## Performance Analysis of Non-Coplanar Synergetic Maneuvers

Maneuvers employing atmospheric forces to assist in orbital changes hold potential for significant fuel savings over purely exoatmospheric propulsive methods. The term synergetic has been coined to describe the combination of propulsive and atmospheric forces used by a maneuvering flight vehicle. This thesis concentrates on non-coplanar synergetic maneuvers using two different control methods for various lifting bodies over a range of heating rates and orbital speeds. The objective of this thesis is to study the aerocruise and aerobang maneuvers. The aerocruise maneuver has been studied for more than twenty years and is commonly thought to be the fuel-optimal solution to a maneuver flown at a constant heating rate. A new maneuver, the aerobang, has recently laid doubt as to the optimality of the aerocruise maneuver. The aerobang maneuver demonstrates the ability to yield a higher inclination change for a given amount of fuel as compared to the aerocruise maneuver. Within this thesis a computer code is developed to model both the aerobang and aerocruise maneuvers. It is shown that there exist flight regimes where the aerobang method is superior to the aerocruise method.

ABSTRACT

Maneuvers employing atmospheric forces to assist in orbital changes hold potential for significant fuel savings over purely exoatmospheric propulsive methods. The term synergetic has been coined to describe the combination of propulsive and atmospheric forces used by a maneuvering flight vehicle. This thesis concentrates on non-coplanar synergetic maneuvers using two different control methods for various lifting bodies over a range of heating rates and orbital speeds. The objective of this thesis is to study the aerocruise and aerobang maneuvers. The aerocruise maneuver has been studied for more than twenty years and is commonly thought to be the fuel-optimal solution to a maneuver flown at a constant heating rate. A new maneuver, the aerobang, has recently laid doubt as to the optimality of the aerocruise maneuver. The aerobang maneuver demonstrates the ability to yield a higher inclination change for a given amount of fuel as compared to the aerocruise maneuver. Within this thesis a computer code is developed to model both the aerobang and aerocruise maneuvers. It is shown that there exist flight regimes where the aerobang method is superior to the aerocruise method.

I. INTRODUCTION

The concept of maneuvering within the atmosphere by flight vehicles moving at orbital or near orbital speeds dates back to Sanger's idea of a suborbital spacecraft using aerodynamic lift to extend its range [Ref. 1]. While the idea is not new, the practical application, using lifting bodies at hypervelocities, may be within reach. New materials, propulsion, and engineering techniques have revived the idea of a synergetic maneuver. The term synergetic has been coined to describe the maneuvering of a spacecraft within the atmosphere using the combination of propulsive and aerodynamic forces. A maneuver using atmospheric forces to assist in orbital changes holds the potential for significant fuel savings over a purely exoatmospheric propulsive method [Ref. 2]. Mission applications of these types of maneuvers have been identified in three contexts; 1) synergetic plane change, 2) planetary missions, and 3) high earth orbit to low earth orbit rendezvous [Ref. 3: p. 3]. These three categories encompass the totality of useful application of this type of maneuver. This thesis is concerned with category one, the synergetic plane change. This application deals with non-coplanar orbital transfers, the interest of which is limited to the inclination change. A typical flight profile of a spacecraft executing a maneuver of this nature would require a deorbit burn which would put the spacecraft into a trajectory grazing the atmosphere, an aerodynamic turn, and finally a circularization maneuver at the desired altitude (Figure 1).
A. THESIS SCOPE

In the search for the optimum synergetic maneuver, three methods have been studied: the aeroglide, the aerocruise, and the aerobang. The aeroglide maneuver uses no propulsive force during the atmospheric interaction, theoretically giving this method an infinite inclination change per kilogram of fuel used. The penalty for the aeroglide maneuver is the extremely high heating rates caused by the dense atmosphere from the required low altitudes. The aerocruise maneuver was developed to overcome the heating rate problem created by the aeroglide method. In order to maintain a constant heating rate the aerocruise maneuver uses a combination of propulsion and aerodynamics to...
achieve an inclination change. For more than twenty years, this method has been studied to determine the optimal regimes of operation for this maneuver. A recent study has raised doubt to the optimality of the aerocruise maneuver and proposed another maneuver based on a maximum throttle setting and a modulation of the angle of attack [Ref. 3]. This new aerobang maneuver demonstrates the ability to yield a higher inclination change per kilogram of fuel used when compared to the aerocruise maneuver under like conditions.

This thesis analyzes two control methods of synergetic maneuvers, the aerocruise and the aerobang method. Each of the two maneuvers have similar goals of maintaining a constant heating rate while executing the aerodynamic turn. An evaluation, analysis, and comparison of the two maneuvers over a range of maximum lift to drag ratios ($(L/D)_{\text{max}}$) and heating rates will shed light on the capabilities and inadequacies of each control method. The analysis is limited to the actual maneuver itself at the necessary altitude required for its execution. It was assumed that the method of entry or exit from the atmosphere for the two maneuvers would be identical and would not be a factor in the overall efficiency of the maneuver.

The study includes a program developed specifically to model the aerocruise and aerobang control laws. The performance of each of these strategies are analyzed over a variety of orbital speeds and altitudes. The intent is to develop insight into the range of capabilities for each method and conditions under which aerobang might be more efficient than aerocruise.

B. BACKGROUND

Synergetic non-coplanar orbital transfers utilize a portion or all of the lift generated by the body in a direction perpendicular to the orbital plane. A force
applied in this direction will cause a change in the inclination of the orbit. The effect of the force on the inclination is maximized at the ascending and descending nodes of the orbits but has no effect at the apex of the orbit (i.e. 90 degrees from the nodal crossing). This maximizing effect at the node necessitates that the maneuver be completed within a short time span relative to the orbital period of the flight vehicle. Three methods of inclination change have been proposed so far: aeroglide, aerocruise, and aerobang. While this thesis deals with only two of these, the third method, aeroglide, would be of use in bringing the spacecraft to the appropriate position in which to commence the maneuver.

1. Aeroglide

During a non-coplanar transfer the aeroglide maneuver seeks to change the orbital inclination of the spacecraft. The maneuver consists of three parts, the deorbit, the aerodynamic turn, and the reorbit. The first and last segments of the maneuver are purely propulsive and generic to any of the three methods discussed within this thesis. To describe the aerodynamic turn of the aeroglide maneuver, it must be understood that no propulsive forces are used within the atmosphere. In order to maximize the plane change, the maneuver is most efficient at an angle of attack that produces the maximum lift-to-drag ratio. The lifting body is oriented with the generated lift vector normal to the spacecraft’s orbit. To generate the necessary lift for an effective plane change, the vehicle is flown at an orbital speed and a low altitude where the atmosphere is very dense. This flight profile results in an extremely high heating rate for the flight vehicle, possibly beyond the capabilities of the spacecraft. If the heating rate problem can be overcome, the aeroglide maneuver requires fuel expenditures only to
deorbit and reorbit, significantly reducing the fuel required to effect the same plane-change using a pure propulsive method. [Ref. 5: p 104]

The extreme heating rate required by the aeroglide maneuver hinders its use as an effective method for non-coplanar transfers. The heating rate profile of the maneuver begins at a low value as it enters the atmosphere and builds to its highest value at the minimum orbital altitude. A possible use for the aeroglide maneuver would be in conjunction with another synergetic plane change maneuver. A proposed flight profile would be: after the deorbit burn the spacecraft would assume an aeroglide profile until the predetermined altitude, velocity, and heating rate were achieved, then the follow-on maneuver would be executed, and finally an aeroglide maneuver to exit the atmosphere and reboost. Both aeroglide portions of the flight path would not be at the optimum glide profiles for an aeroglide maneuver, but some gain of inclination change would be realized until the selected conditions for the aerocruise or aerobang maneuver are reached.

2. Aerocruise

The aerocruise synergetic maneuver couples the aeroglide maneuver with a propulsive force during the atmospheric interaction. This maneuver is made up of three parts, the deorbit, the aerodynamic turn, and the reorbit, similar to the aeroglide maneuver, the difference being in the method used during the aerodynamic turn. A typical flight profile requires the vehicle to remain on the heating rate boundary; this dictates the aerocruise maneuver to be flown at a specific altitude and speed. Graphically, this profile appears as a point on a speed versus radius graph (Figure 2). This point would just touch the maximum allowable heating rate for the spacecraft. The altitude and speed are
maintained by a combination of engine throttling and modulation of the flight vehicle angle of bank. The speed is held constant by setting the thrust equal to the drag encountered at the flight altitude. Altitude is maintained by banking the spacecraft to allow for a component of the lift force generated to counteract the apparent centrifugal force (Figure 3). This method allows for a plane-change maneuver without incurring the heating rate problems of the aeroglide maneuver. Conventional wisdom requires that the angle of attack be set at \((L/D)_{\text{max}}\) in order to maximize the efficiency of the maneuver [Ref. 3: p. 5]; however, recent studies [Ref. 6: p. 517] have shown that the most efficient (i.e. largest inclination change for a given expenditure of fuel) maneuver is not at \((L/D)_{\text{max}}\), but at a lower \(L/D\) and a higher angle of attack.
3. Aerobang

