 Lightweight Fighter Prototype Model
3. Balance

A one-inch diameter Task Corporation balance was used for force and moment measurements (see Figure 9). The six component strain gage precision balance was on loan to the Naval Postgraduate School from the NASA-Ames Research Center under provisions of the Navy-NASA Joint Institute of Aeronautics. The balance calibration data and data conversion values were provided by NASA and are listed in Appendix A [Ref. 21]. Two strain gages each are dedicated to normal and side force measurements while axial force and rolling moment utilize one gage apiece. Each gage has a separate channel for excitation and output. Table 1 lists...
the balance channel capacities and accuracies. All accuracies are based on maximum load.

The model was constructed with a close tolerance machined channel specifically designed for use with the Task balance. A locating pin through the top of the model secures the model to the balance and locates the balance center with the approximate center of pressure of the model.

4. Model/Balance Support

The model is supported by the balance which is connected to a balance support or sting. The sting extends aft of the model and fits securely into a rigid vertical swinging arm assembly which is securely fixed to the reflection plane turntable at the base and supported by a one-inch steel pin through the three-quarter-inch thick plexiglass viewing window on top (see Figures 10 and 11).

Figure 10. Fighter Model in Wind Tunnel

Figure 11. Fighter Model Viewed From Side Window
The sting mount and swinging arm assembly permit pitch angles of -35 degrees to +90 degrees, yaw angles of plus or minus 5, 10 or 15 degrees, and 360 degrees of roll. The arm assembly pivot point, model center of pressure and balance center all coincide. The effects of vibration are kept to a minimum by heavy duty construction and the cross sectional areas of the mount assemblies are such that the effect on the test section airflow is minimal. The turntable is supported by a heavyweight pedestal that rotates via an electric motor powered chain drive gear assembly. Pitch angle and pitch rate can be controlled manually or through the computerized data acquisition system. Pitch angles are read to an accuracy of 0.1 degrees through a ring scale located on the pedestal.

5. Flow Visualization System

A flow visualization system using smoke and a laser sheet for illumination was installed in the low speed wind tunnel [Ref. 7]. Major components of the system include a portable smoke generating machine, a portable smoke rake and smoke tube, a 5W Argon-ion laser and associated optics mounted on a traverse mechanism to permit complete coverage of the wind tunnel test section. Each major component is briefly discussed below. The reader is directed to Reference 7 for detailed information on the entire flow visualization system.
A Rosco model 1500 Fog/Smoke machine, originally intended for theatrical use provides smoke through the vaporization of fluid specifically designed for use with the machine. The operating temperature, pressure and exit nozzle are factory set and not adjustable. The volume of smoke produced is adjustable and can be controlled via a 25-foot remote control. The smoke has proven to be safe to use and suitable for illumination by laser sheet. [Ref. 7]

The smoke is injected into the wind tunnel airstream through either a 21-tube smoke rake or a single outlet smoke tube. The smoke is fed to the injection device via a three-inch diameter flexible hose. The smoke rake tubes are 3/16 inch in diameter, 18 inches in length and spaced one and one-half inches apart along the trailing edge of the rake airfoil. The single outlet smoke tube also attaches to the three-inch smoke feed hose. The smoke enters a cylindrical settling chamber, passes through a honeycomb flow straightener and then exits a one-inch diameter tube after going through a 10:1 contraction section. Both injection devices are designed to allow positioning at varying locations in the tunnel to ensure adequate coverage for all anticipated model configurations and pitch angles.

A Spectra Physics, Model 164, 5W Argon-ion laser provides illumination of the smoke. Laser output is routed to the light sheet optics through a ten-meter long fiber optics cable which simplifies the physical set-up of the
system and greatly enhances the safety. The light conversion optics, which consist of a collimator, a beam expander and a plano-cylindrical lens create a laser sheet which is approximately two millimeters thick. The entire optics set is mounted on a six-inch rail which is attached to a traverse mechanism designed to provide horizontal and vertical travel through the entire test section.

6. Data Acquisition Hardware

Figure 12 shows the data acquisition system hardware components required to support the use of the Task balance [Ref. 13]. In addition to the thermometer and manometers discussed earlier a data acquisition circuit is necessary to utilize the balance output. A signal conditioning circuit for each individual strain gage in the balance supplies voltage for calibration and zeroing. The signal conditioner output is fed to a Hewlett-Packard relay multiplexer which sequentially cycles through each balance channel as specified by the data acquisition software. An amplifier (1000 gain, low noise) boosts the output signal to improve resolution after which the analog voltage signal is converted to a digital signal by a Hewlett-Packard digital multimeter for use in the data acquisition software program. An IBM-AT microcomputer controls data acquisition and model positioning during the experiment and stores the collected data.
Figure 12. Data Acquisition Hardware
7. Data Acquisition Software

