**Title:** An Approach to Integration of Real-Time Software for an Autonomous Underwater Vehicle

**Authors:** Leatherman, Brent L.

**Type of Report:** Master's Thesis

**Date of Report:** June 1991

**Page Count:** 76

**Abstract:**

The Naval Postgraduate School (NPS) is currently involved in a long-term project to investigate and develop real-time software for command and control of Autonomous Underwater Vehicles (AUV). In support of this goal, NPS is currently designing and fabricating a testbed AUV. This thesis describes the design development, and testing of a real-time scheduling software package to act as the top layer of control software for the AUV. Also discussed are the various real-time scheduling policies available along with the features of the assigned operating system that allow the implementation of the scheduler.
AN APPROACH TO INTEGRATION OF REAL-TIME SOFTWARE FOR AN AUTONOMOUS UNDERWATER VEHICLE

The Naval Postgraduate School (NPS) is currently involved in a long term project to investigate and develop real-time software for command and control of Autonomous Underwater Vehicles (AUV). In support of this goal, NPS is currently designing and fabricating a testbed AUV.

This thesis describes the design, development and testing of a real-time scheduling software package to act as the top layer of control software for the AUV.

Also discussed are the various real-time scheduling policies available along with the features of the assigned operating system that allow implementation of the scheduler.
I. INTRODUCTION

A. GENERAL

The Naval Postgraduate School (NPS) is developing an autonomous underwater vehicle (AUV) - an untethered, intelligent, robot submarine. The current AUV, AUV-II, is the second in a series of three vehicles to be built. It has been designed as a testbed for research in adaptive control, mission planning and execution, data collection and analysis, and the uses of various sensors.

AUV-II is driven by a pair of 4" propellers and four hovering thrusters. These and the eight control surfaces used allow for a high degree of vehicle control. The vehicle's sensors include four sonars, a depth cell, and a speed indicator. Positional data is provided by three on-board gyroscopes and a magnetic compass.

The on-board computer hardware is centered around a twelve slot G-96 bus supplied by the GESPAC corporation [Dibble 90]. The bus hosts a Motorola 68030-based processor board along with 2.5 Megabits of RAM and 4 Megabytes of EPROM. Five other slots are dedicated to a 200 Megabyte hard disk drive, parallel and serial communication ports, an analog-to-digital channel from the sensors, and a digital-to-analog channel to the effectors. The remaining slots are expected to
be used for additional memory and Transputer boards. Figure 1.1 [HEALY 90] shows the internal and external configurations of AUV-II.
The computer uses the OS-9 operating system developed by MICROWARE for GESPAC [GESPAC 88]. OS-9 is a complete operating system having a file system, native compilers, a built-in editor, the ability to support local area networks, multitasking abilities, real-time features such as timers, process creation and deletion primitives, process priority assignments, and signal sending and receiving structures. It has the added advantage of having been used in prior AUV research [HEALY 90]. The AUV-II project is ongoing, and has had many successful trials in the NPS pool.

B. COMPUTATIONAL REQUIREMENTS OF THE AUV

For successful mission completion, AUV-II must be able to execute a complex set of both periodic and aperiodic processes (or tasks) that may have widely varying attributes such as variable execution times, frequencies and response times. These tasks may include: mission planning, path planning, guidance, effector control, sensor control, collision avoidance, and data collection [HEALY 90]. The inter-relationship of these are shown in Figure 1.2 [HEALY 90]. As can be seen in Fig. 1.2, the operator starts, and controls the entire mission. The focus of this thesis is to provide real-time control for that mission, consisting of many tasks with widely differing computational requirements. For example, block 8, collision avoidance, is an aperiodic task - since obstacles cannot be predicted - while block 6, navigation,
predicted - while block 6, navigation, requires periodic computer attention. Also, while both block 6 and block 5, sonar, are periodic, their respective periods are quite different; sonar having the higher frequency. Since obstacle avoidance has not yet been completely integrated in the AUV, this thesis concentrates on periodic task scheduling and execution. Once the parameters of aperiodic tasks have been finalized, it should require very little extra work to incorporate aperiodic scheduling into the existing control software. A more detailed analysis of Figure 1.2 may be found in [HEALY 90]. Computational resources must be used such that all tasks complete execution within their respective periods, or, in real-time terms, meet their deadlines in a predictable and reliable manner regardless of the difference in their attributes.

In the current vehicle software, all processes are executed in an infinite loop operating at roughly 10 Hz. Although this is adequate for the simple missions now being executed, it lacks the necessary sophistication for the more complex missions planned. These missions may include, for instance, tasks that are required to be executed at different frequencies. For example the sonar system operates at 5 Hz while the motion control loop operates at 10 Hz.

A recent study [BIHARI 90] of the processing requirements of this project delineates the necessity of an efficient, hard real-time scheduler to ensure the correct functioning of the
AUV DATAFLOW DIAGRAM
Baseline System

Figure 1.2: Data Flow Diagram for the AUV
vehicle. A scheduler is the top layer of AUV-II software, which coordinates the task set to ensure that all process deadlines are met in a reliable and predictable manner. The scheduler must be able to, at a minimum, access at least one accurate time base, run processes at specified points in time, support synchronous and asynchronous communications between processes, and place bounds on the response time of aperiodic processes and events. An important attribute of a scheduler is how it responds to an overload condition in which it is not possible for all tasks to meet their deadlines because they exceed the net processing reserves available. Overload may occur in two ways, transient or sustained. Transient overload is caused by the execution of an aperiodic event that requires the suspension of one or more periodic events. Sustained overload is caused by unexpected increases in process execution time such that the processor load exceeds its resources. A scheduler must be able to handle overload conditions in a stable manner. For a scheduler to be considered stable, two requirements must be met. The first being that a subset of the most critical tasks always meet their respective deadlines. The second is a quick return to normal operation once the overload condition has passed.