This method of control is similar to the aerocruise model in that the heating rate of the vehicle is to remain constant, but this is where the similarity ends. The aerobang flight profile allows the vehicle to change its altitude and speed as necessitated by the control law governing the maneuver (Figure 2). As mentioned previously, the most effective use of the lifting force for the orbital plane change is to orient the force normal to the orbital plane; this dictates an angle of bank of 90 degrees for the spacecraft. If the angle of bank is to remain fixed, the only variables left for modulation are the thrust of the vehicle and the angle of attack. The aerobang maneuver modulates the angle of attack and fixes the thrust at the maximum available value. It can be shown that for certain conditions, the aerobang maneuver will achieve a higher inclination change for a given fuel expenditure than the aerocruise maneuver.
I. FLIGHT VEHICLES

To properly understand the similarities and differences between the aerocruise and aerobang maneuvers, a parameter analysis of more than one flight vehicle would be necessary. Ideally, the flight vehicles would be similar in every respect except one, and changes observed on the data output could then be attributed to that differing parameter. Early investigators of synergetic maneuvers came to two main conclusions: first, the lifting body should operate at \((L/D)_{\text{max}}\), and second, the \(L/D\) should be greater than one to be superior to an all propulsive maneuver [Ref. 3: p. 5]. The emphasis on \((L/D)_{\text{max}}\) brought this investigation to select two vehicles for comparison, one which would operate at \((L/D)_{\text{max}}\) of approximately 1.8 and the other at 2.6. Flight vehicles which have been designed and have data available provide a sense of reality to the analysis, whereas an imaginary flight vehicle and data might skew the study. The two flight vehicles investigated in this thesis are the ERV (Entry Research Vehicle) and the MRRV (Maneuverable Reentry Research Vehicle).

A. ENTRY RESEARCH VEHICLE

The ERV was designed with the idea of investigating and exploiting maneuvers involving long downrange, high crossrange, and synergetic plane changes. The vehicle is 7.62 m long and has a wing span of only 3.96 m, allowing the vehicle to be launched from the cargo bay of the space shuttle. The slenderness ratio of the fuselage is approximately 0.167. Figure 4 shows a three-view sketch of the ERV. Three Marquardt R-40-B rocket motors make up the propulsion system, providing a total of 14679 Newtons of thrust at a specific
impulse (ISP) of 295 seconds. Separation weight from the Space Shuttle is planned for 5443 kg with 50% of that made up of fuel. [Ref. 7: pp. 489-90]

For the purpose of modeling within a computer program, the aerodynamic data were approximated by a least squares binomial fit (Figures 5 and 6). Wind-tunnel data for the ERV were obtained from the Martin Marietta Corporation [Ref. 8] and included coefficient of lift and drag data up to Mach 10. These data were used for flight velocities from 8.3 km/sec down to 7.1 km/sec. Although these velocities correspond to Mach numbers of 26 to 22 at the maneuvering altitude, the data from Mach 10 can realistically apply because of the limiting characteristics exhibited by the bow shock and the pressure distribution over the lifting body [Ref. 9: pp. 387-388]. The curve fit was done using a linear statistical model [Ref. 10] and then the coefficients were modified to obtain an L/D vs angle of attack similar to the actual data taken from the wind tunnel tests. From the L/D curve (Figure 7), we see that (L/D)\text{max} occurs at approx 10.5 degrees with a value of 1.8.
Figure 5. Coefficient of Lift vs Angle of Attack for ERV

Figure 6. Coefficient of Drag vs Angle of Attack for ERV
Figure 7. $C_L/C_D$ vs Angle of Attack for ERV

B. MANEUVERABLE REENTRY RESEARCH VEHICLE

Although the MRRV is similar in size and weight to the ERV, that is where the similarity ends. The MRRV has a maximum lift to drag ratio on the order of 2.6, much higher than the ERV. Figure 8 show a three-view sketch of the MRRV and when compared to Figure 4 the differences between the MRRV and the ERV become apparent. The MRRV is a much more slender design; the slenderness ratio of the fuselage is approximately one eighth. The overall length is 7.62 m and because of the sharper design of the vehicle it has an effective wing area of 11.7 square meters, 4.7 square meters less than the ERV. The propulsion system is identical to the ERV using three Marquardt R-40-B rocket motors, providing a total of 14679 Newtons of thrust at a specific impulse of 295 seconds. [Ref. 3: p. 7]
Figure 8. Three-view Diagram of MRRV

The method used to find the coefficient of lift and drag curves for the ERV was employed to find those for the MRRV. Figure 9 shows a plot of the curve fit for the coefficient of lift with the wind tunnel data obtained for the MRRV, and Figure 10 displays the coefficient of drag. It is interesting to note that even though Figure 11 shows the MRRV to have a higher lift to drag ratio than the ERV, a comparison of the actual coefficient of lift and drag show the ERV to have higher actual values. The lower lift and drag coefficients coupled with the decreased wing area of the MRRV will be of importance during the analysis to follow.

Figure 10. Coefficient of Drag vs Angle of Attack for MRRV

\( C_d = 0.047 - 0.447\alpha + 2.04\alpha^2 \) (\( \alpha \) in radians)
Figure 11. $\frac{C_L}{C_D}$ vs Angle of Attack for MRRV
III. EQUATIONS OF MOTION

The equations of motion for a hypervelocity lifting body are derived, free of singularities. Six specific variables are utilized to describe the spacecraft's position and velocity. Referenced to an inertial frame XYZ, the vehicle's position is represented by spherical coordinates r (radius), θ (right ascension), and φ (declination) and the vehicle's motion as speed V, and direction by the angles γ (flight path angle) and ψ (heading angle). The flight path angle, γ, is positive above the local horizon and negative below. The heading angle is the angle the horizontal projection of the velocity vector makes with the local horizon.
latitude. Figure 12 graphically shows the six variables and their relationship to each other.

Assumptions made in the derivation of these equations are: a spherical, non-rotating, Earth and negligible atmospheric winds. The Earth's oblateness is not considered due to the short nature of the atmospheric interaction by the spacecraft. Future studies may find a need to include these effects. Additionally, the thrust vector of the spacecraft was assumed to be in line with its longitudinal axis.

A. DERIVATION OF EQUATIONS

Three coordinate systems are defined for the derivation of the equations of motion. The inertially fixed system, XYZ. A rotating system, xyz, in which the origin is coincident with that of the inertial system and the positive x axis remains fixed to the spacecraft. Finally, a system x'y'z' which is fixed to the spacecraft with the y' axis oriented along the velocity vector and the x' axis within the xy plane, the origin of the system lies at the end of the radius vector in the xyz system, (Figure 12). The transformation from the inertial system into the xyz system is done using a body 3-2 rotation through angles $\theta$ and $\phi$ respectively. Additionally, to obtain the xyz system from the x'y'z' a body 3-1 rotation must be done using angles $\gamma$ and $\psi$. Using the following DCMs (direction cosine matrix) all of the parameters can be described in the rotating xyz system.

The DCM for the transformation from the inertial system to xyz system is expressed as the multiplication of two matrices the right matrix representing the body-3 rotation and the left matrix representing the body-2 rotation.
Consolidating the two matrix transformations for a body 3-2 rotation, we have

\[
\begin{bmatrix}
X \\
Y \\
Z
\end{bmatrix} =
\begin{bmatrix}
\cos \phi & 0 & \sin \phi \\
0 & 1 & 0 \\
-\sin \phi & 0 & \cos \phi
\end{bmatrix}
\begin{bmatrix}
\cos \theta & \sin \theta & 0 \\
-\sin \theta & \cos \theta & 0 \\
0 & 0 & 1
\end{bmatrix}
\begin{bmatrix}
X \\
Y \\
Z
\end{bmatrix}
\]  

(3.1)

Similarly, the DCM for the transformation from the \(x'y'z'\) spacecraft system to \(xyz\) system is expressed below:

\[
\begin{bmatrix}
X' \\
Y' \\
Z'
\end{bmatrix} =
\begin{bmatrix}
1 & 0 & 0 \\
0 & \cos \psi & -\sin \psi \\
0 & \sin \psi & \cos \psi
\end{bmatrix}
\begin{bmatrix}
\cos \gamma & \sin \gamma & 0 \\
-\sin \gamma & \cos \gamma & 0 \\
0 & 0 & 1
\end{bmatrix}
\begin{bmatrix}
x \\
y \\
z
\end{bmatrix}
\]  

(3.3)

Completing the algebra the body 3-1 rotation, we get,

\[
\begin{bmatrix}
X' \\
Y' \\
Z'
\end{bmatrix} =
\begin{bmatrix}
\cos \gamma & \sin \gamma & 0 \\
-\sin \gamma & \cos \gamma & -\sin \psi \\
-\sin \gamma & \cos \gamma & \cos \psi
\end{bmatrix}
\begin{bmatrix}
x' \\
y' \\
z'
\end{bmatrix}
\]  

(3.4)

