Linear Impact of Thermal Inhomogeneities on Mesoscale Atmospheric Flow with Zero Synoptic Wind

July 15, 1991

Abstract

In this paper we present an analytical evaluation of the perturbations to mesoscale atmospheric flows induced by thermal inhomogeneities in the convective boundary layer. We study the time evolution of these perturbations as a function of the intensity and of the horizontal and vertical scales of the diabatic forcing. The problem is approached using Laplace transform theory for the time behavior and Green function theory for the spatial structure. Results show that the growth of the atmospheric perturbations closely follows the growth of the convective boundary layer; the transient being characterized by a number of inertia-gravity oscillations of decreasing intensity. The vertical scale is determined by the depth of the convective boundary layer; and the horizontal scale is determined by the local Rossby deformation radius. Sinusoidally periodic thermal forcing induce periodic atmospheric cells of the same horizontal scale.
The intensity of mesoscale cells increases for increasing values of the wave number, reaches its maximum value when the wavelength of the forcing is of the order of the local Rossby radius, and then decreases as the wavelength of the forcing decreases. However, because of the destructive interference between mesoscale cells, the intensity of the vertical velocity is only a weak function of the wave numbers, for large wave numbers. Periodic square wave surface thermal inhomogeneities are more effective than sinusoidal waves in generating mesoscale cells, i.e. the intensity of the flow is generally stronger.

1 Introduction

Subgrid-scale parameterization is of considerable importance in regional and larger scale models because these models seldom have more than few grid points within a Rossby radius, yet the mesoscale flow driven by thermal horizontal inhomogeneities in the Convective Boundary Layer may be significant. Therefore mesoscale effects need to be introduced in parametric form into those large scale models.

Terrain in the real world is almost never uniform, for instance, in natural areas there may be a variety of vegetation types and patches of vegetated or unvegetated areas which can modify the mesoscale atmospheric flow. Horizontal thermal inhomogeneities in the planetary boundary layer are a well known source of mesoscale circulation systems. Thermally-forced mesoscale systems such as land and sea breezes, mountain-valley winds, and urban heat island circulations have been the subject of many studies (e.g., see references in Pielke, 1984, and Pielke and Segal, 1986). Some thermally-generated mesoscale circulations are due to horizontal inhomogeneities in ground wetness, vegetation cover, snow cover, cloud cover etc (e.g. Zhang and Anthes, 1982; Garrett, 1982; Yan and Anthes, 1988; Segal, et al., 1988). In addition there are also anthropogenic modifications of soil and vegetation, such as irrigated or non-irrigated fields, crops at different stages of development, inhabited areas, etc. (Hanna and Swisher, 1971; Anthes, 1984; Segal et al., 1984; Segal et al., 1989). Such thermal inhomogeneities may extend from few square meters to hundreds or even thousands of square kilometers (Wetzel and Chang, 1988). A number of studies, observational, numerical and analytical, have been made of these physiographically forced circulations (Abbs and Pielke, 1986; Mahfouf et al., 1987; Mahrer and Pielke, 1977; McCumber and Pielke, 1981; Zhang and Anthes, 1988).
Since the fine horizontal structure of the terrain thermal inhomogeneities is not usually resolved, however, in regional and large scale non-linear numerical models, it is important to give an analytical quantitative evaluation of their impact on the atmospheric flow. In this paper, we present an analytical theory for resolving the atmospheric perturbation and for evaluating the vertical velocities, resulting from thermal inhomogeneities in the absence of large scale flow (or in presence of very weak large scale flow) in the limit of a linear theory.