C. OBJECTIVES OF STUDY

OS-9 scheduling policy cannot provide hard real-time performance without the addition of a control layer of
software to schedule the task sets required by the AUV. Therefore, the main objective of this study is to develop a real-time scheduler that meets the following requirements:

1. It must use only OS-9 real-time primitives, with no modifications to the operating system.
2. It must be capable of maintaining a relatively high processor utilization without missing task deadlines.
3. It must be able to support task sets with varying characteristics.
4. It must remain stable under transient overload. Rapid recovery after elimination of the overload is of prime importance in this case.
5. It must remain stable and degrade gracefully under sustained overload. In this case, the important feature is meeting the deadlines of a subset of more critical processes while sacrificing those that are less critical.
6. Since the scheduler will be implemented on an already functioning vehicle, it must be able to integrate and communicate with the existing motion control software with as few modifications as possible to that software. AUV software modules are being designed by different project members that have little knowledge of the scheduler; therefore, it must be simple to use and maintain. In order to simplify the use of the scheduler,
D. METHOD OF APPROACH

This thesis deals with the implementation of a theoretical method of real-time scheduling into a practical working scheduler robust enough to handle the various situations that are to be expected on a functioning vehicle. As such, not only must the scheduler meet the requirements of the selected scheduling policy, but also account for the real world conditions such as process switching overhead and variable process execution times that will degrade performance below theoretical values. It was necessary to determine what processor loads were feasible and what characterization of processor set provided the required performance. To facilitate this implementation the following steps were taken:

1. Selection of a suitable scheduling policy.
2. Implementation of the policy using OS-9 dependent resources.
3. Experimental determination of the available utilization and observation of scheduler stability under various loads and task set characteristics.
All programming for this project was done using the resident C compiler provided by MICROWARE, and is closely tied to the OS-9 operating system [MICROWARE 87]. Porting to another system would require extensive modification of the scheduler.

This project successfully implemented a scheduling layer of software that can determine if a given periodic task set can be successfully scheduled to deliver processor utilization exceeding 85%. Aperiodic tasks can be scheduled on a more limited basis by treating them as periodic events with a period equal to infinity. The improvement over the passive OS-9 policy is clearly demonstrated in a later chapter of this thesis.

E. THESIS ORGANIZATION

Chapter II presents a discussion of various real-time scheduling policies and outlines the reasons for using rate monotonic scheduling for AUV-II. Chapter III is a more complete and detailed study of rate monotonic scheduling theory. Chapter IV details the implementation of rate monotonic scheduling using the OS-9 operating system. Chapter V presents the methods and experiments used to determine scheduler performance and veracity. Chapter VI summarizes the results of this study and describes future directions for study.
II. AN OVERVIEW OF REAL-TIME SYSTEMS

A. GENERAL

A real-time system is defined to be one in which the various processes adhere to time constraints determined by the application. Although real-time systems are often associated with extremely fast processing speeds, this is not an accurate interpretation. A real-time system refers to the timely occurrence of events and the intervals involved may range from microseconds to years [LEVI 90].

Real-time systems can be loosely divided into two categories, hard deadline and soft deadline systems. Hard deadline systems are those where the missing of a process deadline is catastrophic. Conversely, while making all deadlines is desirable on a soft deadline system, missing one is not a fatal error [LEVI 90].

Assigning priorities to different concurrent processes is a common mechanism used to share computational resources in a real-time system. Based on how the priorities may be assigned, real-time systems can be further classified as fixed priority systems in which all process priorities are fixed at run time, or dynamic priority systems in which priorities can be changed during execution. Rate monotonic scheduling [LIU 73] is an example of a scheduling policy that uses fixed prioritization.
Conversely, earliest deadline scheduling policy [LEVI 90] makes use of dynamic scheduling for successful operation. If these two types of systems are combined, a hybrid is achieved that is known as a mixed priority system [LEVI 90].

B. OS-9 SPECIFIC REAL-TIME PRIMITIVES

The OS-9 operating system contains a wide range of real-time primitives that can be used to implement a functioning real-time scheduler. This section describes these primitives in a general fashion; a detailed listing of the commands and their functions may be found in Appendix D.

OS-9 is, inherently, a multi-tasking system. This is demonstrated by the process priority assignment embedded in OS-9. Processes may be assigned a priority from one of 65,536 separate priority levels when they are forked into existence. The forked processes are placed on a ready-to-execute queue in direct order of their priority. The process at the head of the queue is executed for one or more ticks. A tick is the smallest unit of time the system recognizes and may be set by the system operator for a duration as low as 10 milliseconds. Once a process has started executing, it will execute until it has completed execution or until the end of the current tick. All non-executing processes have their priorities increased by one for each tick spent in the ready-to-execute queue, a process referred to as aging [MICROWARE 87]. Aging is normally
used to ensure that all processes eventually receive the
attention of the processor regardless of their priority. Once
a process has executed, it is reduced to its original
priority. The queue is checked every tick to determine which
process has the highest priority and, therefore, the right to
the processing unit. Process switching times are on the order
of 50 microseconds [DIBBLE 88].