For a system of equations to completely describe the spacecraft's motion and position at any moment in time, an equation of the time derivative for each of the six variables must be established. By equating the spacecraft's velocity vector to the time derivative of the spacecraft's position vector, the derivatives for \(r\), \(\theta\), and \(\phi\) can be expressed as functions of \(r\), \(\theta\), \(V\), \(\gamma\), and \(\psi\). The time derivatives for \(V\), \(\gamma\), and \(\psi\) are also found by taking the time derivative of the spacecraft's velocity vector and equating them to the forces acting on the spacecraft using the relationship \(\mathbf{F} = m\mathbf{a}\).
The vectors for the spacecraft's position and velocity in the \(xyz\) system are

\[
\vec{r} = r \hat{i}
\]  

and

\[
\vec{V}_j = V \sin \gamma \hat{i} + V \cos \gamma \cos \psi \hat{j} + V \cos \gamma \sin \psi \hat{k}
\]  

Additionally, the angular velocity of the spacecraft is

\[
\vec{\Omega} = \sin \phi \frac{d\theta}{dt} \hat{i} - \frac{d\phi}{dt} \hat{j} + \cos \phi \frac{d\theta}{dt} \hat{k}
\]  

Taking the derivative of Equation 3.5, yields an equivalent velocity vector,

\[
\vec{V} = \frac{d\vec{r}}{dt}_{XYZ} = \frac{d\vec{r}}{dt}_{\hat{i}} + (\vec{\Omega} \times \vec{r}) = \frac{d\vec{r}}{dt}_{\hat{i}} + r \cos \phi \frac{d\theta}{dt} \hat{j} + r \frac{d\phi}{dt} \hat{k}
\]  

Equating the components of Equations 3.6 and 3.8 gives the first three equations of motion. These three equations describe the spacecraft's position in spherical coordinates for any time:

\[
\frac{dr}{dt} = V \sin \gamma
\]  

\[
\frac{d\theta}{dt} = \frac{V \cos \gamma \cos \psi}{r \cos \phi}
\]  

\[
\frac{d\phi}{dt} = \frac{V \cos \gamma \sin \psi}{r}
\]  

Similarly taking the derivative of the velocity vector (Equation 3.6) the final three equations of motion can be found. The last three equations will describe the spacecraft's movement through space at any particular time.

\[
\frac{d\vec{V}}{dt} = \frac{d(V \sin \gamma)}{dt} \hat{i} + V \sin \gamma \frac{d\hat{i}}{dt} + \frac{d(V \cos \gamma \cos \psi)}{dt} \hat{j}
\]

\[
+ V \cos \gamma \cos \psi \frac{d\hat{j}}{dt} + \frac{d(V \cos \gamma \sin \psi)}{dt} \hat{k} + V \cos \gamma \sin \psi \frac{d\hat{k}}{dt}
\]
Expanding, we have
\[
\begin{align*}
\frac{d\vec{V}}{dt} &= \left[ \sin \gamma \frac{dV}{dt} + V \cos \gamma \frac{\gamma}{dt} \right] \hat{i} + \left[ V \sin \gamma \left( \cos \phi \frac{d\phi}{dt} \hat{j} + \frac{d\phi}{dt} \hat{k} \right) \right] \\
&+ \left[ \cos \gamma \cos \psi \frac{dV}{dt} - V \cos \psi \sin \gamma \frac{\gamma}{dt} - V \cos \gamma \sin \psi \frac{d\psi}{dt} \right] \hat{j} \\
&+ \left[ V \cos \gamma \cos \psi \left( -\cos \phi \frac{d\phi}{dt} \hat{i} + \sin \phi \frac{d\phi}{dt} \hat{k} \right) \right] \\
&+ \left[ \cos \gamma \sin \psi \frac{dV}{dt} - V \sin \psi \sin \gamma \frac{\gamma}{dt} + V \cos \gamma \cos \psi \frac{d\psi}{dt} \right] \hat{k}
\end{align*}
\]
(3.12)

Replacing \(d\theta/dt\) and \(d\phi/dt\) in Equation 3.12 using Equations 3.10 and 3.11 yields
\[
\begin{align*}
\frac{d\vec{V}}{dt} &= \left[ \sin \gamma \frac{dV}{dt} + V \cos \gamma \frac{\gamma}{dt} \right] \hat{i} \\
&+ \left[ \cos \gamma \cos \psi \frac{dV}{dt} - V \cos \psi \sin \gamma \frac{\gamma}{dt} - V \cos \gamma \sin \psi \frac{d\psi}{dt} \right] \hat{j} \\
&+ \left[ \frac{V^2 \sin \gamma \cos \gamma \cos \psi - V \cos^2 \gamma \sin \psi \cos \psi \tan \phi}{r} \right] \hat{j} \\
&+ \left[ \frac{\cos \gamma \sin \psi \frac{dV}{dt} - V \sin \psi \sin \gamma \frac{\gamma}{dt} + V \cos \gamma \cos \psi \frac{d\psi}{dt}}{r} \right] \hat{k}
\end{align*}
\]
(3.13)

The forces acting on the spacecraft in the \(x'y'z'\) coordinate system can be expressed as (Figure 13)
\[
F_x = (T \sin \alpha + L) \cos \sigma \quad (3.14)
\]
\[
F_y = T \cos \alpha - D \quad (3.15)
\]
\[
F_z = (T \sin \alpha + L) \sin \sigma \quad (3.16)
\]
Restating the fundamental equation of motion as a derivative of velocity with respect to time

\[ \vec{F} = m_a \vec{a} = m_a \frac{d\vec{V}}{dt} \]  

\( (3.17) \)

Figure 13. Spacecraft Forces During Atmospheric Interaction

Using the DCM from Equation 3.3 the forces from the spacecraft's frame of reference \( (x'y'z') \) can be transformed into the rotating frame of reference \( (xyz) \) using

\[
\begin{bmatrix}
F_x \\
F_y \\
F_z
\end{bmatrix} =
\begin{bmatrix}
\cos \gamma & \sin \gamma & 0 \\
-\sin \gamma \cos \psi & \cos \gamma \cos \psi & -\sin \gamma \\
-\sin \gamma \sin \psi & \cos \gamma \sin \psi & \cos \psi
\end{bmatrix}
\begin{bmatrix}
F_{x'} \\
F_{y'} \\
F_{z'}
\end{bmatrix} \]

\( (3.18) \)

With the above transformation matrix and using Equations 3.14, 3.15, and 3.16, the forces acting on the spacecraft can be expressed in the rotating system as

\[ F_x = (T \sin \alpha + L) \cos \sigma \cos \gamma + (T \cos \alpha - D) \sin \gamma - m_a g \]  

\( (3.19) \)

\[ F_y = - (T \sin \alpha + L) \cos \sigma \sin \gamma \cos \psi \]

\[ + (T \cos \alpha - D) \cos \gamma \cos \psi - (T \sin \alpha + L) \sin \sigma \sin \psi \]  

\( (3.20) \)
and

\[ F_z = - (T \sin \alpha + L ) \cos \sigma \sin \gamma \sin \psi \]

\[ + (T \cos \alpha - D ) \cos \gamma \sin \psi - (T \sin \alpha + L ) \sin \sigma \cos \psi \]  \hspace{1cm} (3.21)

Now setting the components of Equation 3.17 equal to the spacecraft force equations expressed in the rotating coordinate system, three independent equations are obtained for evaluation and reduction namely

\[ \hat{i} : (T \sin \alpha + L ) \cos \sigma \cos \gamma + (T \cos \alpha - D ) \sin \gamma - m_g g = \]

\[ m_a \left[ \sin \gamma \frac{dV}{dt} + V \cos \gamma \frac{dV}{dt} - \frac{V^2 \cos^2 \gamma}{r} \right] \hspace{1cm} (3.22) \]

\[ \hat{j} : -(T \sin \alpha + L ) \cos \sigma \sin \gamma \cos \psi + (T \cos \alpha - D ) \cos \gamma \cos \psi \]

\[ - (T \sin \alpha + L ) \sin \sigma \sin \psi = m_a \left[ \cos \gamma \cos \psi \frac{dV}{dt} - V \cos \psi \sin \gamma \frac{dV}{dt} \right. \]

\[ - V \cos \gamma \sin \psi \frac{dV}{dt} + \frac{V^2}{r} \cos \gamma \cos \psi (\sin \gamma - \cos \gamma \sin \psi \tan \phi ) \]  \hspace{1cm} (3.23)

\[ \hat{k} : -(T \sin \alpha + L ) \cos \sigma \sin \gamma \sin \psi + (T \cos \alpha - D ) \cos \gamma \sin \psi \]

\[ + (T \sin \alpha + L ) \sin \sigma \cos \psi = m_a \left[ \cos \gamma \sin \psi \frac{dV}{dt} - V \sin \psi \sin \gamma \frac{dV}{dt} \right. \]

\[ + V \cos \gamma \cos \psi \frac{dV}{dt} + \frac{V^2}{r} \cos \gamma (\sin \gamma \sin \psi + \cos \gamma \cos^2 \psi \tan \phi ) \]  \hspace{1cm} (3.24)