2 Governing Equation and Evolution of the Horizontal and Vertical Scales

From Rotunno (1983), and Dalu and Pielke (1989) the linearized two-dimensional primitive equations describing thermally-forced atmospheric flow, in the absence of a large-scale wind, can be reduced to a single equation for the streamfunction:

\[
\left( \frac{\partial}{\partial t} + \lambda \right)^2 + N^2 \frac{\partial^2}{\partial x^2} \psi + \left( \frac{\partial}{\partial t} + \lambda \right)^2 + f^2 \frac{\partial^2}{\partial z^2} \psi = - \frac{\partial}{\partial x} Q.
\]

where \( f \) is the Coriolis parameter, \( N \) is the Brunt-Väisälä frequency, and \( \lambda^{-1} \) is the damping time due to friction, i.e. the persistency of the mesoscale flow when the diabatic forcing vanishes. In this paper we use the following values for the Brunt-Väisälä frequency, inertia frequency and friction time scale:

\[
N = 10^{-2} \text{s}^{-1}; \quad f = 2\omega \sin \alpha = O(10^{-4}) \text{s}^{-1}; \quad \lambda = O(\omega); \quad \omega = \frac{2\pi}{\text{day}}.
\]

\( Q \) is the diabatic buoyancy source

\[
Q = \frac{g}{\rho c_p} \frac{F_0 r(x)q(t)}{h} \text{He}(h - z) = Q_0 r(x)q(t) \text{He}(h - z)
\]

uniformly distributed through the depth \( h \) of the convective layer (CBL), as indicated by the Heaviside function \( \text{He} \) in eq. (3). \( F_0 r(x)q(t) \) is the heat flux at the ground, which has a horizontal distribution \( r(x) \) and a time behavior \( q(t) \).

(a) Non-dimensional Time Variables

Statement A per telecon
Dr. Robert Abbey ONR/Code 1122
Arlington, VA 22217-5000

NWW 1/6/92
We first define the characteristic time scale of the system $T$, and we use it to non-dimensionalize time:

$$T = \frac{1}{\sqrt{f^2 + \lambda^2}} = O(10^4) \text{ s} \quad \tau = tT^{-1};$$

$T$ decreases with increasing latitude and friction (friction keeps the time scale $T$ finite at the equator). We introduce the Laplace transform, defined as

$$\hat{f}(s) = L\{f(\tau)\} = \int_0^\infty f(\tau) \exp(-s\tau) d\tau \quad \text{and} \quad LL^{-1}\{f(\tau)\} = f(\tau)$$

We recall also that:

$$f(\tau \to \infty) = \lim_{s \to 0} s\hat{f}(s)$$

i.e. $f(\tau) \approx s\hat{f}(s)$ when $s << 1$ and $\tau = \tau_0 >> 1 \Rightarrow t = t_0 >> T$

$t_0$ is the time when an almost stationary state is reached; $t_0$ is larger than the characteristic response time, $T$, of the system.

(b) Evolution of the Vertical and Horizontal Scales, and the Non-dimensional Coordinates

We recall the relation between the diabatic forcing $Q$ and the height $h$ of the CBL (Green and Dalu, 1980):

$$r(x) h(t) = r(x) \frac{2Q_0}{N^2} \int_0^t dt' q(t'); \quad h_0 = \frac{2Q_0}{N^2} \int_0^{t_0} dt' q(t')$$

The Laplace transforms of the CBL height, $\hat{h}$ and the non-dimensional vertical coordinate, $\hat{\eta}$, are:

$$\hat{h} = h_0 \frac{\hat{q}(s)}{s}; \quad \hat{\eta} = \frac{z}{\hat{h}}$$

The Laplace transforms of the horizontal scale, $\hat{R}$, and the non-dimensional horizontal coordinate, $\hat{\xi}$, are:

$$\hat{R} = \hat{h} \left( \frac{N^2 + p^2}{f^2 + p^2} \right)^{1/2} \approx \frac{\hat{h} N}{\sqrt{f^2 + p^2}}; \quad p = s + \lambda; \quad \hat{\xi} = \frac{z}{\hat{R}}$$

The horizontal scale evolves in time as:

$$R(t) = R_0 \int_0^t dt' \frac{h(t - t')}{h_0} \exp(-\lambda t') J_0(ft'); \quad R_0 = h_0 \frac{N}{\sqrt{f^2 + \lambda^2}}.$$
Friction acts to reduce the horizontal scale $R_0$ and exponentially damps the inertial oscillations described by the Bessel function, which provides some damping even with no friction, eq. (10).