OS-9 uses this queue and various commands to support
real-time operations. These commands include timing commands
that check absolute, relative, and elapsed times. These
commands all have a resolution of a tick. System commands are
also provided that allow processes to suspend themselves. A
suspended process is removed from the ready-to-execute queue
and does not age until reactivated. Reactivation can be
accomplished by either an elapsed time counter, an absolute
time event or upon the receipt of a signal from another
process. Signal sending and receiving mechanisms are closely
coupled with process suspension and are used to provide
interprocess coordination and timing. Signals can be used to
either wake up or kill a process. Customized signals are also
supported. Another class of primitives that help in the
development of real-time systems are the ones that allow for
access to process identities, states, and parameters [GESPAC
88].
C. IMPLEMENTATION

The rate monotonic scheduling algorithm was chosen as the method to implement upon AUV-II, due to it being the optimal fixed priority scheduling algorithm [LIU 73]. While dynamic scheduling can increase overall processor utilization, it is much more difficult to implement in a practical fashion due to the problem most operating systems have in arbitrarily reassigning priorities during execution [LIU 73]. Rate monotonic scheduling is presented in greater detail in the following chapter.
III. RATE MONOTONIC SCHEDULING THEORY

A. INTRODUCTION

The rate monotonic scheduling (RMS) algorithm was chosen as the basis for the scheduler on AUV-II; its practical aspects having been recently analyzed [SHA 90]. RMS uses the following model of the workload.

1. The workload must consist of independent processes; an independent process being one that does not require the execution of any other process to function.
2. All process priorities are fixed at the time of execution.
3. The system must provide for pre-emptive execution; i.e. higher priority processes will interrupt the execution of lower priority processes.

Given these conditions, RMS guarantees that in the worst case conditions, all deadlines will be met for at least a 69.3% processor load. Processor load is defined to be the sum of the execution times of each process divided by the respective period of each process. This function is shown in Equation (3.1).
\[ X = \frac{C_1}{T_1} + \frac{C_2}{T_2} + \ldots + \frac{C_n}{T_n} \]

where

- \( X \) is the processor load
- \( C_i \) is the execution time of process \( i \)
- \( T_i \) is the period of process \( i \)
- \( n \) is the number of processes

The above mentioned limit is known as the Liu-Layland bound named for the two men who derived it [LIU 73].

B. PERIODIC TASK SCHEDULING

One of the most important attributes of a task set is its phasing; the order and timing in which the various tasks are to be executed. The Liu-Layland bound represents the worst case task set phasing; i.e. one with the maximum of number of task preemptions. A system may be able to support a higher processor utilization if the task set phasing is more favorable. Two theorems have been developed to determine if the higher processor load is schedulable [LEHOCZKY 89]. For a task set to be considered schedulable, all tasks must meet their respective deadlines under all task set phasings.

The first method used in determining schedulability is given by Equation (3.2) [SHA 90].
\[
\frac{C_1}{T_1} + \frac{C_2}{T_2} + \ldots + \frac{C_n}{T_n} \leq n(2^{1/n} - 1)
\]

where

- \( C_i \) is the execution time of process \( i \)
- \( T_i \) is the period of process \( i \)
- \( n \) is the number of processes

The upper limit of 1.0 decreases monotonically until, as \( n \) approaches infinity, the right side of Equation (3.2) yields the Liu-Layland bound of 0.693, or, 69.3%. If the processor load is less than or equal to this bound, the task set is always schedulable. The second method for determining schedulability is more complex, but more exact, and is given in Equation (3.3). The term scheduling points in Equation (3.3) refer to the arrival times for all processes in the task set within the longest period in the task set. For example, a task set consisting of four tasks periods 4, 6, 12, and 25 units, would have the following set of scheduling points: 4, 6, 8, 12, 16, 18, 20, 24, and 25 [SHA 86].

\[
\forall i, 1 \leq i \leq n
\]

\[
\sum_{j=1}^{k} C_j \cdot \frac{1}{lT_k} \cdot \left\lfloor \frac{lT_k}{T_j} \right\rfloor \leq 1.0
\]

\((k, l) \in R_i\)

where

- \( C_j \) is the execution time of process \( j \)
- \( T_j \) is the period of process \( j \)
- \( R_i \) is the collection of scheduling points for the task set
- \( l \) is the ratio of \( \left\lfloor \frac{T_k}{T_j} \right\rfloor \)
Equation (3.3) is evaluated for the entire set of scheduling points and the results compared to the value 1.0. If any of these values are less than, or equal to, 1.0, the task set is always schedulable under RMS. Once schedulability has been determined, RMS assigns a fixed priority to each process. This assignment is in inverse proportion to the period of the process; the shorter the period, the higher the priority. Once priorities have been assigned, the processes can be executed using the preemption functions provided by the system. Although neither of the two methods of determining schedulability guarantees more than a 69.3% utilization under worst case conditions, average case utilization values can range from 85-90%, well above the Liu-Layland bound. This higher utilization value is attributable to the concept of the critical instant [SHA 90]. A critical instant is one in which all processes are initiated at the same instant, thus creating the maximum number of preempted processes. It has been determined that the higher the number of critical instants, the lower the achievable utilization [SHA 86]. This then can be used to predict worst case performance and, by judicious selection of task periods (assuming some flexibility in period selection), a task set can be 'tuned' to achieve high utilization.