The data acquisition program is listed in Appendix B. A shell program controls the Hewlett-Packard instrument package and a data collection/conversion program transforms each balance channel's output into a compatible format. The balance readings are time averaged and combined with the appropriate calibration constants (Appendix A), to present normal, side and axial force values in pounds and pitching, rolling and yawing moments in foot-pounds. The two balance channels for normal force and two balance channels for side force are combined in this process to give but one reading for each. These readings are then converted to coefficient form by the computer program listed in Appendix C for ease of data comparison. Conversion of the data to coefficient form allowed comparison of data among the various angles of attack taking into account the test section differences due to model blockage. The force coefficients were obtained by nondimensionalizing forces with the free stream dynamic pressure and the frontal area of the model. Moment coefficients were calculated using the above parameters and a balance reference length of one.

B. EXPERIMENTAL CONDITIONS

The goal of the experiment was to measure the effects of low speed, high angle of attack flight on the aircraft as a whole and gain an understanding of the physics involved through flow visualization.
To meet this goal, the experiment was carried out in two phases. The first phase involved the measurement of forces and moments on the model for angles of attack varying from -35 degrees to +85 degrees at speeds of 10 m/s, 35 m/s and 50 m/s. The second phase involved extensive flow visualization of the model for the same angle of attack range at a velocity of 10 m/s. Flow visualization using one-inch smoke tube was accomplished first in an attempt to gain an appreciation for the overall effect of various flow patterns on the aircraft dynamics.

C. EXPERIMENTAL PROCEDURE

1. Balance Calibration

Calibration of the Task balance was carried at the NASA Ames Calibration Laboratory. The necessary balance constants and individual channel accuracies were determined and are listed in Appendix C. The balance was mounted on the model support system and the entire assembly installed in the wind tunnel. The model was not mounted at this time. The balance output leads were connected and the data acquisition hardware energized. A balance channel excitation voltage of 5.00 DC volts was then applied through the signal conditioner. Variation of the excitation voltage was less than 0.003 volts. The data acquisition system was then allowed a warm-up period of one hour prior to use. A gain setting of 1000 was used as the signal amplifier was zeroed and each balance circuit was zeroed to within 200 nanovolts.
across the wheatstone bridge circuitry. Prior to mounting the model calibrated weights were suspended from the balance and the data acquisition software run to compare balance output with the calibration specifications. The normal and side force readings were accurate to within 0.05%. The model was then mounted on the support assembly and the initial tare readings were obtained. The data acquisition system remained energized through the completion of the experimental procedures to maintain the balance circuit excitation voltages.

2. Prerun Calibration and Testing

Prior to each day's run the data acquisition system was cycled for approximately 30 minutes to allow the circuitry to settle at operating temperature. The static weight test was then repeated with the model mounted to ensure the balance circuits were still within calibration accuracy. If a discrepancy was noted, the model was removed and the balance calibration procedures repeated.

3. Data Collection

Data collection was divided into two separate stages. In the first stage force and moment data were taken. Runs between -5 and +5 degrees angle of attack at test section velocities of 10, 35 and 50 meters per second were made to determine the zero-lift angle of attack. After this determination runs at the same three velocities between -35 and +85 degrees angle of attack in increments of five degrees
were completed. Finally, repeated runs at 50 m/s were accomplished for angles of attack between 15 and 70 degrees angle of attack. The Reynolds number at 50 m/s was $3.49 \times 10^5$. This value is based on the mean aerodynamic chord of the model (3.88 inches).

In the second stage of the investigation, flow visualization was accomplished using the one-inch smoke tube at a velocity of 10 m/s. Cross sectional photographs of the flow over the model were taken to identify the areas most likely affected by vortex generation and separation.

D. EXPERIMENTAL CORRECTIONS

Corrections to account for model blockage were calculated from the following equations [Ref. 22]:

\[
q = q_m(1+2\varepsilon)
\]
\[
U = U_m(1+\varepsilon)
\]

where:

- $q = \text{dynamic pressure (lb/ft}^2$)
- $q_m = \text{measured reference pressure (lb/ft}^2$)
- $U = \text{horizontal velocity (ft/sec)}$
- $U_m = \text{measured horizontal velocity (ft/sec)}$
- $\varepsilon = \text{blockage factor}$

and:

\[
\varepsilon = 0.25*\left(\frac{\text{model frontal area}}{\text{test section area}}\right)
\]

The model frontal area was highly angle of attack dependent.
The blockage corrections are shown in Table 2 and Figure 13. These corrections are applied in the data conversion program listed in Appendix C. The minimum and maximum values for percent blockage are based on the cross sectional areas of the model at zero and 90 degrees angle of attack, respectively. A linear interpolation between these values was then used to generate a blockage formula which was angle of attack dependent.

Figure 13. Blockage Correction Factors
III. RESULTS AND DISCUSSION

The results of this investigation are presented and discussed in two parts. First, a series of 32 photographic sequences of flow phenomena will be presented and analyzed. Second, the force and moment data collected in the investigation will be examined.