The evolution of the vertical scale $h(t)$ and of the horizontal scale $R(t)$ are shown in Fig.1a for a sinusoidal in time thermal forcing, and Fig.1b for an impulsive thermal forcing; for different values of friction. In both cases, the growing time of the boundary layer is about half a day, $t_0 \approx \text{day}$. The horizontal scale grows as the convective boundary develops, through inertia-gravity oscillations. The relative amplitude of these wave is of the order of $O[\exp(-\lambda t) J_0(ft)]$: i.e. the inertia-gravity oscillations decay as a Bessel function or faster (exponentially) in the presence of friction, and their amplitude is usually negligible when $t \geq t_0 \approx 0.5 \text{ day}$.

(c) Local Rossby Radius

When two adjacent regions both experience a warming of similar intensity, the diabatic heat, in eq.(3), is given by

$$ Q = Q_0 q(t) [H e(x) + (1 - \gamma)H e(-x)] H e(h_0 - z) $$

with $\gamma < O(1)$ indicating that the two regions have similar heating; then the Brunt-Väisälä frequency difference between the two regions is of the order of

$$ N_\gamma^2 = |\gamma| N^2 $$

(12)

The Rossby radius $R_0$ has been replaced by the local Rossby radius $R_\alpha$, equal to

$$ R_\alpha = h_0 \left( \frac{N_\gamma^2 + \lambda^2}{f^2 + \lambda^2} \right)^{1/2} \approx h_0 \frac{N_\gamma}{\sqrt{f^2 + \lambda^2}} $$

(13)

Because of the reduction of the Brunt-Väisälä frequency (eq. 12), the horizontal scale (eq. 13) is correspondingly reduced, while the vertical scale remains of the order of $h(t)$. The aspect ratio becomes:

$$ A = \left( \frac{f^2 + \lambda^2}{N_\gamma^2 + \lambda^2} \right)^k $$

Atmospheric cells, generated by thermal inhomogeneities having a wavelength smaller than twice the local Rossby radius, will interact with each other.

(d) Non-dimensional Equation for the Streamfunction
Using the definitions stated above, the streamfunction equation (1) can be written as:

\[
\frac{\partial^2 \psi}{\partial \xi^2} + \frac{\partial^2 \psi}{\partial \eta^2} = -\hat{\beta}(p) \frac{\partial}{\partial \xi} \hat{Q}
\]  
(14)

\[
\hat{\beta}(p) = \left( \frac{1}{N^2 + p^2} \right)^{1/2} \left( \frac{1}{f^2 + p^2} \right)^{1/2} \approx \frac{1}{N} \frac{1}{\sqrt{f^2 + p^2}}
\]  
(15)

The variables with the tilde are non-dimensional; the variables with the hat are their Laplace transforms.

(e) Boundary Conditions and Green Functions

We assume that the terrain is flat and that the vertical velocity vanishes at the ground:

\[
w(x, z = 0, t) = \hat{w}(\xi, \eta = 0, \tau) = \hat{w}(\xi, \eta = 0, s) = 0
\]  
(16)

When the operator in eq. (14) is elliptic, the Green function is:

\[
\hat{g}_\psi = -\frac{1}{2\pi} \ln \left[ \frac{(\xi - \xi')^2 + (\eta + \eta')^2}{(\xi - \xi')^2 + (\eta - \eta')^2} \right]^{1/2}
\]  
(17)

The perturbation is trapped, i.e. vanishes at \(\infty\):

\[
\hat{w}(\xi = \infty, \eta = \infty, s) = 0
\]  
(18)

When the operator in eq. (14) is hyperbolic, the Green function is:

\[
\hat{g}_\psi = \frac{1}{2} \left[ H e(\eta - \eta' - |\xi - \xi'|) - H e(\eta + \eta' - |\xi - \xi'|) \right]
\]  
(19)

The perturbation is a propagating wave.

Important Note:

When the operator is elliptic, the intensity of the perturbation decays as the logarithm of the ratio between distance from the source (\((\xi', \eta')\)) and from its mirror image (\((\xi', -\eta')\)). eq. (17) (the perturbation is confined in the neighborhood of the source and of its image). The presence of poles in inverting the solution in the transformed space, gives propagating inertia-gravity waves vanishing at \(\infty\) in the physical space; the related solutions are in terms of Bessel and trigonometric functions (Dalu and Pielke, 1989).
The case when the operator becomes hyperbolic (non-vanishing propagating waves) under sinusoidal forcing has been treated by Rotunno (1983), and by Dalu and Pielke (1989). Furthermore, Sun and Orlanski (1981) have shown that some modes can become unstable for some values of the pulsation and the wave number.