C. APERIODIC TASK SCHEDULING

Aperiodic tasks are tasks that appear on an irregular,
unpredictable basis. An example of an aperiodic process for the AUV-II would be collision avoidance. RMS services aperiodic tasks using a sporadic server; that is, a mechanism that executes the task if a request is sent from the aperiodic task, and if there are sufficient reserve computational resources to process the request. In other words, the system workload must be low enough that the aperiodic event can be served without disrupting the periodic task set. Provisions must be made for the case where the aperiodic event is crucial and therefore needs to be able to preempt all, or part, of the periodic task set [SHA 90].

C. PERIOD TRANSFORMATION

RMS always guarantees that a certain subset of the task set will meet their deadlines under worst case conditions. This subset is known as the critical set. Since process priority is in inverse proportion to period lengths, under some circumstances, a process with a long period and lower priority may serve a more critical function than a process with a shorter period and must be included in the critical subset [SHA 90].

This problem is solved using a technique known as period transformation. This method requires splitting the critical process into two logical parts, each one having 1/2 the worst case execution time of the process and 1/2 the requested period. Priority is then assigned to the process according to
the reduced period length and, thus, elevated. Once task set execution begins, the critical process executes 1/2 of its worst case execution time in the first half of its period and then suspends itself. The other half of the execution comes during the second half of its main period. This is shown in Figure 3.1 [SHA 90].

\[ \text{TIME} \]

\hline
\end{tabular}

Figure 3.1 Time Line Showing Period Transformation

Given the limitations of the OS-9 operating system, some of the features of RMS were more difficult to implement than others. The RMS attributes implemented in this thesis include schedulability checking, periodic process serving, a limited ability to service aperiodic tasks, and the ability to remain stable under overload conditions. The details of this implementation are described in the next chapter.
IV. AN IMPLEMENTATION OF RMS ON OS-9

A. GENERAL

The scheduling software, as implemented on the GESPAC computer, consists of five logical parts. These are: the scheduler startup process, initialization, schedulability analysis, the master scheduler, and the modifications that need to be made to the processes called by the scheduler. Due to the limitations of the OS-9 operating system, and the specification that no modifications be made to this system, this was a non-trivial problem. As mentioned before, the scheduler is highly OS-9 dependent; therefore, there has been an effort made to highlight all non-standard C commands used in order that future modifications to the scheduler can be accomplished without excessive difficulty. Figure 4.1 illustrates the sequence of steps in the scheduling software. These are more fully explained in sections B through F of this chapter.

B. SCHEDULER STARTUP

To function correctly, the run time module must have the highest priority on the system. This is due to its function as the coordinator of the AUV-II software; in other words, it must not be preempted by a called process while it is
Figure 4.1 Step Sequence of Scheduling Software
executing the scheduling process. In the OS-9 operating system, run-time priority is set by the command, os9forkc, and cannot be changed in the process itself. Thus, it was necessary to develop a small calling program to establish the scheduler's initial high priority. It first spawns the scheduler and then suspends itself until the completion of the mission. It should be stated that all processes to be called using the os9forkc command are required to have an executable module located in a directory available to the scheduler. Since they will be called by OS-9 commands, the called processes should not be linked together during the compilation process.

As stated in Chapter II, OS-9 provides for 65,536 distinct priority levels. It was arbitrarily determined that a priority level for the scheduler of 62,000 would be appropriate. This is high enough to preempt all other system processes, but still leaves some higher priorities for emergency processes such that the scheduler would be deliberately interrupted. This priority can be easily changed in the startup module. The source code for the startup module is located in Appendix A.

C. SCHEDULER INITIALIZATION

Scheduler initialization begins by entering task set parameters. The first parameter is the number of processes in the task set. Once this has been entered at the keyboard, a loop is started that brings in the names of the processes,
their periods and execution times. Although this is currently entered manually at the keyboard, it may be changed to a file input/output system for implementation on the vehicle if desired. Process execution times can be obtained in two ways; the first is direct input by the system operator, the second is done by the scheduler as it forks slightly modified versions of the modules and times their lengths of execution. This procedure is outlined in Appendix B.

Once the task set parameters are available to the scheduler, the program sorts the processes by period from shortest to longest with ties broken arbitrarily. This is accomplished by a standard heap sort routine. This sort also establishes the relative priorities of the process from highest to lowest in inverse proportion to the length of the respective periods.

Absolute priorities must be assigned to each process before they can be forked off for execution. Due to the inherent conflict between the fixed priority requirements of RMS and the automatic aging of non-executing processes as implemented by OS-9, it became necessary to space process priorities far enough apart to ensure that no processes priority could overtake another. This scheme successfully negates the run-time aging of process priorities inherent to OS-9 and gives the illusion of fixed priorities to the scheduler.