A. FLOW VISUALIZATION DATA

Flow visualization by laser sheet, though a very recent development, has already proven to be of enormous value in the detailed study of flow structure [Ref. 17]. The system installed in the Naval Postgraduate School low speed wind tunnel test facility certainly provides this capability but is not without its limitations. Problems with the flow quality in the tunnel test section and with smoke injection techniques were recognized by Chlebanowski when the flow visualization system was installed [Ref 7]. Consequently, this investigator's initial efforts were directed toward determining what improvements, if any, could be made in the basic system prior to its use in this high angle of attack research project. A summary of these efforts and the results are included in Appendix D.

In excess of 900 frames of 35mm black and white film were exposed and over nine hours of videotape recorded during the investigation. The results of the 35mm photography are
presented in a series of 32 numbered photographic sequences which are presented as Figures 14 through 130 in Appendix E. Each sequence is listed below with the corresponding figure numbers and an analysis of the observed flow phenomena. Results are presented depending on aircraft orientation in the three categories of pitch only, pitch and roll and pitch and yaw. Model attitude was varied between 0 and 90 degrees of pitch, 0 and 45 degrees of roll and 0 and 15 degrees of yaw. The majority of flow visualization photography was performed between 20 and 70 degrees of pitch and to the maximum values of roll and yaw previously specified. "Station" refers to the number of inches aft of the nose at which the laser sheet cuts the longitudinal axis. Table 3 lists some prominent stations and model features at these locations. Figure 7 is scaled for visual reference.

1. Pitch Only

Sequence Number 1, Figures 14 through 18. Figure 14 shows a pair of symmetric nose generated vortices at station 2 and 45 degrees angle of attack. Increasing the angle of attack to 50 degrees results in the asymmetric vortices shown in Figure 15. As the laser sheet scans from station 2 to station 6 the development of the asymmetric flow can be traced until both vortices have been shed from the aircraft model. This flow behavior is well-documented for slender forebodies such as the nose section of the YF-17.

Sequence Number 2, Figures 19 through 21. This series of three photographs taken at stations 1, 3 and 5 and 65 degrees angle of attack show the vortices rapidly becoming asymmetric and shedding from the body of the model. Figure 19 clearly shows the vortices already becoming asymmetric although the photograph was taken at station 1. Figure 20, taken at station 3 shows no evidence of vortex flow and Figure 21, at station 6 shows the expected wake-like flow.

2. Pitch and Roll

Sequence Number 3, Figures 22 through 24. This sequence shows the change in vortex symmetry at station 1 as the roll angle is increased from 15 degrees to 45 degrees with the pitch angle held constant at 65 degrees. Comparison of Figure 22 with Figure 19 shows little change in the
orientation of the two vortices other than a slight separation of the bottom vortex from the nose surface. Figure 23 shows the development of a significant separation of the bottom vortex which increases as the model is rolled to 45 degrees in Figure 24. The nose geometry of the YF-17 is a major factor in this phenomenon.

Sequence Number 4, Figures 25 through 27. The roll angle is increased from 15 degrees to 45 degrees at station 1 as in the previous sequence but at a reduced angle of attack of 55 degrees. The degree of asymmetry between the various roll angles is much less severe than at the higher angle of attack.

Sequence Number 5, Figures 28 through 31. With the laser sheet positioned at station 2 and angle of attack set at 65 degrees the effect of changing roll angle is evidenced by the asymmetry which was also evident at station 1. It is interesting to note the degree of separation between the two vortices and their position relative to one another.

Sequence Number 6, Figures 32 and 33. A comparison of nose generated vortex positions at station 6 with the model at 60 degrees angle of attack and roll angles of 0 degrees and 45 degrees respectively shows the vortex closest to the body becomes stronger and better defined with the increased roll angle. The reduced relative angle of attack of the upwind side of the model appears to promote this behavior.
Sequence Numbers 7 through 11, Figures 34 through 63. This series of 30 photographs follows the development and shedding of nose generated vortices between 45 degrees and 70 degrees angle of attack from model stations 2 through 6 at 15 degrees of roll. Comparisons between the degrees of asymmetry, vortex shedding points, and turbulent flow transitions are possible with a great amount of continuity. Photographs taken at station 2 reveal the effect changing pitch and changing yaw. Figures 34 through 39 reveal the bottom vortex sheds sooner with increasing pitch while the top vortex weakens but remains attached to the fuselage. At 70 degrees of pitch the flow is in transition from vortex to wake-like. Figures 34 through 39 confirm the increase in asymmetry with roll angle noted at station 1. Figures 40 through 45 illustrate how the vortices tend to rotate toward the centerline which had previously separated them when they were symmetric. Figures 44 and 45 also show the transition of the flow from asymmetric shed vortices to wake-like. The top vortex which barely remains attached in Figure 44 has separated and essentially disappeared in Figure 45. Photographs taken at station 4 are presented in Figures 46 through 51. Photographs taken at station 5, and included herein as Figures 52 through 57, clearly demonstrate the separation of the nose generated vortices from the body of the model aircraft. Between 50 and 55 degrees of pitch and the top vortex sheds and the flow rapidly becomes wake-like
in the vicinity of the fuselage. The vortices are still present but separated by a great distance from the model. At station 6, Figures 58 through 63 show the vortices separated from the body with completely wake-like flow occurring at approximately 50 degrees of pitch.