In order to obtain the last three equations of motion, Equations 3.22, 3.23, and 3.24 must be algebraically manipulated and reduced. Taking Equation 3.23 and multiplying by \cos(\psi) and Equation 3.24 and multiplying by \sin(\psi), then adding the two resulting equations together gives

\[ (T \cos \alpha - D ) - m_g g \sin \gamma = m_a \frac{dV}{dt} \]  \hspace{1cm} (3.25)
Substituting this result back into Equation 3.22 and reducing yields

\[ V \frac{d\gamma}{dt} = \frac{(T \sin \alpha + L) \cos \sigma - mg \cos \gamma + \frac{V^2}{r} \cos \gamma}{m_a} \]  

(3.26)

A final substitution into Equation 3.23 gives us the sixth equation of motion for the flight vehicle, namely

\[ V \frac{dv}{dt} = \frac{(T \sin \alpha + L) \sin \sigma - \frac{V^2}{r} \cos \gamma \cos \psi \tan \phi}{m_a \cos \gamma} \]  

(3.27)

Making one final reduction by defining variables \( A_R, A_S, \) and \( A_W \) which are the components of the acceleration of the flight vehicle in the radial, tangential, and binormal directions respectively, we have from Equations 3.14, 3.15, and 3.16,

\[ A_R = \frac{(T \sin \alpha + L) \cos \sigma}{m_a} \]  

(3.28)

\[ A_S = \frac{T \cos \alpha - D}{m_a} \]  

(3.29)

and

\[ A_W = \frac{(T \sin \alpha + L) \sin \sigma}{m_a} \]  

(3.30)

The last three equations of motion can now be written as

\[ \frac{dV}{dt} = A_S - g \sin \gamma \]  

(3.31)

\[ V \frac{d\gamma}{dt} = A_R + \frac{V^2}{r} - g \cos \gamma \cos \phi \]  

(3.32)

and

\[ V \frac{dw}{dt} = \frac{A_W}{m_a} + \frac{V^2}{r} \cos \gamma \cos \psi \tan \phi \]  

(3.33)
B. DERIVATION OF THE INCLINATION

The six equations of motion, Equations 3.9-3.11 and 3.31-3.33, when integrated numerically yield the spacecraft's position in spherical coordinates at any time during the orbit. For facilitating a comparison between orbits, a relationship between the orbital elements and the spherical coordinates is necessary. In non-coplanar transfers, an orbital element which indicates performance of the maneuver is inclination. The necessity to convert from spherical coordinates to inclination of the orbit for the purpose of performance evaluation is the basis for this derivation. As shown in Equations 3.5 and 3.6 the radius and velocity vectors can be written in terms of the rotating frame of reference. The angular momentum vector \( \mathbf{h} \) is defined as the cross product of the radius and the velocity vector; thus

\[
\mathbf{h} = \mathbf{r} \times \mathbf{V} = -V_r \cos \gamma \sin \psi \mathbf{j} + V_r \cos \gamma \cos \psi \mathbf{k} \tag{3.34}
\]

The magnitude of the momentum vector is, consequently

\[
|\mathbf{h}| = \sqrt{(V_r)^2 \cos^2 \gamma \sin^2 \psi + (V_r)^2 \cos^2 \gamma \cos^2 \psi} \tag{3.35}
\]

giving

\[
|\mathbf{h}| = V_r \cos \gamma \tag{3.36}
\]

The inclination of an orbit is defined as the angle between the angular momentum vector and \( \mathbf{k} \), the direction of the Z axis of the inertial coordinate system. The inclination can be found by defining \( \mathbf{k} \) within the rotating xyz system and then using the dot product definition to find the angle between the \( \mathbf{h} \) and the \( \mathbf{k} \) vectors. Since

\[
\mathbf{k} = \sin \phi \hat{i} + \cos \phi \hat{k} \tag{3.37}
\]
\[ \mathbf{h} \cdot \mathbf{k} = |\mathbf{h}| \cos i \]  
\hfill (3.38)

and
\[ V \tau \cos \gamma \cos \psi \cos \phi = |\mathbf{h}| \cos i \]  
\hfill (3.39)

Utilizing Equations 3.36 and 3.39, the cosine of the inclination can be found explicitly in terms of \( \psi \) and \( \phi \), thus
\[ \cos i = \cos \psi \cos \phi \]  
\hfill (3.40)

This result, exhibits no constraint on whether the path of the orbiting vehicle is Keplerian or not.
IV. CONTROL LAWS

Aerocruise and aerobang each have unique methods for controlling the space vehicle's trajectory during an atmospheric encounter. Aerocruise uses two distinct rules to maintain the proper flight path. First, the spacecraft's velocity is controlled by setting the component of thrust in the direction of travel to exactly counteract the vehicle's drag. Second, the altitude is maintained constant by modulating the flight vehicle's angle of bank. This is done by balancing the vertical component of the lift and thrust to the vehicle's weight minus the centrifugal force. The method of control used by the aerobang maneuver is less complicated, in that only one parameter of the flight vehicle is modulated during the maneuver. The angle of bank during the aerobang maneuver is set at a constant value, typically 90 degrees; this maximizes the inclination change caused by the aerodynamic lift. Additionally, the thrust is not modulated but set to the maximum available thrust. The modulated parameter is the flight vehicle's angle of attack, and the spacecraft is not constrained by a particular speed or altitude, but to the maximum allowable heating rate.

A. AEROCRUISE CONTROL LAW

Early investigations of the aerocruise maneuver dictated that superior results could be achieved if the spacecraft operated at \((L/D)_{max}\) [Ref. 3: p. 5]. The development of the control law for the angle of bank required to maintain a constant altitude and velocity, and hence a constant heating rate, utilizes this concept. Counterbalancing the drag on the flight vehicle with the thrust produced demands a prediction of the drag encountered at various altitudes. The
density in the U.S. Standard Atmosphere, 1976, [Ref. 11: p. 7] is approximated by an exponential behavior in the altitude range from 50 km to 120 km, namely

\[ \rho = \rho_s e^{-\beta(r-s)} \]  

(4.1)

where

\[ \rho_s = 3.0968 \times 10^{-4} \text{ kg/m}^3 \]
\[ \beta = 1.41 \times 10^{-4} \text{ m}^{-1} \]
\[ r_s = 6438 \text{ km} \]

This density approximation coupled with the speed of the spacecraft and the coefficient of drag on the vehicle, at \((L/D)_{\text{max}}\), yields a drag force which is constant throughout the aerocruise maneuver. Looking back at Figure 13, the thrust required for aerocruise to balance the drag force by the component of thrust along the spacecraft's direction of motion is given by

\[ T = \frac{D}{\cos \alpha} \]  

(4.2)

where

\[ D = \frac{1}{2} \rho V^2 S C_D \]  

(4.3)

In order to calculate the required angle of bank for the aerocruise maneuver it is necessary to look at Equations 3.28 and 3.32, which are repeated here for convenience

\[ A_R = \frac{(T \sin \alpha + L) \cos \sigma}{m_s} \]  

(3.28)

\[ \frac{dy}{dt} = A_R + \left( \frac{V^2}{r} - g \right) \cos \gamma \]  

(3.32)

The flight path of the vehicle during the aerocruise maneuver is circular and thus the flight path angle \((\gamma)\) is zero and will remain zero throughout the maneuver.
Combining this information, with the substitution of Equation 3.28 into Equation 3.32 and solving for the angle of bank (\(\sigma\)) yields

\[
\sigma = \cos^{-1}\left[ \frac{m_{a}(g - \frac{V^2}{L})}{(T \sin \alpha + L)} \right]
\]  \hspace{1cm} (4.4)

Obviously, from Equation 4.4, the angle of bank becomes 90 degrees when the spacecraft's velocity is equal to the velocity required to maintain a circular orbit at the given altitude. As the speed of the spacecraft becomes higher than circular speed, the angle of bank also increases beyond 90 degrees, causing the lift vector to be directed Earthward to maintain the circular path of the vehicle. Likewise, as the spacecraft's velocity decreases below circular speed, the angle of bank decreases and the lift vector is directed upward to sustain the circular path. Examining Equation 4.4, it is clear that there is a limitation in the angle of bank which can be used to control the flight path; this limitation occurs when the absolute value of the terms within the square bracket exceeds 1. In this case, there is not enough lift generated to maintain the desired flight path. To correct for this condition, the vehicle would have to abandon flight at \((L/D)_{\text{max}}\) and choose a higher angle of attack in order to generate the necessary lift.

**B. AEROBANG CONTROL LAW**

Differing from the aerocruise method, the aerobang maneuver allows the vehicle to vary the altitude and velocity in order to maintain a constant heating rate on the spacecraft. In order to determine how the angle of attack is modulated to keep the flight vehicle at a constant heating rate, the modeling of the heating rate must first be discussed. Heating rate is modeled as a function of atmospheric density \((\rho)\) and vehicle speed \((V)\), by the expression [Ref. 9: p. 291],

\[
\text{Heating rate} = f(\rho, V)
\]
\[ Q = k \rho^n V^m \]  

(4.5)

where \( K, n, \) and \( m \) are constants.