Absolute priority assignment is accomplished by first
finding the least common multiple of the periods of all processes in the task set. Once the least common multiple is established, priorities are set using Equation (4.1).

\[ P_i = P_0 - \frac{\left(\prod_{j=1}^{i} C_j\right)}{\left(\prod_{j=1}^{i} T_j\right)} \frac{LCM}{i} \]

where

- \( P_i \) is the processes priority
- \( P_0 \) is the highest priority process
- \( C_j \) is the execution time of process \( j \)
- \( T_j \) is the period of process \( j \)
- \( LCM \) is the least common multiple of all periods

The process with the shortest period, and therefore the highest priority, is assigned a priority of 60,000. This is \( P \) and was chosen to be well below the priority of the scheduler, while being large enough to permit a wide range of priorities under it. To illustrate the use of Equation (4.1), consider a task set consisting of two processes. Process one has a period of 50 ticks, and an execution time of 12 ticks. Process two has a period of 100 ticks, and an execution time of 15 ticks. Process one is automatically assigned a priority of 60,000, the maximum available. Process two has its priority assigned by subtracting the product of both execution times, a value of 180, and dividing it by the product of the periods, a value of 5000. This quotient is 0.036 and is multiplied by the LCM of the two periods, 100, giving a final value of 3.6. This is
rounded up to the next highest integer, 4.0, and subtracted from the value of the highest priority process. Process two, then, is assigned a priority of 59,996.

Although Equation (4.1) gives the correct absolute spacing between process priorities, under certain conditions, it can cause abnormally wide spacings between the priorities. This is usually caused by a large number of processes with different periods resulting in a large least common multiple. An example of this is given by considering two, two-process sets. Set one has two tasks with periods of 50 and 100 while set two has two task with periods of 51 and 100. Although these two sets are virtually identical, the first has a least common multiple of 100 while the second is 5100. When these least common multiples are used in Equation (4.1), the spacings would place the priorities of the second set much farther apart than in the first set. If there were an infinite supply of priority levels, this would be no problem, but, as mentioned earlier, OS-9 supplies only 65,536 priorities which are quickly spanned by a reasonably large task set. The solution to this problem was to first detect the large spacings and then reassign them the priority equal to the priority of next highest priority process minus the value equal to the number of ticks of the longest period in the task set. This value is theoretically the most any one process could age before it is executed. This two pronged approach to prioritization has proven to be successful in all tests and experiments using the scheduler.
There were no recorded cases of a lower priority process overtaking a higher priority process.

D. SCHEDULABILITY ANALYSIS

The schedulability of a task set uses the process described by theorem three [SHA 90]. The steps are described in a series of Equations (4.2-4.5) shown below.

The first step, given in Equation (4.2), is to determine the processor demands made by the task set as a function of time [Lehoczky 89]. The second step is to normalize the results to achieve a value between 0.0 and 1.0. This

\[ W_i(t) = \sum_{j=1}^{i} \frac{C_j}{T_j} \]

where

- \( W_i(t) \) is processor load as a function of time (4.2)
- \( 1 \leq i \leq n \)
- \( n \) is the number of processes in the task set
- \( C_j \) is the execution time of process \( j \)
- \( T_j \) is the period of process \( j \)
- \( t \) is time as a continuous variable

is accomplished in Equation (4.3) by dividing by time and is simply an intermediate step in the process of converting the results from continuous to discrete values. The next step is

\[ L_i(t) = \frac{W_i(t)}{t} \] \hspace{1cm} (4.3)

given is Equation (4.4) where the continuous time variable, \( t \),
is converted, by the computation of scheduling points, to the discrete variable, $s$, as discussed in Chapter II.

$$L_i = \min(0 \leq s_i \leq T_i)L_i(s_i)$$

where

$s_i$ are the various scheduling points

The final step is a check to determine if $L_i$ has a value less than or equal to 1.0, as shown in equation (4.5).

$$L_i \leq 1.0$$

If the task set meets schedulability requirements, a confirmation message is sent to the system operator and the master scheduler initiated. If the task set does not meet schedulability requirements, an error message is sent to the operator and the scheduler is suspended until a workable task set is developed.

E. THE SCHEDULER

Once priorities have been calculated and schedulability determined, scheduling analysis is complete and task set execution may begin. The analysis and execution functions are currently part of the same software module. This means that analysis is done in the field prior to the beginning of the
mission. Since the task set has presumably been checked before the various field tests, only the executable module needs to be ported to the AUV, with the various values generated by the analyzer being read from a disk file prior to the start of a mission. This will require some minor modifications to the scheduler.

The first step is the creation of the individual processes that are listed in the task set. This is done using the OS-9 commands `os9forkc` and `os9exec`. The original program specifications had called for a scheme that created a process at the start of each period, executed the process and then killed the process prior to the end of the period. This proved to be unworkable when it was found that the procedure for creating a process took a random time varying between 220 and 340 milliseconds. Since at least one vehicle control module was required to run at 10 Hz, this method was fatally flawed. A more sophisticated approach was developed that entailed creating each process once, at the beginning of the scheduler module, and then, after execution, suspending the process until receipt of a signal from the master scheduler. This method reduced the task switching time to 55 microseconds, some 400,000% faster than the original method. The second method had the added benefit of reducing the amount of processor time conducting the 'garbage collection' required in the creation and killing of processes.

As the scheduler creates each process, two entries are
made in the table that is the heart of the scheduler and is shown in Figure 4.2.