Sequence Number 12, Figures 64 through 69. With the laser sheet at station 4 and the roll angle set at 30 degrees the pitch angle was varied between 45 and 70 degrees angle of attack. When compared to the previous sequences which were recorded at 15 degrees of roll the degree of vortex asymmetry at first appears to be greater for the higher roll angle as the pitch angle increases. However, this trend reverses as the pitch angle passes approximately 55 degrees until there is virtually no difference in the flow patterns between the two roll angles.

Sequence Number 13, Figures 70 through 73. The laser sheet was held steady at station 7 while the model was pitched from 45 degrees to 60 degrees angle of attack at a constant roll angle of 30 degrees. The forebody vortex generated on the upwind side of the model has shifted over to the downwind side of the fuselage as expected and is easily seen in Figure 70. Increasing the angle of attack slightly to 50 degrees results in the separation of this vortex from the body. Further increases in the angle of attack reveal completely separated and turbulent flow at station 7 by 60 degrees angle of attack.
Sequence Number 14, Figures 74 through 76. With the model at 45 degrees angle of attack and the laser sheet positioned at station 8 the effect of rolling from 15 degrees to 45 degrees is dramatic. The strake generated vortex on the downwind side of the fuselage gains strength as can be seen by the tightening of the flow and improved definition of the vortex core. The reduction in relative angle of attack on the downwind strake with increasing pitch is responsible.

Sequence Number 15, Figures 77 through 79. The same phenomena present in the previous sequence is evident here at an angle of attack of 55 degrees. The difference between successive roll angles at the higher angle of attack is much more pronounced with the flow going from completely turbulent in Figure 77 to asymmetric and semi-attached at 45 degrees of roll in Figure 79.

Sequence Number 16, Figures 80 through 82. Increasing the angle of attack to 70 degrees and rolling from 15 degrees to 45 degrees reveals that reducing the effective angle of attack no longer causes the generation and strengthening of the vortices as was the case in the previous two sequences. The flow remains turbulent and wake-like at all roll angles.

Sequence Number 17, Figures 83 through 86. The disappearance of the upwind strake generated vortex and the stability of the downwind strake generated vortex are documented in this series of four photographs taken at
station 10 with the model angle of attack increasing from 25 degrees to 45 degrees and the roll angle held constant at 30 degrees. Station 10 is the point on the fuselage where the leading edge of the wing meets the leading edge of the LEX. At 25 degrees angle of attack strake generated vortices are visible on both sides of the fuselage. The left side vortex is slightly larger indicating less strength and stability. This is predictable given the higher relative angle of attack on that side. Increasing the angle of attack to 30 degrees cause the left side vortex to burst while the right side, or downwind vortex weakens slightly but remains intact. Figures 85 and 86 complete the sequence.

Sequence Number 18, Figures 87 through 89. At a constant 45 degrees angle of attack, the flow at station 10 is visible as the roll angle is increased from 15 degrees to 45 degrees. The completely turbulent flow seen in Figure 87 is altered drastically by the increasing roll angle as evidenced by the well developed vortex flow visible in Figure 89. The upwind side of the fuselage remains immersed in turbulent flow throughout.

Sequence Number 19, Figures 90 through 92. This series of photographs taken at station 10 with a roll angle of 45 degrees, shows little or no change in vortex position or strength as the angle of attack increases from 35 degrees to 45 degrees. The high roll angle keeps the downwind side
of the fuselage at a relatively low angle of attack thus minimizing the effects on that vortex in this regime.

Sequence Number 20, Figures 93 and 94. These two photographs illustrate the transition from vortex flow to turbulent flow. Figure 93 clearly shows the vortex core at station 11 on the downwind wing of the model at 40 degrees angle of attack and 30 degrees of roll. With the laser sheet at station 12, as in Figure 94, the vortex core is no longer visible and the smoke has dispersed to fill the entire illuminated region. The remains of the downwind forebody generated vortex are also visible in both photographs appearing as the large curls visible in the upper left portion of the laser sheet.