Coupling Equation 4.5 with Equation 4.1, the exponential atmospheric model, the speed of the spacecraft can be shown to be a function of the vehicle’s geocentric radius for any given heating rate. Equation 4.6 shows this relationship and is the basis for the aerobang control law.

\[ V = \left( \frac{Q_0}{k \rho_0^n e^{-\frac{\beta n}{m} (r - r_0)}} \right)^{\frac{1}{m}} \]  

(4.6)

The derivative with respect to time of Equation 4.6 is necessary in order to couple the equations of motion for the spacecraft to the constant heating rate flight path. Thus,

\[ \frac{dV}{dt} = \left( \frac{\beta n}{m} \right) V \frac{dr}{dt} \]  

(4.7)

\[ \frac{dV}{dt} = \left( \frac{\beta n}{m} \right) V^2 \sin \gamma \]  

(4.9)

Combining Equation 3.9 with Equation 4.8, \( dr/dt \) can be eliminated and \( dV/dt \) can be expressed as a function of \( V \) and \( \gamma \)

Substituting Equation 3.29 into Equation 3.31 and eliminating the variable \( \Delta s \), another equation for \( dV/dt \) is derived (Equation 4.10). The two Equations, 4.9 and 4.10, yield a final relationship

\[ \frac{dV}{dt} = \frac{T \cos \alpha - D}{m_a} - g \sin \gamma \]  

(4.10)

Equations 4.9 and 4.10 together enable the evaluation of the angle of attack for any given flight condition, from the equation
\[ 0 = T \cos \alpha - D - m_a \sin \gamma (g + \frac{\beta n}{m} V^2) = f(\alpha) \] 

(4.11)

However, since the drag term, \(D\), is also a function of \(\alpha\), solving for \(\alpha\) is not as straightforward as it might at first appear.

1. Mechanics of Convergence

Equation 4.11 is made up of three distinct terms, a thrust component, a drag component, and a component which depends on the vehicle's velocity and flight path angle. The first two of these terms are dependent on the angle of attack of the vehicle, while the third term remains constant for a given flight condition, independent of the angle of attack. Figure 14 graphically show the relationship of these terms in solving for the angle of attack of the flight vehicle. The terms which contain the flight path angle and the drag are summed and

![Graphical Example of Angle of Attack Solution](image)

**Figure 14. Graphical Example of Angle of Attack Solution**
plotted together with the thrust term, the intersection of these two lines occur at the proper angle of attack to maintain a flight path along a constant heating rate line.

For a given flight vehicle, the thrust curve shown in Figure 14 is fixed for any flight condition, while the drag and flight path terms increase with increasing flight speed. As the flight speed continues to increase, the converged angle of attack needed to maintain a stable flight path decreases, and at some point there exists a flight condition where the two curves would not intersect. At this point, the thrust curve lies below the curve representing the sum of the drag and flight path terms, and no solution exists for an angle of attack.

2. Newton's Method of Convergence

The nature of Equation 4.11 does not allow a direct solution for the angle of attack, and another method must be used. An iterative process developed by Sir Isaac Newton lends itself well to applications involving computer methods [Ref. 12: p. 142]. The method involves following the tangent of the function down to the zero of the function as expressed by

\[ \alpha_{n+1} = \alpha_n - \frac{f(\alpha_n)}{f'(\alpha_{n+1})}, \quad f'(\alpha_n) \neq 0 \]  

where,

\[ f'(\alpha) = -T \sin \alpha - \frac{dD}{d\alpha} = -T \sin \alpha - (C_5 + 2C_6|\alpha|) \frac{1}{2} \rho V^2 S \]

and \( C_5 \) and \( C_6 \) are the coefficients of the first order and second order terms in the binomial curve fit of drag vs. angle of attack. The iterative nature of this process requires an accurate initial guess for the angle of attack in order to reduce the time of computation.
3. Initial Guess of Angle of Attack

Properly setting the initial angle of attack close to the correct value can significantly decrease the required number of iterations needed to converge to the solution. The method employed here involves simplifying the information already presented in order to obtain a direct solution. Two assumptions are made in order to provide this starting point for the solution of $\alpha$. These two assumptions are that initially the acceleration component in the tangential direction is nearly zero and that the angle of attack is small enough that its cosine is approximately unity. Applying these two simplifications in Equation 3.29 leaves the expression that thrust ($T$) equals the drag ($D$). Therefore

$$ \frac{T}{\frac{1}{2} \rho V^2 S} = C_4 + C_5 \alpha + C_6 \alpha^2 $$ \hspace{1cm} (4.14)

yielding the solution

$$ \alpha = \frac{C_5 + \sqrt{C_5^2 + 4 \left( \frac{T}{\frac{1}{2} \rho V^2 S} \right) - C_4 C_6}}{2 C_6} $$ \hspace{1cm} (4.15)

While this is only an approximation, it enables the initial angle of attack to start closer to the solution than if some arbitrary value for $\alpha$ were selected. As will be shown later, these assumptions are close to the actual value for a flight vehicle with a circular or near circular velocity.
V. PROGRAM DEVELOPMENT

A computer program was developed using VAX FORTRAN to simulate a lifting body within the atmosphere. The program utilized a fourth order Runge-Kutta routine to integrate the differential equations of motion derived in Chapter III. Equations of motion for the simulation were left in a dimensional form because the accuracy of the computations was considered adequate using double precision variables within the program. The limited gain in accuracy and computational time using non-dimensional equations and programming techniques was considered insufficient to justify the increased time for implementing the equations in a non-dimensional form. Redundant checks were made both internal and external to the program to ensure the integration time step of the Runge-Kutta routine was kept small enough to insure the accuracy of the program.

The program was written in a modular format with the main program controlling six subroutines. Three of the subroutines, CNTRL, ACEL, and ORB, deal with the flight mechanics of the spacecraft. Two of the subroutines, HDR and WRT, control the output of the program and the last subroutine, RK4, is a standard fourth order Runge-Kutta routine. The source code of the program is given in Appendix A.

A. MAIN PROGRAM

The main program, pages 68 through 70 of Appendix A, acts as a control center for the subroutines, and computations within the main program are kept to a minimum. Only the calculation of the spacecraft mass is done within

Figure 15. Flow Chart for Main Program
the main program. Figure 15 is a flow chart of the main program operations. Two input files were used in order to separate the orbital parameters from the vehicle aerodynamic parameters. Sample input files are included in Appendix A. One output file was used for both a hard copy text and input into a separate graphics program. A quick health check of the program was displayed to the terminal for verification of proper inputs and progress through the program. The first call to subroutine CNTRL and ACEL are for output purposes only, the values at time zero are displayed in the output file after calling these two routines. The main loop of the program proceeds through the aerodynamic, atmospheric, and orbital dynamic models at each integration time step, the time interval is then compared with the time print interval and an output written if necessary. The last part of the loop is to change the spacecraft mass in accordance with the time interval, thrust on the spacecraft, and the specific impulse of the rockets. A double check is used to determine the end of the program: if either the final time or final mass is reached, the program is terminated.

B. SUBROUTINES

1. Subroutine CNTRL

This subroutine, as the acronym implies, deals with the control laws used for the different atmospheric interaction models. A flow chart of this subroutine is shown in Figure 16. Both the aerobang and aerocruse models were included in the subroutine and each was accessed through the variable CSE. The atmospheric model, which is common to both models, is executed prior to the control functions. A test is then done in order to determine which model to turn
Begin subroutine CNTRL

Dimension variables set constants for gravity and atmospheric model

Calculate local gravity Calculate local density

What case?

Aerocruise

Set angle of attack to (L/D) max

Calculate lift and drag

Calculate required thrust Equation 4.3

Will the absolute value of the argument of Equation 4.4 be greater than one?

Yes

No

Calculate angle of bank Equation 4.4

No

Stop

Is the change from last loop larger than this loop?

No

Stop

Yes

Has angle of attack changed significantly?

Yes

No

Figure 16. Flow Chart of CNTRL Subroutine
on; for convenience, the order of discussion will be the same as their appearance within the subroutine.

a. Aerobang Control Model

This model is made up three distinct parts. The first part calculates an initial guess of the angle of attack for the flight vehicle. While the convergence routine will converge on the correct angle of attack using any initial guess, a good first guess is determined to decrease the computation time of the program. The second portion of the convergence routine uses Newton's method of convergence. First, the coefficients of drag and lift for the flight vehicle for a given angle of attack are computed. This information is then used to calculate the value of the $f(\alpha)$ in, Equation 4.11, and its derivative using, Equation 4.13. These two values dictate the change in the angle of attack and the whole process is repeated until there is little change to the angle of attack in sequential loops. The final part of the model is an automatic internal check. It is quite possible for the model to have no angle of attack on which to converge. Two possibilities exist for this happening: one, the model is unable to maintain a constant heating rate for the given flight conditions and two, that the integration step size is too large, forcing the vehicle off the constant heating rate curve. If there were no check within the routine, the output would be questionable, or, the routine might enter into an infinite loop looking for a nonexistent answer.

b. Aerocruise Control Model

The second model within the CNTRL subroutine incorporates Equations 4.3 and 4.4. The model sets the angle of attack for $(L/D)_{\text{max}}$ and lift and drag are calculated. Using this drag prediction, the thrust is set to a value which will exactly match the drag. Using all these values, the angle of bank
necessary for circular flight is found. A check is also done to assure that there is an angle of bank which will satisfy the given flight conditions; if one does not exist, then the program is stopped at this point.