3 Atmospheric Response

The atmospheric response is given by the inverse Laplace transform of eq. (20)

\[
\dot{\psi} = \tilde{\dot{Q}}_{0}\tilde{q}(s)\tilde{\hat{H}}(\xi, \eta); \quad \dot{u} = \tilde{\dot{Q}}_{0}\tilde{q}(s)\tilde{\hat{H}}_{u}(\xi, \eta); \quad \dot{w} = \tilde{\dot{Q}}_{0}\tilde{q}(s)\tilde{\hat{H}}_{w}(\xi, \eta);
\]

\[
\dot{v} = -\frac{\dot{J}}{p} \dot{u}; \quad \dot{b} = \frac{1}{p} \left[ \dot{Q} - X^{2} \dot{w} \right] \quad (20)
\]

where \( \hat{G}(\xi - \xi', \eta) = \int_{h}^{h'} d\eta' \hat{g}(\xi - \xi', \eta - \eta') \)

The integration limit, \( h \), is the Laplace transform of the depth of the CBL. In addition,

\[
\hat{H}(\xi, \eta) = \int_{D} d\xi' \hat{G}(\xi - \xi', \eta) \frac{\partial \hat{r}(\xi')}{\partial \xi'}.
\]

\( D \) is the horizontal region with non-zero forcing. When \( D \) is finite, \( \hat{H} \) can be written also as:

\[
\hat{H}(\xi, \eta) = -\int_{D} d\xi' \hat{r}(\xi') \frac{\partial}{\partial \xi'} \hat{G}(\xi - \xi', \eta).
\]

Where

\[
\hat{G}_{w}(\xi, \eta) = \frac{1}{2\pi} \ln \left\{ \frac{\left[ \xi^{2} + (\eta + 1)^{2} \right]^{1/2}}{\left[ \xi^{2} + (\eta - 1)^{2} \right]^{1/2}} \right\}
\]

\[
\hat{G}_{w}(\xi, \eta) = -\frac{1}{2\pi} \left[ \tan^{-1} \left( \frac{\eta + 1}{\xi} \right) - 2 \tan^{-1} \left( \frac{\eta}{\xi} \right) + \tan^{-1} \left( \frac{\eta - 1}{\xi} \right) \right]
\]

\[
\hat{G}_{w}(\xi, \eta) = \frac{1}{2\pi} \left\{ \xi \left[ \tan^{-1} \left( \frac{\eta + 1}{\xi} \right) - 2 \tan^{-1} \left( \frac{\eta}{\xi} \right) + \tan^{-1} \left( \frac{\eta - 1}{\xi} \right) \right] \right\}
\]

7
\[ + (\dot{\eta} + 1) \ln \left[ \delta^2 + (\dot{\eta} + 1)^2 \right]^{1/2} - 2\dot{\eta} \ln \left[ \delta^2 + \dot{\eta}^2 \right]^{1/2} \]

\[ + (\dot{\eta} - 1) \ln \left[ \delta^2 + (\dot{\eta} - 1)^2 \right]^{1/2} \]

In physical units we have:

\[ \psi(x, z, t) = \frac{Q_0 h_0}{N} \{ q(t) \ast \{ \exp(-\lambda t) \cdot \{ J_0(ft) \ast H_0(x, z, t) \} \} \} \]

where \{ \ast \} denotes the convolution product in time. The time-dependent transfer functions can be written in terms of Bessel functions, trigonometric functions and exponentials (see Dalu and Pielke, 1989). The time evolution is then reconstructed through the use of the Faltung theorem (Fodor, 1965). The resulting behavior is similar to the one shown in Fig.1 for the Rossby radius; i.e. the flow evolves through a series of damped inertial-gravity waves, the oscillations are not generally in-phase at different locations. Making use of the knowledge that the flow decays almost exponentially, i.e. with an e-folding distance equal to the Rossby radius, as shown in Fig.2, the structure function can be approximated as:

\[ \hat{G}_\psi(\hat{\xi}, \hat{\eta}) \approx \hat{G}_\psi(\hat{\xi} = 0, \hat{\eta}) \exp \left( -|\hat{\xi}| \right) \]