Sequence Number 21, Figures 95 through 97. The flow over the downwind wing of the model at 40 degrees, 35 degrees and 25 degrees is examined between stations 11 and 12 at a constant roll angle of 45 degrees. Figure 95, at 40 degrees, shows the existence of a single, strake generated vortex. Figure 96, at 35 degrees, reveals the presence of a small vortex located mid-span in addition to the expected strake generated vortex visible near the wing root. Figure 97, at 25 degrees clearly shows the presence of this mid-span vortex and indicates the increase in strength due to the reduced angle of attack. The second vortex was generated by the leading edge of the wing. Of secondary interest is the plume of smoke visible in Figure 97. This plume results from the
airflow through the boundary layer bleed air slots located between the LEX's and the fuselage. The slots were eliminated from the F/A-18 because of the deleterious effect they had on the strake generated vortices.

Sequence Number 22, Figures 98 through 103. At a constant 30 degrees angle of attack and roll the laser sheet was moved from station 8 to station 12. This series of photographs shows the degeneration of the downwind strake generated vortex to the point of bursting.

Sequence Number 23, Figures 104 through 108. Degeneration of the downwind strake generated vortex is examined at station 13 with the model increasing in angle of attack from 15 to 35 degrees. Roll angle remains constant at 30 degrees. As the angle of attack increases the vortex loses definition until it eventually cannot be distinguished from the turbulent flow over the remainder of the wing.

Sequence Number 24, Figure 109. This solitary figure is included because of an interesting observation in the photograph. The model is oriented at 25 degrees angle of attack and 15 degrees of roll. The LEX generated vortex visible on the upwind strake is at station 9. A second vortex, much smaller and of opposite rotational direction than the main vortex, can be seen inside the LEX vortex core. This secondary vortex appears to be generated by the sharp edge of one of the boundary layer bleed slots mentioned in a previous sequence.

43
3. Pitch and Yaw

Sequence Number 25, Figures 110 and 111. The difference in the formation of nose generated vortices is clear when comparing Figures 110 and 111. At a yaw angle of 5 degrees with the laser sheet at station 1 the model was pitched from 50 degrees angle of attack to 65 degrees angle of attack. The vortices in Figure 110 are nicely formed and very nearly symmetric. With the angle of attack increased to 65 degrees as in Figure 111, the vortices have already begun to go asymmetric. There was no evidence of vortex unsteadiness at the higher angle of attack.

Sequence Number 26, Figures 112 through 115. The rapid development of asymmetry and ultimate shedding of the vortex flow is detailed in this series of four photographs. The model is steady at 60 degrees angle of attack at a yaw angle of 15 degrees. The vortices are completely asymmetric at station 1 in Figure 112 although shedding has not yet occurred. By station 2, shown in Figure 113, the top vortex has been shed and the other vortex has weakened nearly to the point of separation. Figures 114 and 115 complete the flow development and provide a graphic depiction of the rapidity with which such a drastic change in the flow pattern can occur.

Sequence Number 27, Figures 116 through 119. With a yaw angle of 5 degrees and an angle of attack of 30 degrees, the bursting of the upper wing vortex is traced from station
10 to station 15. The loss of vortex coherence is clear when Figures 117 and 118 are compared. In Figure 119, the vertical tails are immersed in completely turbulent flow which has proven, in other investigations, to be a major factor in reducing the fatigue life of the tail structures.

Sequence Number 28, Figures 120 and 121. The two photographs in this sequence were taken less than two seconds apart at station 2 with the aircraft at a constant 50 degrees angle of attack and 5 degrees of yaw. The unsteadiness of the forebody generated vortices is evident when the orientation of the vortex cores are compared. Both vortices remained attached but never in the same place for very long.

Sequence Number 29, Figures 122 and 123. As in the previous sequence, the nose generated vortices visible in this pair of photographs taken only seconds apart show the great degree of unsteadiness in the flowfield. The laser sheet was positioned at station 3 with the aircraft at pitch and yaw angles of 55 degrees and 10 degrees respectively. The vortex cores are much larger than those in the previous figures due to the slightly higher yaw and angle of attack.

Sequence Number 30, Figures 124 through 126. The impact of angle of attack on the formation and structure of vortex flow is very evident in this series of three photographs. With the laser sheet at station 2 and the yaw angle set at 10 degrees the angle of attack was increased from 45 degrees to 65 degrees. Figure 124, taken at 45
degrees, shows the nose generated vortices relatively symmetric and attached. A marked degree of asymmetry in Figure 125 depicts the effect of increasing the angle of attack by 10 degrees to 55 degrees. At 65 degrees angle of attack, as in Figure 126, the vortices have completely separated yet maintain their asymmetry with respect to the fuselage of the model.

Sequence Number 31, Figures 127 and 128. Both figures are photographs taken of the model at 45 degrees angle of attack, 5 degrees of yaw and station 6. The pronounced difference is representative of the degree of unsteadiness which was present. Vortex core movement was of quite a large magnitude and extremely unpredictable.