<table>
<thead>
<tr>
<th>PROCESS ID NUMBER</th>
<th>TIME UNTIL NEXT EXECUTION</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>50</td>
</tr>
<tr>
<td>2</td>
<td>100</td>
</tr>
<tr>
<td>3</td>
<td>150</td>
</tr>
<tr>
<td>4</td>
<td>250</td>
</tr>
<tr>
<td>n</td>
<td>Tn</td>
</tr>
</tbody>
</table>

Figure 4.2 Table Data Structure with Sample Entries

The first column in the table is the identification number of each process. The second column is the next time to execution for each process. The master scheduler enters an infinite loop, once all processes have been created and placed on the ready-to-execute queue. Once in the loop, the scheduler scans the second column for zero values which indicates that the process is ready to start execution. If a zero entry is found, the process identification number is recorded and the scan continued through the table. Once all entries in the table have been checked, a time stamp is taken and the flagged processes are sent wake up signals from the scheduler. When the last signal has been sent, another time stamp is taken and the elapsed time from the start of the signaling procedure to the end is recorded and all signaled processes have their next time to execute entry reset to their original period. All
table entries then have the elapsed time subtracted from the second column of the table. This is done to prevent scheduler overhead from affecting the scheduling process. The scheduler then scans the second column for the smallest value present. This value is subtracted from all second column entries and the main scheduler is then suspended for this length of time to allow the called processes to begin execution. The possible conflicts between the children processes are resolved through the preemption allowed by the priorities assigned. This entire process, in pseudo-code, is illustrated in Figure 4.3.

```
While(true)
    scan table for zero entries;
    if entry = 0,
        record id number;
    take time stamp #1;
    for i=0 to m /* m = number of processes to be signaled */
        find process(i) id number;
        signal process(id number);
    end for loop
    take time stamp #2;
    adjustment = time stamp #2 - time stamp #1;
    for i = 0 to n /* all processes */
        table entry(i) = table entry(i) - adjustment;
    scan table for smallest entry (in ticks);
    for i=0 to n /*all processes */
        table entry(i) = table entry(i) - smallest entry;
        suspend scheduler for smallest entry ticks;
end while;
```

Figure 4.3 Psuedo Code for Signaling Process
During program development, the control loop was modified from an infinite loop to a finite loop controlled by the number of signals sent. It is recommended that onboard the AUV it remain an infinite loop with logic implemented to halt the loop from an outside source such as a keyboard interrupt or a time signal from the system clock or an elapsed time counter. This will allow for a more graceful exit from the program than the currently required rebooting of the system. A copy of the source code for the scheduler is found in Appendix B.

F. MODIFICATIONS OF CALLED PROCESSES

One goal in the original specifications for the scheduling software was that the other software modules would not have to be modified, that they could run 'as is.' This led to the original plan of create/execute/kill discussed earlier. When this proved unworkable, it was determined that a minimum amount of modification would have to be made in the other software modules in the system. These were designed to be quickly and easily installed in only a few minutes per module.

To implement the first modification, it is necessary to determine the sections of software that are to be executed each period versus those that are to be only run once, such as process initialization. Once these sections are identified an infinite while loop is installed around them. The second modification is to install the signal catching commands in the loop between the last local line of code and the end of the
infinite while loop. These modifications are demonstrated in Figure 4.4. The command most suitable for this is the OS-9

```c
main()
{
    initialization commands;
    
    while(1)
    {
        repeated commands;
        
        wait();
    }
    exit();
}
```

Figure 4.4 Modifications to Called Processes

command wait() with nc parameters. If it becomes desirable to return data or instructions back to the parent process, the OS-9 command exit() could be used. The wait() command suspends the child process (removes it from the ready-to-execute queue) until it receives a signal from the scheduler. During normal execution only two signals would be sent: a '1.0' to wake the process up, or a '0.0' indicating that the process is to be killed and its allotted memory returned to the system. The '0.0' is normally sent at the end of the mission to ensure a graceful termination of the scheduler.

The emphasis on the graceful conclusion of the scheduler is based on practical experience on the OS-9 system. When a process finishes without an exit() command, the process identification table and the processes allotted memory remain
allocated by the system until the system is rebooted. It takes surprisingly few of these to fill and fragment the system memory. When the system is in this condition it will continue to attempt to function normally, but no processes will execute. This is annoying in a PC-based machine, and possibly dangerous to an operating vehicle.

The last modification is used if the operator intends to allow the scheduler to measure the execution times of the processes. Since the time only needs to be measured over one execution of the process, the infinite loop is removed and the wait() command is replaced with the exit() command. The modified process is named the same as the original process with the letter 'a' appended to it. As with the original process a executable module must be available to the system.

G. APERIODIC EVENTS AND PERIOD TRANSFORMATION

Aperiodic events are handled by the scheduler in the current implementation by treating them as a periodic event with an infinite period. This method assumes that aperiodic events can be sent a wake up signal by a process other than the scheduler, whereupon it executes in the same fashion as a periodic event. Upon completion of the aperiodic event, the process suspends itself until signaled the next time. A more sophisticated approach would require modifications to the timing table in the master scheduler and the prioritization of the processes. This would entail marking the aperiodic events
with a flag and then schedule them in the same manner as periodic events with the proper priorities. The next step is done while scanning the table for executable processes and would require the addition of logic to check for the flag on aperiodic events and only signal them if circumstances warranted.

Period transformation was not implemented in the current scheduler due to limitations in the OS-9 operating system. To function correctly with a minimum of modification to the called processes, a method is needed to not only wake up the called processes from the master scheduler, but also to suspend the called processes. This is not possible; although a method has been derived in which period transformation could be implemented on, at least, a limited basis. This method would require that extensive modifications be made to the called processes and is beyond the scope of this study [SHUKLA 91].