2. Subroutine ACEL

This simple routine computes the accelerations on the flight vehicle, excluding gravity, using Equations 3.28-30. These equations have been isolated within their own subroutine for future program users. Accelerations experienced by the flight vehicle during a maneuver can be evaluated using the information provided by this routine.

3. Subroutine ORB

Subroutine ORB calculates the differential values contained within the equations of motion derived in Chapter III. These equations are defined within the subroutine using the dimensioned variables X and XDOT. This is done in order to make it easier to pass the variables and their derivatives to the Runge-Kutta routine and to make the routine more generic in nature.

4. Subroutines HDR and WRT

These are the output subroutines and HDR is called only once during each execution of the program. The subroutine HDR prints the header at the top of the output file. This header contains some of the selected input data in order that one may readily associate the conditions that created it. The subroutine WRT prints the output data and is called at every time print interval as specified by the user. It is necessary to limit printing of the output to every 1000 to 2000 integration time steps in order not to be overloaded with minutiae.
5. Subroutine RK4

This subroutine was taken from the public domain collection of fortran subroutines held at the Naval Postgraduate School. It was written by Professor I. M. Ross and is a standard fourth order Runge-Kutta routine. It is used by passing the computed values for the variables and their derivatives to the routine via the variables X and XDOT. The routine actually requires four passes for the integration of one time step and during each of these four passes, the program goes back and recalculates the variables X and XDOT. The variable INDEX keeps track of the looping requirements for this routine.

C. PROGRAM USAGE

Proper operation of the program requires the manipulation of two input files. As previously mentioned, one file, AERO.DAT, contains the aerodynamic inputs and DATA.DAT contains the orbital dynamic inputs. The output file, OUT.DAT, contains the time history of ten important variables used in the analysis of the orbital plane changes. To set up a run, the user must first edit the AERO.DAT file to reflect the aerodynamics of the flight vehicle. The file AERO.DAT contains fifteen variables; each variable and the corresponding unit is explained in Table 1. The second file DATA.DAT corresponds to the starting conditions of the flight vehicle. The file DATA.DAT contains eleven input variables all of which are contained in Table 2 along with the meanings of the variable and the necessary units. Once these two files have been set for the particular flight vehicle, the program ORBIT can be executed to obtain a time history output of the maneuver.

D. PROGRAM VALIDATION

The program was validated in two ways, the first method involved testing the orbital mechanics portion of the program and the second method involved matching data output from a previously run problem. For the orbital mechanics validation all of the aerodynamic and thrust parameters were set to zero, while the control models were turned off and the flight velocity and altitude were set to a known orbital condition. The values output from the computer program were then compared to the calculated values. The comparison is summarized in Table 3. As the data show, there is no appreciable difference between the calculated values and the computer output values.

Reference 13 contains enough data to reconstruct the necessary inputs for an accurate simulation. The data taken from the article was all in a non-dimensional format and it was necessary to take it back to a dimensional form for use in the program, ORBIT. Both outputs are summarized in Table 4 and as can been seen, they match very closely.
VI. ANALYSIS

Evaluation of the data gathered from modeling the atmospheric interaction of the two chosen flight vehicles will determine for what flight conditions the aerobang method is superior to the aerocruise. The analysis will demonstrate the similarity of the two control methods and the fact that the aerocruise model may be thought of as an aerobang maneuver constrained to a particular altitude and angle of attack.

A. FORMULATION OF THE SOLUTION

The objective was to conduct a numerical investigation into the efficiency of both the aerocruise and aerobang control laws. Efficiency of the maneuver is defined as the inclination change a maneuver produces for a given amount of fuel expended. The effects of three separate parameters on the efficiency of each maneuver were studied. The three parameters were the flight vehicle speed, the \((L/D)_{\text{max}}\) of the vehicle, and the stagnation heating rate. In short, the maneuvers were conducted over a varying range of flight velocities for two different heating rates using first the ERV and then the MRRV.

Flight vehicle velocities ranged from super- to subcircular velocities. The terms super- and subcircular are defined as faster or slower than the circular orbital velocity at that particular altitude. A parameter \(k\) can be defined as

\[
k = \frac{V_c}{V}
\]

which is the ratio of the circular speed \((V_c)\) to the flight speed. Thus, \(k>1\) is subcircular speed and \(k<1\) is supercircular speed. These two ranges are of interest because the control law for the aerobang maneuver dictates that at
supercircular speeds, the flight vehicle gains altitude, while at subcircular speeds, it might lose altitude. If the maneuver proves to be more efficient at supercircular speeds, the increase in altitude and velocity would only add to the efficiency by requiring less fuel to reorbit the spacecraft at termination of the atmospheric interaction. On the other hand, if the aerobang maneuver proves to be more efficient at subcircular speeds, a further analysis must be conducted to account for the loss in altitude and velocity. In this study, the altitude was maintained using two different methods. The first method involved giving the flight vehicle a small positive flight path angle, rather than a zero flight path angle; the upward tendency of the trajectory would offset the altitude loss by the maneuver. The second method was to tilt the angle of bank using some of the lift for the inclination change to keep the flight vehicle at a constant altitude.

The maneuver simulations were conducted for two different heating-rate values in order to determine the effect different altitudes and velocities would have on the model of each maneuver. The heating rates were chosen to be $0.9088 \times 10^6$ and $1.42 \times 10^6$ Watts per square meter, referenced to a 1-ft radius sphere [Ref. 7: p. 490]. For the ERV, the maximum heating rate value would correspond a stagnation temperature of 4180 degrees Fahrenheit during a plane change maneuver lasting 1500 seconds [Ref. 14: pp. 278-9]. To effect an equitable comparison of the two flight vehicles using the same flight profiles, these heating rate values were also imposed on the MRRV, though the MRRV is designed to handle higher heating rates [Ref. 6: p. 516].

It is noted that the values of $k$ selected for evaluation varied for each flight vehicle and for different heating rates. In order to evaluate the aerocruise and
aerobang maneuvers during similar flight condition the k values for the simulations are confined to a subset of flight speeds common to both maneuvers.

B. SUPERCIRCULAR PROFILES

1. High Heating Rate

a. ERV

A stagnation heating rate of $1.42 \times 10^6$ watts per square meter was taken for the ERV. Simulations were run for two different supercircular speeds corresponding to values of k from .94 and .95. Each run was allowed to expend fuel up to 2% of the initial mass. The aerobang maneuver in either case did not

\includegraphics[width=\textwidth]{inclusion2.png}
\caption{Inclination Change for ERV k=.95}
\end{minipage}\hfill
\begin{minipage}{.48\textwidth}
\includegraphics[width=\textwidth]{angle2.png}
\caption{Angle of Attack vs Mass Fraction for ERV k=.95}
\end{minipage}
\end{figure}
complete the full 2% mass expenditure. The maneuver was unable to maintain the constant heating rate curve, thus terminating the flight profile. As shown in Figures 17 and 19 the aerobang maneuver did display a more efficient process of inclination change as compared to the aerocruise maneuver for supercircular speeds.

For \( k = 0.94 \), the aerobang maneuver terminated at 1% mass fraction with a 0.226 degree inclination change, while the aerocruise achieved only 0.186 degrees inclination change. At 75% mass fraction the inclination difference was at a maximum of 0.05 degrees. A strategy for maximizing inclination change would be to conduct multiple passes through the atmosphere such that at each pass, the flight profile would be terminated at the point of maximum inclination change difference. The \( k = 0.95 \) flight profile displays similar characteristics to the \( k = 0.94 \) case except that the aerobang maneuver became less efficient at approximately 5% mass fraction of fuel. At lower values of fuel mass fraction the inclination change for the aerobang and aerocruise maneuvers were nearly indistinguishable from each other.

No cases for \( k < 0.94 \) were run because of the inability of the aerocruise control law to maintain a constant heating rate while flying at the angle of attack corresponding to \((L/D)_{\text{max}}\). The aerocruise control law required angles of bank of 134 and 153 degrees for the \( k = 0.95 \) and the \( k = 0.94 \) cases respectively. For \( k = 0.93 \), the force required to balance the centrifugal force of the flight vehicle exceeded the lift generated, making it impossible for the flight vehicle to maintain the desired heating rate. In contrast, the aerobang maneuver could be executed under the restrictions/specifications of higher orbital speeds. A limitation encountered in the aerobang maneuver is that at faster speeds, the
angle of attack decreases to zero sooner, making the length of the maneuver shorter.