Sequence Number 32, Figures 129 and 130. The only incidents of vortex position switching occurred with the model at a yaw angle of 5 degrees between 55 degrees and 60 degrees angle of attack. Figures 129 and 130 recorded such a switching episode at station 4 and 60 degrees angle of attack. The switching was quite random with the interval between averaging three to five seconds.

B. FORCE AND MOMENT DATA

Appendix F presents the raw force and moment data generated by the data acquisition program. The data is presented in graphic form, as Figures 131 through 142, for ease of interpretation. This raw data was processed through the coefficients translation program in Appendix C to
nondimensionalize the data, taking into account the test conditions and model blockage factors. The reduced data is presented in Appendix G as Figures 143 through 154. The differences between the raw data and the reduced data are minimal. The force and moment analysis that follows refers to the reduced data in Appendix G.

The normal force plots in Figures 143 and 144 show a characteristic rise with increasing angle of attack to a maximum value where the magnitude attains a near steady state even though angle of attack continues to rise. Figure 143 plots separate curves for each roll angle. The normal force coefficients are nearly equal through 30 degrees angle of attack where they start to level off and separate. At this point, the roll angle and normal force coefficient become inversely proportional with the highest roll angle experiencing the lowest normal force. This makes perfect sense in that the higher roll angle configuration presents less surface area. Leveling of the normal force curves can be correlated to the transition of the flow over the model from vortex flow to separated wake-like flow. Sequence numbers 17, 21 and 23 clearly show this degeneration of airflow over the model with increasing angle of attack. At 35 degrees angle of attack and 30 degrees of roll, Figure 108 in sequence 23 captures separated flow on the downwind wing just after vortex bursting occurred. The curve for 30 degrees of roll angle in Figure 143 reveals the normal force
coefficient levelling at this point. The curves corresponding to the four different yaw angles are presented in Figure 144. The plots are nearly identical due to the unchanged planform area and provide a degree of confidence in the balance readings given the time separation between data collection for each angle. The curves exhibit the same levelling tendency as the zero degree roll angle curve in Figure 143 for exactly the same reasons.

The side force coefficient plots in Figures 145 and 146 contain data which can be correlated to the observed flow phenomena present at certain angles of attack, roll and yaw as discussed in the previous section. Each curve in Figure 145 represents a different roll angle. At zero degree angle of attack and zero degree of roll angle the force coefficients for each curve intersect at zero. The side force magnitude generally increases with increasing pitch and roll to a point where the magnitude levels off except in the case of zero degrees of roll. The peak in the curve for zero degrees of roll between 45 degrees and 65 degrees angle of attack corresponds to a region of active nose vortices. The asymmetric shedding of these vortices are responsible for the variation in side force coefficient evident in the curve. Photographic sequence numbers 1 and 2 show the asymmetric shedding of vortices responsible for the region of increased side force seen in the zero degree roll curve in Figure 145. The same type of shedding vortex behavior can be seen for all
roll angles in sequences 3 through 12. However, the curves for roll angles greater than zero do not clearly define the areas of increased side force due to the shedding vortices because of the offsetting effect of the crossflow component of the freestream velocity. The shedding vortices are active but somewhat negated.

Figure 146 plots side force coefficient versus angle of attack for four different yaw angles. In the vicinity of zero degree angle of attack all curves for yaw angles greater than zero exhibit rise in magnitude in response to the crossflow component of the relative wind. All the curves show the same characteristic peak between 45 degrees and 65 degrees angle of attack, though the curves corresponding to positive yaw angles peak to a lesser degree than the curve for zero degree yaw. Maximum asymmetric vortex activity was identified in numerous photographic sequences in this angle of attack range and unquestionably accounts for the side force fluctuations present in the coefficient plots. Sequence number 30 is especially clear in its tracing of the development and eventual shedding of nose generated vortices between 45 degrees and 65 degrees angle of attack. Sequence number 28, records the unsteadiness of these vortices with the model at 50 degrees angle of attack and only 5 degrees of yaw. The curve for a yaw angle of 5 degrees indicates a certain degree of unsteadiness in this region.
Figures 147 and 148 present the rolling moment coefficients data for roll angles and yaw angles, respectively. The peak seen in Figure 147 between 30 degrees and 60 degrees angle of attack is a result of the asymmetry between the LEX generated vortices on either side of the fuselage. Sequence numbers 14 through 19 contain the supporting photographic evidence which shows that the largest magnitude of rolling moment coefficient should correspond to an angle of attack of 45 degrees and a roll angle of 45 degrees. Figures 87, 88 and 89 capture the development of a strong downwind wing vortex with increasing roll angle while the upwind wing remains immersed in separated flow. The maximum rolling moment coefficient in Figure 147 reflects this observation. The minimum rolling moment in the same angle of attack range belongs to the zero degrees roll curve. This should be expected as this is the model attitude which generates the least asymmetry between the LEX generated vortices. Figure 148 also shows a peak in the 30 degrees to 50 degrees angle of attack range. The greatest magnitude of rolling moment coefficient corresponds to a yaw angle of 15 degrees which can be expected to generate the greatest asymmetry between the LEX generated vortices in the yaw only test configuration.