Upon the completion of the scheduler software development, numerous tests and experiments were conducted to confirm the scheduler's veracity, reliability and limitations. These results are reported in the next chapter of this thesis.
V. EXPERIMENTS AND RESULTS

A. GENERAL

Once the scheduler was written, it was necessary to devise methods to ensure the scheduler's veracity and to demonstrate the improvement it offered over passive OS-9 as installed. It was also necessary to determine what processor loads it was able to effectively schedule, and how various task sets affected the scheduler performance. These results could then be used to fine tune task sets for the desired performance. Lastly, because the scheduler is implemented on a functioning vehicle, real world events were simulated by constructing task sets of random length execution times.

Task sets were constructed of identical dummy processes consisting of C-language program headers combined with the OS-9 primitives required to send and receive signals. Data was gathered and sent to data files for later analysis in such a way as to not interfere with the execution times of the processes. Execution times were controlled by varying a timing loop in the individual processes.

B. SCHEDULER VERIFICATION

To verify scheduler performance, it was first necessary to show that the scheduler met the theoretical requirements of RMS. These requirements included pre-emption of lower priority processes by higher priority processes and a reliable means of
meeting process deadlines. The dummy tasks were modified in such a way that the start and stop times of execution were recorded. At the end of the sample run, these values were written to a file for analysis by hand. The results of a sample run with four tasks in the task set are shown in Figure 5.1 as a time-line similar to the time-lines found in [SHA 90].

<table>

<td>30</td>
</tr>
</tbody>
</table>

Figure 5.1 Time Line Displaying Preemptive Scheduling

Preemption can clearly be seen as process P1, the process with the highest priority, forces the delay of all other processes in the set until it has completed execution. Likewise, P2
delays all processes, save P1, until it has completed. It is also clear that all processes met their assigned periods. Although this example has only four tasks, it demonstrates that the scheduler meets the theoretical requirements of RMS. Other sample runs confirm these results for sets with a larger number of processes.

C. IMPROVEMENT OVER OS-9

OS-9 is advertised as a multi-tasking operating system, that supports real time operations [MICROWARE 87]. A test to show that a separate scheduler was needed to improve performance above that provided by OS-9 as implemented was required. The test consisted of two tasks sets, both with six processes running at 10 Hz. The first set was executed using OS-9 alone; the other using the scheduler software developed. Scheduler breakdown was measured as the percentage of missed deadlines. Missed deadlines were determined by comparing the number of signals sent vice the number of signals received by each process. All graphs have the percentage breakdown on the abscissa and the percentage of processor load on the mantissa. As shown in Figure 5.2, OS-9 began missing deadlines at processor loads of 30% while the implemented scheduler does not miss a deadline until the 90% point, a clear improvement. The poor performance of OS-9 was expected, as it implements no real-time structure, but, rather, the primitives used to construct those structures.
D. PROCESS LOAD VARIATIONS

In order to ensure an effective scheduler on-board the vehicle, experiments were conducted by varying task set parameters to test scheduler performance. Standardization between experiments was maintained by executing all task sets over ten cycles where a cycle being defined as the least common multiple of all periods in the task set.

1. Experiment 1

This experiment was designed to determine under what load the scheduler started to breakdown, or miss process deadlines. The task set consisted of six processes at a frequency of 10 Hz. Figure 5.3 shows that scheduler breakdown
began to occur at a 90% load, close to the maximum predicted by [SHA 90].

![Figure 5.3 Performance for six 10 Hz processes](image)

The processor load was varied by increasing or decreasing process execution times while maintaining constant process frequencies. Initial processor load was 50% and increased at 5% intervals up to 110%. Processor loads over 100% were included to study scheduler stability characteristics.

2. Experiment 2

This experiment replaced one of the 10 Hz processes in the first task set with a 20 Hz process. The sample run consisted of the same processor loads as the first experiment. As shown in Figure 5.4, the results were quite different from the first experiment.
The earlier breakdown was explained, theoretically, as being due to the increased overhead caused by the increased number of task swaps incurred by the higher frequency process. After more experimentation, it was determined that the highest practical frequency for a process is 10 Hz. If higher frequencies are required, processor loads must be limited to no more than approximately 50%.

3. Experiment 3

This experiment determined the number of lower frequency processes that could be executed successfully. Figure 5.5 shows four different task sets consisting of eight tasks each, with the number of 10 Hz processes varying from
zero to three. The remaining processes are executed at 5 Hz. Processor loads were the same as in the first two experiments. It is interesting to note that while all task sets broke down at approximately the 90% point, the breakdown was accelerated proportional to the number of higher frequency processes present. The various task groups are represented as follows: solid line, eight 5 Hz tasks; dashed line, one 10 Hz task plus seven 5 Hz tasks; dotted line, two 10 Hz tasks plus six 5 Hz tasks; combination dotted and dashed line, three 10 Hz tasks plus five 5 Hz tasks. From this it was determined that the scheduler is more greatly affected by task frequencies than by task execution times.

![Figure 5.5 Performance with Different High Frequency Processes](image)

Figure 5.5 Performance with Different High Frequency Processes
4. Experiment 4

This experiment was an attempt to devise and execute a 'typical' task set for the vehicle. A typical set being one that could be expected to be found on AUV-II during a normal mission. This set was constructed after discussion with project members who were developing software modules for guidance, control and sonar. The set consisted of eight processes; two at 10 Hz, four at 5 Hz, and two at 2 Hz. The results are plotted in Figure 5.6.