**Stationary State:** When \( t \to t_0 \) and \( r(x) = H e(x) \), we have:

\[ \psi = \psi_0 G_\psi(\xi, \eta) \quad \text{with} \quad \psi_0 = \frac{Q_0 h_0 t_0}{N} = \frac{N h_0^2}{2} \]

The flow from eq. (24), shown in Fig.3a, is approximately contained in a region \( 2R_0 \) by \( 2h_0 \). The horizontal and the vertical momentum components are:

\[ u = u_0 G_u(\xi, \eta) \quad \text{with} \quad u_0 = \frac{\psi_0}{h_0} = \frac{N h_0}{2} = \frac{R_0}{2T} \]

\[ w = w_0 G_w(\xi, \eta) \quad \text{with} \quad w_0 = u_0 \frac{h_0}{R_0} = \frac{\psi_0}{R_0} = \frac{h_0}{2T} \]

with \( \eta = \frac{x}{h_0}; \quad \xi = \frac{x}{R_0} \)

From eq. (25) and eq. (26) we deduce that:

\[ \frac{\partial}{\partial t} = O \left( \frac{1}{T} \right); \quad u \frac{\partial}{\partial x} = O \left( \frac{u_0}{R_0} \right) = O \left( \frac{1}{2T} \right) \quad \text{and} \quad w \frac{\partial}{\partial z} = O \left( \frac{w_0}{h_0} \right) = O \left( \frac{1}{2T} \right) \]
i.e. the advection terms are smaller than the linear term, but of the same order; thus the linear theory underestimates the perturbations predicted by a nonlinear theory. For a quantitative evaluation of the nonlinear contribution see the paper by Pielke et al (1991). The along-front momentum component is:

\[ v \approx -\frac{t_0}{2} f u \]  

(27)

The temperature perturbation is:

\[ \theta = H e(x) H e(h_0 - z) \left( h_0 - z \right) \Xi_z - \left[ H e(-x) + H e(x) H e(z - h_0) \right] \Delta_z \Xi_z \]  

(28)

Here we refer to heated land but the temperature perturbation will be positive whenever a CBL occurs due to superadiabatic lapse rate at the surface (e.g. over warm water patches also). \( \Delta_z \) is the vertical displacement of the air parcels:

\[ \Delta_z(x, z, t_0) \approx \frac{t_0}{2} w(x, z, t_0) \]

When the flow results from adjacent differentially heated regions in eq. (11), the intensity of the mesoscale flow reduces to:

\[ \psi_{0,} = \gamma \psi_0 \]  

(29)

The flow intensity is proportional to \( \gamma \). If we set the threshold for the generation of significant mesoscale flow at 20\%, the influence of the mesoscale flow need to be included (explicitly or in parametric form) when:

\[ \frac{\psi_{0,}}{\psi_0} > 0.20 \Rightarrow \gamma > 0.20 \]

We will refer to this measure as the resolution threshold suggesting that for \( \gamma < 0.2 \), the influence of the spatial heterogeneity can be ignored. The flow shown in Fig.3b refers to the case when \( \gamma = 0.5 \) in eq. (11), i.e. the upstream region experiences 50\% less heat than downstream of the thermal discontinuity. The mesoscale flow shown in Fig.3b is less intense, (from eq. (13)), and is less extensive than the flow shown in Fig.3a.
4 Atmospheric Response to Periodic Thermal Forcing

Throughout this section in evaluating the averages and the convolution integrals along the horizontal coordinate we make use of the fact that the intensity of the flow decays exponentially with an e-folding distance equal to the Rossby radius (Fig.2):

\[ \psi = \psi_0 \, g(z) \exp \left( -\frac{|z|}{R_0} \right) \quad w = -\frac{\partial \psi}{\partial x} \]  

\[ g(z) = G_\psi(x = 0.0, z) = \frac{1}{2\pi h_0} \ln \left| \frac{z^2 - h_0^2}{z^2} \right| + \frac{1}{2\pi} \ln \left| \frac{z + h_0}{z - h_0} \right| \]