Figures 149 and 150 plot the yawing moment coefficients for the various roll and yaw angles. Both graphs present extremely erratic data in different angle of attack ranges.
The data in Figure 149, showing roll angles between zero degree and 45 degrees appears to be responding mostly to the side forces generated by crossflow. The two large magnitude fluctuations seen at 70 degrees angle of attack for the zero degree roll angle and at 80 degrees angle of attack for the 45 degree roll angle do not readily correspond with any of the observed flow phenomena. In addition, the large fluctuations seen in the curves in Figure 150 between zero degree and 45 degrees angle of attack were not expected in view of the degree of unsteadiness observed in the flow in sequence numbers 29 and 31. The large yawing moments would have seemed more likely to occur near 55 degrees angle of attack where the greatest unsteadiness in the flow was visually recorded. It is suspected that the data acquisition system was too slow to accurately reflect changes in yawing moment.
IV. CONCLUSIONS AND RECOMMENDATIONS

A low speed wind tunnel investigation was made into the high angle of attack aerodynamics of a fighter aircraft model using flow visualization and balance measurements. The investigation marked the first attempt at qualitative flow analysis using the newly installed laser sheet flow visualization system to identify flow phenomena that may prove important in the design and performance of supermaneuverable aircraft. The following conclusions are drawn from the results of the experimental investigation:

1. The Naval Postgraduate School low speed wind tunnel facility laser sheet flow visualization system is a valuable research tool subject to limitations resulting from restricted visual access to the test section and moderate test section turbulence.

2. A correlation between the observed flow phenomena and force and moment measurements existed between 25 degrees and 70 degrees angle of attack.

3. The predominant aerodynamic force between 45 degrees and 65 degrees angle of attack is the asymmetric shedding of vortices generated by the slender nose and leading edge extensions (strakes) of the model. Maximum side forces are generated in this angle of attack range.
4. Below 45 degrees angle of attack, the flow characteristics are governed by complex multiple vortex interactions along the upper surface of the fuselage and wings coupled with nose generated vortices.

The following recommendations are made based on the results of this investigation:

1. Extensive wind tunnel modifications to improve visual access to the test section and reduce turbulence are required to utilize the laser sheet flow visualization system to its full potential.

2. Motorize the laser optics to render the data gathering effort less labor intensive.

3. Expand the flow visualization effort on the fighter aircraft model to include negative angles of attack to -45 degrees.

4. Perform laser Doppler velocimetry and hotwire measurements to quantify the flow phenomena identified in this investigation.

5. Incorporate the capabilities of the Department of Aeronautics and Astronautics water tunnel flow visualization system into the current high angle of attack research effort.

APPENDIX B
DATA ACQUISITION PROGRAM

2900 'Program to scan with the DMM and RELAY.MUX.01
2910 'This program was written by T.SESTAK and modified by
2920 'D. LEEDY for use with the VLSAM model.
2940 'This section after the SHELL program directs reading
2950 'the voltages from the balance, computes forces measured
2960 'by the strain guages, then stores the values in two 2965
2970 'arrays,
2980 'one for the TARE one for FORCE. This data file can then
2985 'be used for graphs or other displays. Each test run
2990 'will generate a windtun.dat file which should be copied
3000 'under another name before the next test run so that it
3010 'will not be overwritten.
3030 'dimension arrays
3040 DIM READING[7],FORCE[140,8],TARE[8],TREAD[7,10]

This part of the program is to preserve the data if
if the program is aborted in mid run. Parity errors
in the Hewlett Packard PC Instruments setup caused by
electrical noise and undervoltage at NPS requires
this. A voltage regulated, uninterruptible power source
would ameliorate this problem. Just in case- this little
sequence allows reentry into the program and the data
arrays with minimal inconvenience.

'These equations take voltage readings from the balance, converts them to counts, then applies the primary force equations to the results. These values are applied to the balance interaction equations. Each channel has separate equations for positive and negative readings and may have a "+" or "-" reading on any test run so the rather involved logic path below is my solution to the problem. For more information consult Calibration laboratory guidelines at NASA Ames Research Facility for TASK balances
CONVERT SIGNAL TO FORCES

Direct balance readings are multiplied by a scale factor of 5000000 then divided by the balance excitation voltage to get a reading in COUNTS. The program will send each reading to the appropriate equation and convert to force or moment then return to send the next reading for calculation. The data acquisition system for using this program used an amplifier with 1000 gain. The scale factor is divided by 1000.