![Figure 5.6 Performance for a Typical Task Set for AUV-II](image)

5. Experiment 5

This experiment was an attempt at developing a task set that more realistically represented actual vehicle operation. The same task set was used as in experiment 4 with randomized execution times included. A random number generator was added.
to each child process along with the logic needed to apply a normal distribution curve to the execution times. This code is given in Appendix C. The distribution was such that 50% of the executions were run at the mean time of execution; 40% of the executions were run at +/- 10% of the mean time; the remaining 10% of the executions were run at +/- 20% of the mean time. The lower utilization rate shown in Figure 5.7 was predictable. A process cannot 'save' excess allotted time from shorter than expected executions to make up for the longer than expected executions later encountered.

Figure 5.7 Performance for a Typical Task Set with Variable Execution Times

6. Experiment 6

This experiment was virtually the same as experiment 5 with slight variations in the periods and execution times. Figure 5.8 shows the results of the changed task set and is
included to show the breakdown qualities of the scheduler during sustained overload. The 'staircase' pattern was predicted prior to the experiment and was caused by preemption of the various lower priority processes. The more nearly vertical lines are caused by deadlines missed. When the graph first levels, all deadlines in the lowest priority process have been preempted, but all higher priority processes are still meeting their deadlines. The graph began to move upward again when the next lowest priority process began to miss deadlines.

This 'shedding' of lower priority processes would continue until only the highest priority process is still executing. This orderly break down ensures stability and allows for more efficient and safe vehicle operation under sustained overload.

Figure 5.8 Scheduler Stability Under Sustained Overload
conditions.

The experiments reported are a representative subset of a much larger number of sample runs made to establish scheduler reliability and performance. As can be seen by these results the scheduler objectives listed in Chapter I have been met in all cases and the scheduler, as implemented, can be considered sophisticated enough for the present needs of AUV-II.
VI. CONCLUSIONS AND FUTURE RESEARCH

A. CONCLUSIONS

The primary objective of this research was to provide an efficient, hard real-time scheduler for the AUV that would be capable of maintaining a reasonably high processor utilization rate. This was to be accomplished over the varying group of task sets that the vehicle could be expected to encounter.

As implemented, the scheduler provides reliable, real-time scheduling with utilization rates above 80% for almost all variations of task sets. Under worst case conditions, and with varying task set execution times, a 75% utilization rate was not difficult to achieve. If care is used in developing the task set to be used, the system operator should have little trouble achieving utilization rates of 80% or higher.

Aperiodic events can also be handled with the current implementation, although not as smoothly as with periodic events.

As per the original specifications, the scheduler is stable under overload. Lower priority tasks are always suspended before higher priority tasks during overload conditions, so a subset of the most critical processes always meet their deadlines. Of course, the critical subset varies with processor load.
B. FUTURE RESEARCH

Although the scheduler meets all original specifications and should serve well into the future of the project, several modifications could be made to improve its performance and capabilities. These could include the following:

1. A more sophisticated approach to aperiodic events. The current method works well, but will not cover all possible eventualities. An alternative method was proposed in chapter V of this thesis.

2. Period transformation may be implemented to deal with long period processes that need a high priority.

3. A graphical interface could be included that allows for a running record of processor utilization, breakdown, and overload conditions.

4. A user-producer algorithm could be implemented to deal with the problem of dependent processes.

5. Once the appropriate compiler is available from GESPAC, the software should be translated from C to Ada to more accurately reflect Department of Defense policies.

6. Once Transputer boards are installed, modifications will be needed to allow the scheduler access to the increased resources available.

7. Finally, if an increase in utilization rates are required, a hybrid scheduling policy combining RMS and dynamic priority assignment may be implemented.

  }
The following code finds the minimum $L_i$ for $0 < t < T_i$ as described by eq. 4.4 of chapter IV. *

```c
for (i = 0; i < n; i++)
    Lint[i] = 10000; /* arbitrarily large number */

for (i = 0; i < n; i++)
    for (t = 0; t < count; t++)
        if (Li[i][t] < Lint[i])  /* Eqn (4.4) */
            Lint[i] = Li[i][t];
```

The following code computes the maximum value of $L_i$. If this value is less than, or equal to 1 the task set is schedulable, else it can not be done. This routine will also tell the user how much excess processor time is left *

```c
L = 0;
for (i = 0; i < n; i++)
    if (Lint[i] > L)
        L = Lint[i];

U = 0; /* determines processor load */
for (i = 0; i < n; i++)
    U = U + C[i] / T[i]; /* if processor load > 1.0, not sched. */
if ((L < 1) && (U <= 1))  /* Eqn 4.5 */
    printf("Process set schedulable.\n\n");
if ((L > 1) || (U > 1))
    printf("Process set not schedulable\n\n");
printf("Total remaining processor time is: 
%.2f", (1 - U) * 100);
printf(" percent\n\n\n");
```

APPENDIX D. OS-9 SPECIFIC REAL-TIME PRIMITIVES

The following is a list of real-time primitives supported by the OS-9 operating system. All descriptions come from [MICROWARE 87].

- `os9forkc`: used to create a process
- `exit`: used to terminate a process
- `wait`: used to suspend process until a signal is received
- `sleep`: used to suspend a process for a specified number of seconds
- `tsleep`: used to suspend a process for a specified number of ticks
- `alm_atdate`: used to send signal at specified Gregorian date
- `alm_atjul`: used to send signal at specified Julian date
- `alm_cycle`: used to send signals at constant intervals
- `alm_set`: used to send a signal after a specified elapsed time
- `kill`: used to delete a process
- `abort`: used to stop process from keyboard
- `wake`: used to place suspended process on ready to execute queue