When the diabatic heat is sinusoidally periodic over the entire horizontal domain, with \( L_m \) as wavelength:

\[ Q = Q_0 \tilde{q}(t) \, H(e(h - z)) \left[ \frac{1}{2} + \frac{1}{2} \sin \left( \frac{m\pi x}{R_0} \right) \right]; \quad m = \frac{2R_0}{L_m} \]

then the streamfunction is given by

\[ \psi = \frac{\psi_0}{2} \int_{-\infty}^{\infty} \frac{m\pi dx'}{R_0} \cos \left( \frac{m\pi(x - x')}{R_0} \right) G_\psi(x', z) \]

\[ = \psi_0 g(z) \frac{m\pi}{(m\pi)^2 + 1} \cos \left( \frac{m\pi x}{R_0} \right) \]

Here \( m \) is the number of wavelengths in a \( 2R_0 \) distance (\( m \) need not be integer). If we set the resolution threshold at 0.20:

\[ \frac{\psi_0 m}{\psi_0} > 0.20 \Rightarrow \frac{m\pi}{(m\pi)^2 + 1} > 0.20 \Rightarrow 0.4 < m < 1.2 \]

Thus the mesoscale flow need to be included (explicitly or in parametric form) when \( 0.4 < m < 1.2 \).

The intensity of the atmospheric response as a function of \( m \) is shown in Fig.4a. The intensity of the mesoscale cells monotonically decreases for \( m \) large (see also shown in Fig.5). The vertical velocity is:

\[ w = -\frac{\partial \psi}{\partial x} = w_0 g(z) \frac{(m\pi)^2}{(m\pi)^2 + 1} \sin \left( \frac{m\pi x}{R_0} \right) \]
When $m > 1$, the vertical velocity is a weak function of the wave number (Fig. 4c). When the forcing is a periodic square wave over the entire horizontal domain, with $L_m$ as wavelength:

$$Q = Q_0 q(t) \, H(e(h-z)) \left[ \frac{1}{2} + \frac{1}{2} \sum_{n=1,3,5,\ldots}^{\infty} \frac{4}{n\pi} \sin \left( \frac{mn\pi x}{R_0} \right) \right] ; \quad m = \frac{2R_0}{L_m}$$  \hspace{1cm} (34)

then the streamfunction is given by

$$\psi = \psi_0 g(z) \sum_{n=1,3,5,\ldots}^{\infty} \frac{4}{n\pi} \frac{mn\pi}{(mn\pi)^2 + 1} \cos \left( \frac{mn\pi x}{R_0} \right)$$  \hspace{1cm} (35)

If we set the resolution threshold at 0.20:

$$\frac{v_0}{v_0} > 0.20 \Rightarrow \sum_{n=1,3,5,\ldots}^{\infty} \frac{4}{n\pi} \frac{mn\pi}{(mn\pi)^2 + 1} > 0.20 \Rightarrow 0.05 < m < 2.2$$

Thus for square heating patches, the mesoscale flow needs to be included (explicitly or in parametric form) when $0.05 < m < 2.2$. The intensity of flow as a function of $m$ for a periodic square forcing is shown in Fig. 4b, and the circulation cells are shown in Fig. 6. The intensity of the flow, in general, is larger for a periodic square forcing than for a sinusoidal forcing; the difference being larger at small wave number. At large wave number the mesoscale cells interact destructively, reducing the intensity of the flow. The vertical velocity (Fig. 4d) is:

$$w = -\frac{\partial \psi}{\partial x} = w_0 g(z) \sum_{n=1,3,5,\ldots}^{\infty} \frac{4}{n\pi} \frac{(mn\pi)^2}{(mn\pi)^2 + 1} \sin \left( \frac{mn\pi x}{R_0} \right)$$  \hspace{1cm} (36)

and the temperature perturbation is:

$$\theta = H(e(h_0-z)) \left[ \frac{1}{2} + \frac{1}{2} \sum_{n=1,3,5,\ldots}^{\infty} \frac{4}{n\pi} \sin \left( \frac{mn\pi x}{R_0} \right) \right] (h_0-z) \Theta_z$$

$$- \left\{ 1 - \frac{H(e(h_0-z))}{2} \left[ \frac{1}{2} + \frac{1}{2} \sum_{n=1,3,5,\ldots}^{\infty} \frac{4}{n\pi} \sin \left( \frac{mn\pi x}{R_0} \right) \right] \right\} w(z) \Theta_z \frac{t_0}{2}$$  \hspace{1cm} (37)