The low speed wind tunnel at the Naval Postgraduate School was installed in the mid 1950's. Though a good, basic design, the tunnel was not designed for flow visualization. The main problem in flow visualization is the establishment of a laminar flowfield in the test section. This is complicated by the necessity to inject smoke by some means. Recent developments in West Germany have demonstrated that the production of sharp smoke filaments depends on two critical factors.

First, a perfectly laminar flow is an absolute necessity. This was accomplished at VFW by the use of very fine mesh damping screens, a large settling chamber and high contraction ratios in the final contraction cone. In all, the VFW tunnel produces extremely low turbulence by using an open, flow-through type tunnel with three 2-D contraction cones and 12 anti-turbulence damping screens. A similar tunnel is operated by the University of Notre Dame which also uses 12 anti-turbulence damping screens and a contraction ratio of 24:1 in the final section. The Naval Postgraduate School tunnel has only one contraction cone and two anti-turbulence screens prior to the test section. In addition, the contraction cone and screens are immediately following a 90-degree bend in the tunnel where the flow has just exited a
series of turning vanes. A laminar flow pattern, necessary to keeping the smoke filaments intact, simply cannot be achieved with this apparatus.

Second, the flow into the test section cannot be disturbed by the smoke injection device itself. This is usually accomplished by placing the smoke rake or tube in the contraction cone where the pressure gradient is conducive to keeping the filament intact. This is only possible if the turbulence in the cone is low enough to prevent disruption of the filament. [Ref. 23]

Early in this investigation, numerous methods for injecting smoke into the test section were evaluated. The original system featured a blower which pumped smoke through a 1.25 inch diameter rigid plastic hose to a five-filament smoke rake [Ref. 7]. This system, though adequate for demonstrating the functioning of the laser sheet flow visualization system, was not suitable for use in this experimental investigation. The blower section was not airtight and the motor was too weak to push smoke in any significant quantity through the attached tubing. Numerous leaks reduced the amount of smoke injected through the rake and rapidly filled the tunnel with unwanted smoke. The blower system and 1.25 inch tubing were replaced by a three-inch flexible hose. The length of tubing through which the smoke had to travel was reduced and all connections were made airtight. This modification provided a more efficient means
of routing the smoke to the selected injection device and eliminated the need for the blower assembly.

A new smoke rake was developed incorporating 21 tubes spaced one and one-half inches apart. The airfoil encasing the rake is a hollow aluminum shell that was, in fact, an old flap from an unknown aircraft. The airfoil is symmetrical with a maximum thickness of 1.6 inches and a chord of 15 inches. The rake tubes extend 14 inches aft of the trailing edge of the airfoil. The rake was extremely heavy but incorporated some features that were improvements over the original five-tube rake used when the system was installed. The hollow airfoil allowed space for the smoke to accumulate providing an even and more dense distribution. In addition, the rake was designed to allow replacement of the smoke tube section without creating a whole new airfoil. The smoke accumulation chamber is thus generic requiring only the manufacture of a new trailing edge section.

Though this system provided a thicker and wider sheet of smoke to the test section the problem of smoke filament diffusion still remained. As it developed, the use of a smoke rake for the study of a model aircraft at high angles of attack proved unsuitable and therefore the new rake was not used in this investigation. A smoke-wire injection system was also tried which allowed for much cleaner, less diffused smoke filaments to reach the model because of the much closer positioning possible. This method was also not
used because the non-laminar, vortex flows that dominate at high angles of attack were not adequately highlighted by this method.

Extensive effort was put forth into the development of a method to inject a single, thick tube of smoke into the test section which would provide a satisfactory means of high angle of attack flow visualization. The system ultimately adopted consisted of a three-inch flexible hose feeding from the Rosco smoke machine to a small football-shaped settling chamber which featured a three-inch long, honeycombed flow straightener section prior to a 10:1 contraction ratio section. An eight-foot section of one-inch diameter aluminum tubing exited the contraction section providing the outlet for the smoke. The contraction section of the smoke device was mounted on an adjustable height support stand and positioned in the contraction cone of the tunnel. The exit tube extended into the test section and was supported by an adjustable height rail system just prior to the test section. To minimize the effects of the tube intrusion into the test section the tube was highly polished and the exit orifice was honed razor sharp to prevent turbulence from flow over the edge caused by pipe thickness. The combination of the flow straightener, contraction cone and long tube provided for some acceleration of a one-inch diameter tube of smooth smoke over the model.
Recording the flow over the model also proved to have limitations. The equipment discussed previously was more than adequate for the recording of flow phenomena. The problems resulted from restricted visible access to the tunnel test section through the three available viewing windows. For angles of attack between 45 and 90 degrees direct photography on a line perpendicular to the flow cross section was possible. From 25 to 45 degrees the view was offset by some degree and pure photography of the flow cross section while looking down the longitudinal axis of the model was not possible. Below 25 degrees angle of attack adequate photographic coverage of flow cross sections was not possible from outside the tunnel.