Another difference in these two maneuvers is found in the time to complete the maneuver for a specified mass fraction of fuel. The aerobang maneuver is completed four times faster than the aerocruise maneuver for the same mass fraction burned. This observation has two implications: first, the aerobang maneuver can be completed closer to the node of the orbit giving the maneuver an additional increase in efficiency for long flight profiles, and second, the integrated heat load on the spacecraft is lower for the aerobang maneuver. The temperature of the vehicle will depend on the total heat brought into the vehicle minus the heat which can be dissipated away; if the heat load can be reduced, this would decrease the average temperature of the spacecraft. The reduced time of flight to complete an increased inclination change therefore implies that the aerobang maneuver could possibly allow flight profiles to be executed at a higher heating rate than the aerocruise maneuver, since the integrated heat load would be less, granting that the materials can handle the higher heating rate.

b. MRRV

The MRRV velocities were simulated from values of $k$ from .99 to .98. No speeds greater than $k=.98$ were simulated due to the fact that the aerocruise maneuver could not generate the required lift at $(L/D)_{\text{max}}$. All the simulations required fuel up to 2% of the spacecraft mass. Observing Figures 21 through 23, it is clear that the aerobang maneuver is more efficient at producing an inclination change somewhere between $k=.99$ and $k=.985$. The thrust required to execute the maneuver using the aerobang method was 20 times
greater than the aerocruise method. This thrust differential is passed on to the
time of flight required for each maneuver as the aerobang method required only
19.3 seconds to expend the 2% fuel while it took over 400 seconds for each of
the aerocruise cases. The thrust of the aerocruise maneuver is based on the drag
encountered, while the MRRV has a high \((L/D)_{\text{max}}\) the actual drag force is low
requiring only a small amount of thrust.

![Graphs showing inclination change](image)

Figure 21. Inclination Change for MRRV \(k=.99\)

Figure 22. Inclination Change for MRRV \(k=.985\)

Figure 23. Inclination Change for MRRV \(k=.98\)

2. Low Heating Rate

a. ERV

Simulations were conducted up to a mass fraction of 2% for fuel expended and a stagnation heating rate of \(0.9088\times10^6\) watts per square meter
referenced to a 1 foot diameter sphere. This lower heating rate corresponds to a higher altitude and lower speed for the flight vehicle. The aerocruise simulation was unable to maintain altitude for \( k < 0.97 \) due to inadequate lift generated at \((L/D)_{\text{max}}\). The aerobang maneuver was able to expend all of the 2% mass fraction under these conditions. At \( k = 0.97 \), the aerobang maneuver once again proved to be more efficient at generating inclination change, with a total inclination change of 0.454 degrees at the end of the simulation. The point of maximum inclination difference between the aerocruise method and the aerobang method occurred at approximately 1% mass fraction, with the aerobang maneuver having a 0.265 degrees inclination change and the aerocruise maneuver having only 0.212 degrees inclination change. As an example, for \( k = 0.97 \) and a desired 10 degree inclination change, an aerobang maneuver would save approximately 490 kg of fuel using a multiple pass technique. Additionally, the time involved to conduct the aerocruise maneuver is almost nine times greater than the aerobang method. While there is a region of supercircular velocities where the aerocruise maneuver is more efficient than aerobang, it occurs nearer the circular velocity or \( k = 1 \).

b. MRRV

The low heating rate flight profile for the MRRV was flown for speeds corresponding to \( k = 0.990 \) and \( k = 0.997 \). These velocities are very close to the circular orbital velocity. At the increased altitude and reduced velocity, as compared to the high heating rate simulation of section B.1.ii, the lift generated by the lifting body is reduced even further. Each of the aerocruise maneuvers require over 900 seconds to complete for a maximum inclination change of 1.1 degrees at \( k = 0.997 \). The aerocruise maneuver exceeds the aerobang maneuver in

48
inclination change efficiency until sometime before the velocity exceeds the 
k=.995 level. Once again, the range in which the efficiency of the aerocruise 
method is superior is limited to a band close to the circular orbital velocity and 
beyond this band the aerobang method becomes increasingly more efficient.

C. SUBCIRCULAR PROFILES

Unlike the supercircular velocities the subcircular region requires more 
analysis to truly determine which method of inclination change is more efficient. 
Execution of the aerobang maneuver using a subcircular profile always appears 
to be more efficient but causes the spacecraft to lose altitude. This altitude loss 
must be made up for in order to effect an equitable comparison between the two 
maneuvers. Both methods of altitude maintenance discussed in the above section 
are utilized here to bring the vehicle back to nearly the same initial velocity and 
altitude.

1. High Heating Rate

   a. ERV

   The ERV simulation was conducted for values of k=1.03 to k=1.1. 
   Table 5 summarizes the data from these flight profiles. Column one of the table 
is the standard aerobang maneuver; column two is the aerobang maneuver using 
a positive flight path angle to return the flight vehicle to the original altitude at 
the end of the 2% mass fraction fuel expenditure; column three is the aerobang 
maneuver using an angle of bank to maintain a particular altitude, and column 
four is the aerocruise maneuver for which the comparison is made. Observing 
Table 5, the aerobang maneuver displays expected results: the efficiency of the 
maneuver remains higher than that of the aerocruise maneuver, but with an

attached altitude penalty. The altitude penalty increases as the percentage difference over the aerocruise maneuver increases. At $k=1.03$ the altitude loss is 124 m while the difference over aerocruise is 8.7%; this increases at $k=1.1$ to an altitude loss of 360 m with a difference of 44.9%. As shown in Figure 24 the
most effective method of altitude maintenance utilizes the angle of bank. The angle of bank method can be used over a much larger range of flight speeds than the flight path angle method; the flight path method cannot to be used beyond k=1.07 because no angle of attack solution exists for this combination of variables. From Figure 24, the aerobang maneuver that uses the angle of bank for altitude maintenance becomes more efficient than the aerocruise method at speeds less than k=1.06. As an example, for k=1.1 a 20 degree inclination change using the aerobang method augmented with angle of bank would use 277 kg of fuel less than aerocruise maneuver.

![Figure 24. Fuel Percent Difference over Aerocruise vs k Factor for ERV (High Heating Rate)](image)

Unlike the supercircular case in which the angle of attack during the aerobang maneuver steadily decreases to zero, in the subcircular case, it increases as the flight vehicle descends. The angle of attack could possibly exceed the stall angle of the flight vehicle, terminating the maneuver
prematurely. An unexpected advantage experienced during the angle-of-bank augmented aerobang maneuver is that the angle of attack remains constant throughout the maneuver, similar to the aerocruise maneuver, except the angle of attack is fixed at a higher value. This was observed in all cases where the aerobang maneuver was augmented with the angle of bank. Figures 25 and 26 graphically show this concept. Figure 25 shows the inclination versus mass fraction for the aerobang maneuver at $k=1.1$ and Figure 26 shows the inclination change for the same maneuver augmented with an angle of bank of 71 degrees.

![Figure 25. ERV k=1.1 Angle of Attack Profile unaugmented](image1)

![Figure 26. ERV k=1.1 Angle of Attack Profile AOB augmented](image2)

b. MRRV

The range of speeds at which the MRRV could be flown was significantly reduced when compared to the ERV. The parameter, $k$, ranged in value from 1.01 to 1.02; beyond 1.02 the speed was too slow to provide the necessary lift to maintain the aerocruise maneuver. This same effect was seen for the supercircular flight profiles. Table 6 summarizes the data obtained from the simulations conducted. Under these conditions, the efficiency of the flight path angle method of altitude maintenance was essentially identical to the angle of bank method. This may be attributed to the narrow range of flight velocities
sampled, all of which are closer to circular orbital velocity than the those sampled in the ERV case.

Figure 27 shows the break even point for the efficiency comparison of aerobang to aerocruise to be at approximately k=1.0175; slower than this speed the aerobang method is more efficient in providing an inclination change. At k=1.02, the difference in fuel of the aerobang method over the aerocruise method exceeds 20 percent. This high difference is attributed to the excessive angle of bank required by the aerocruise maneuver to maintain the flight profile.
The aerocruise maneuver for this flight condition is at an angle of bank of 26 degrees, allowing a large portion of the lift to be directed away from the orbit normal and unable to effect the inclination change.

![Graph showing the fuel percentage difference over aerocruise vs k factor for MRRV (High Heating Rate)](image)

**Figure 27. Fuel Percentage Difference over Aerocruise vs k Factor for MRRV (High Heating Rate)**

2. Low Heating Rate

   a. ERV

   The range of flight velocities over which the aerocruise maneuver could operate was narrower from those of the high heating rate. Speeds slower than \( k = 1.05 \) required an unattainable angle of attack for the aerocruise maneuver. Table 7 summarizes the data gathered for the given set of flight conditions. Comparing the values of specific inclination change (ie, fuel/degree inclination) the two aerobang augmented methods were nearly identical. A

Aerocruise

demonstrated disadvantage of the flight path angle method of augmentation is that the angle of attack for each simulation exceeded 40 degrees, beyond the flight vehicle's operating envelope. This excessive angle of attack did not occur for any of the angle of bank augmented simulations and while the angle of attack...
was high it did not exceed the threshold of the model. Additionally, from Figure 28 it is observed that the aerobang maneuver is more efficient at k=1.03 or greater. Once again the aerobang maneuver has a higher specific inclination change compared to the aerocruise maneuver as the velocity differs more from the circular orbital speed. The time for the two methods to complete the flight profile differed greatly: the aerobang method once again was much faster than the aerocruise method, completing the maneuver approximately 6.5 times faster. For short duration atmospheric interactions, a time differential of this nature may not play an important roll, however, if the atmospheric interactions were of

![Figure 28. Fuel Percentage Difference over Aerocruise vs k Factor for MRRV (Low Heating Rate)](image-url)
longer duration, the aerocruise maneuver may approach or exceed a quarter period of its orbit, in which case the inclination change caused by any force in the orbit normal direction is reduced.