5 Conclusions

Making use of the theory developed by Dalu and Pielke (1989), we study the atmospheric response to spatial gradients of diabatic heat fluxes in the convective boundary layer. Results show that, for sudden changes, the atmospheric perturbation decays exponentially with an $\epsilon$-folding distance.
equal to the local Rossby radius. Square wave periodic surface thermal inhomogeneities generate stronger atmospheric cells than sinusoidally distributed inhomogeneities. The intensity of the flow increases as the wave number increases, reaches its maximum when the wave length is of the order of the Rossby radius, and then decreases linearly for large wave number. Thus significant atmospheric cells are generated by periodic thermal inhomogeneous patches only when the wavelength is a significant fraction of the local Rossby radius. It is unnecessary therefore to explicitly resolve in numerical models thermal inhomogeneities on scales much smaller than the local Rossby radius (e.g. as assumed in Avissar and Pielke, 1989). However, since at high wave numbers, the vertical velocities is significant and almost constant, mesoscale heat fluxes may be significant; these subgrid-scale effects need to be introduced in parametric form in LAM and GCM, which have only few grid points within a Rossby radius. Solutions for the atmospheric perturbations in the presence of light ambient winds, can be derived from the theory presented in this paper, and an extension of our theory in this direction is desirable. When the ambient flow is strong, the pattern of the perturbations is quite different (Hsu, 1987; Robichaud and Lin, 1989) however the intensity of the mesoscale perturbation is negligible, since it decays as \(1/U^2\).

Fig. 3 -a- Streamfunction isolines for a discontinuous change of heat flux at \( x = 0.0 \) at 40° of latitude (\( \lambda = \omega \)): \( h_0 = 1000 \text{ m}, \Delta \psi = 0.2 [10^3 \text{ m}^2/\text{s}] \). -b- Streamfunction isolines when one region experiences a heat flux 50% less intense than the adjacent region, i.e. \( \gamma = 0.5 \).

Fig. 4 -a- Intensity of the flow, induced by a sinusoidal periodic forcing, versus horizontal wave number; -b- same as -a- but for a periodic square wave; -c- vertical velocity for a sinusoidal periodic forcing; -d- vertical velocity for a periodic square wave; -e- average vertical mesoscale heat flux for a sinusoidal periodic forcing; -f- average vertical mesoscale heat flux for a periodic square wave.

Fig. 5. - Mesoscale atmospheric cells for four values of the horizontal wave number for a sinusoidal periodic forcing. \( \Delta \psi = 0.2 [10^3 \text{ m}^2/\text{s}] \).

Fig. 6. - Mesoscale atmospheric cells for four values of the horizontal wave number for a square wave periodic forcing, \( \Delta \psi = 0.2 [10^3 \text{ m}^2/\text{s}] \).
a. Sine forcing

\[ \psi \]

\[ Z = 0.8 \text{km} \]
\[ Z = 0.4 \text{km} \]
\[ Z = 0.2 \text{km} \]

\[ m \]

b. Sine forcing

\[ w \]

\[ Z = 0.8 \text{km} \]
\[ Z = 0.4 \text{km} \]
\[ Z = 0.2 \text{km} \]

\[ m \]

\[ \frac{42}{4c} \]
b. square forcing

\[ \Psi \]

\[ m \]

\[ Z = 0.8 \text{ km} \]
\[ Z = 0.4 \text{ km} \]
\[ Z = 0.2 \text{ km} \]

---

d. square forcing

\[ w \]

\[ m \]

\[ Z = 0.8 \text{ km} \]
\[ Z = 0.4 \text{ km} \]
\[ Z = 0.2 \text{ km} \]