**b. MRRV**

The last set of simulations discussed will be that of the MRRV at a low heating rate value. The MRRV range of flight speeds are very narrow at this heating rate: from \( k=1.002 \) to \( k=1.007 \). The aerocruise maneuver cannot be performed at speeds slower than this. As previously stated, the narrow range of

</table>
speeds is attributed to the fact that the MRRV was designed to operate aerodynamically at lower altitudes and higher heating rates than the value used. For comparison to the ERV, the range is adequate. Table 8 is the summary of each set of data and Figure 29 graphically represents the data contained in the table. From Figure 29 the aerobang method of inclination change becomes more efficient at speeds slower than $k=1.0055$. The aerocruise maneuver required nearly 900 seconds to be completed as compared to the 19 seconds for the aerobang maneuver. At 900 seconds the aerocruise maneuver approaches a

![Figure 29. Fuel Percentage Difference over Aerocruise vs k Factor for MRRV (Low Heating Rate)](image)
quarter of an orbital period, beyond the 900 seconds shown, the inclination change per kilogram of fuel falls off to become zero at the apex of the orbit. For this maneuver, the flight vehicle would need to roll over to bring the lift vector to the other side of the orbit or be subject to a decreasing inclination.

D. MASS FRACTION EFFECTS

All of the above analysis was done for fuel expenditure of 2% of spacecraft mass fraction. Because larger inclination changes may be desired, an analysis was done on the possible advantages of expending more than 2% mass fraction of fuel. The effect of longer atmospheric interactions may cause the maneuver to approach the apex of the orbit and decrease the inclination change. The aerobang method is faster at completing the desired inclination change as compared to the aerocruise method. A conclusion can be drawn that the aerobang method should become increasingly better than the aerocruise method as the mass fraction increases. Table 9 shows the effect of increasing mass fraction for the ERV with a flight profile of $k=1.03$ and a high heating rate. Both methods of altitude maintenance were used and compared to the aerocruise method. The flight path angle method was terminated beyond a mass fraction of 4% because the vehicle could not be flown at the constant heating rate. The angle of bank method of altitude maintenance worked throughout the full range of mass fraction. Figure 30 shows the percentage difference over aerocruise vs the mass fraction. The graph indicates that initially the mass fraction has little effect on the percentage difference over the aerocruise model. As more mass fraction is burned, the effect was as expected; the aerocruise method lost some of its advantage because it approaches the apex of the orbit. For this particular flight profile, the aerocruise maneuver took approximately three times longer
than the aerobang maneuver. For flight profiles which have a higher ratio of maneuver times, the mass fraction advantage effect would occur at lower mass fractions than for the case presented.

Figure 30. Fuel Percentage Difference over Aerocruise vs Mass Fraction Fuel Expended for ERV (k=1.03)
VII. CONCLUSIONS AND RECOMMENDATIONS

1. CONCLUSIONS

As demonstrated in Chapter VI, there exists a small range of flight speeds in which the aerocruise maneuver exhibits a greater inclination change for a given amount of fuel than does the aerobang maneuver. This range of flight speeds is always centered around circular orbital speed. Figures 31 and 32 graphically shows the flight range where (within the hash marks), the aerocruise maneuver is predicted to be more efficient. However, use of the aerobang maneuver is predicted to be more efficient as the speeds become either more super- or more subcircular (regions beyond the hash marks). These regions of superior aerocruise efficiency, while bracketing the circular orbit speed are not symmetric in nature and tend to be narrower in the supercircular flight regime.

![Figure 31. Efficiency Regions for the ERV](image)
As discussed in Chapter IV, Section A, the aerocruise maneuver was unable to maintain the desired profile at speeds just possible the region of superior efficiency. This result was expected and shows that the aerobang maneuver has a greater range of operating flight speeds as compared to the aerocruise maneuver.

A higher maneuver efficiency exists for a vehicle with a greater maximum lift-to-drag ratio while executing an aerobang maneuver. The data from the ERV and the MRRV were compared for similar flight profiles, for the case $k=1.03$ and $\dot{Q}=1.42\times10^6$ W/m$^2$. In order to analyze the effect of the lift-to-drag ratio on the inclination change, the effects from factors not associated with the lift-to-drag ratio must be eliminated. A major component which directly influences the amount of inclination change achieved is the lifting force generated by the flight vehicle during the maneuver. Lift generated by the flight vehicle is the product of the dynamic pressure on the vehicle, the coefficient of lift, and the reference wing area. By operating the two vehicles at the same

Figure 32. Efficiency Regions for the MRRV
heating rate and flight speed, the dynamic pressure remains the same for the two simulations. The reference wing area of the ERV and the MRRV differ and must be taken into account in order to isolate the effect the lift-to-drag ratio has on the inclination change.

A scaling factor equivalent to the ratio of the wing areas of ERV and the MRRV is introduced. This scaling factor is used to account for the inclination change lost due to the lower wing area of the MRRV. From Chapter III, the wing area of the MRRV is 28% lower than that of the ERV, yielding a scaling factor of 1.4. Prior to scaling, the inclination change for the MRRV under these flight conditions is 0.693 degrees for a 2% fuel consumption. The ERV attained an inclination change of 0.765 degrees under identical flight conditions. Scaling the MRRV inclination change with the 1.4 factor yields an inclination change of 0.970 degrees, clearly higher than that for the ERV.

As can be seen in Figure 32 the aerocruise-superior flight speed range of operations for the MRRV dramatically narrowed; this may be attributed to the decreased lift force generated by the smaller coefficient of lift rather than the higher lift-to-drag ratio of the MRRV. The time of flight for the aerobang maneuver was unaffected by the change in the lift-to-drag ratio while for the aerocruise maneuver, the time required to burn a 2% mass fraction of fuel increased for the MRRV. This result was not unexpected because the reduced drag coefficient of the higher lift-to-drag ratio vehicle is reflected in the thrust required to maintain altitude.

Operating at a subcircular speed, the aerobang maneuver would normally results in a loss of altitude. In order to compare this maneuver with the aerocruise maneuver, which loses no altitude, two methods of altitude control
were used (Section VI.A). Of the two methods of altitude maintenance, augmentation of the angle of bank proved to be superior to modification of the initial flight path angle. While there was generally little difference in efficiency from using either method, Figure 24 clearly shows the angle of bank method to be more efficient than the flight path angle method. Additionally, the useful range of operation of the flight path angle method is much smaller than that of the angle of bank method. In all subcircular cases, there existed speeds too low for the flight path angle method to maintain a flight profile at a constant heating rate.

From a fuel efficiency point of view, the percentage difference in fuel burned per unit angle of inclination change between the aerobang and aerocruise methods remains unaltered until the time required to complete the maneuver approaches a quarter of an orbital period for the aerocruise maneuver. This means that a low drag environment (drag force $\ll$ maximum thrust), the aerobang maneuver will perform better than the aerocruise as more fuel is expended. The reason for this is that the thrust for the aerobang maneuver is not dependent on the drag environment, while the thrust for the aerocruise maneuver is modulated to counteract the drag.

2. FOLLOW ON TOPICS

Simply put, during the maneuver, the aerobang method modulates the angle of attack and the aerocruise method modulates the angle of bank. As shown within this thesis, there exist regions where one method claims superiority over the other. Following this line of thinking, a method of control which modulates both the angle of attack and the angle of bank to realize the best of each maneuver may be of greater efficiency than either of the two methods studied
here. This would require more sophisticated control laws than those discussed above.

Another topic of interest would be to determine whether to use the angle of bank method of maintaining altitude during an aerobang maneuver, or to accept the energy loss normally associated with the subcircular aerobang maneuver and reestablish the orbit with an additional burn after exiting the atmosphere. It may take less fuel to accept the altitude loss from a true aerobang maneuver than to augment the maneuver in order to maintain a specified altitude.

Comparison of the aerocruise data for two flight vehicles operating at similar flight conditions produced a curious result. It is well established that a vehicle with the higher lift-to-drag ratio produces the more efficient maneuver, this was not observed for the aerocruise maneuver and further investigation is warranted. This may perhaps be attributed to the fact that although the aerocruise maneuver operates at the maximum lift-to-drag ratio for the vehicle, the actual values of the drag and lift may be low. If the lift force is low, then the plane-change achieved will also be low for a given arc length regardless of the maximum lift-to-drag ratio.

Finally, there is reason to investigate the unsymmetric nature of the aerocruise-superior region of operations (Figure 32). For both flight vehicles, the supercircular region of the aerocruise-superior area is narrower than the subcircular region. The flight regime where the aerocruise maneuver is superior was expected to center around the circular orbital speed, but in a symmetric nature. The reason why this occurred is unclear at this time and should be addressed in a follow-on study.
