ABSTRACT

Motion control of underway replenishment operations is achieved through the use of sliding mode control with a Linear Quadratic Gaussian compensator design. External disturbances include first-order wave force and moment as well as slowly varying interaction forces and moments between the two ships. Feedback control is used to provide adequate stability of motions while feedforward control with disturbance estimation and compensation achieves the desired steady state accuracy. The results demonstrate that satisfactory path keeping during operations can be maintained for various ship proximity distances and environmental conditions.

ACKNOWLEDGMENTS

I would like to express my sincere gratitude to my thesis adviser, Professor Fotis A. Papoulias. His expert assistance and continued guidance allowed me to overcome many intractable difficulties.

To Professor George J. Thaler my heartfelt thanks for his knowledgeable advice and patience throughout the course of this research. I really appreciate the time and effort they spent with me.
A. AIM OF THIS STUDY

Accurate course keeping is one of the most important problems for ship maneuvering and especially in an underway replenishment in an open sea. There is an apparent danger in such an operation due to the complex effects of the seaway, and the conventionally slow control loop indicated in Figure 1.1.

In particular, during underway replenishment the ship is subject to a variety of forces and environmental disturbances. The most important of these are the interaction forces and
moments that are generated as a result of the two ships in proximity with one another[Ref. 7][Ref. 8]. These forces depend on the relative positions of the two ships and both their magnitude and sign is not easily predictable by analytical techniques. In a random seaway there exist also first-order irregular wave forces and second-order wave drift forces. The latter appear in the form of long term slowly varying excitations and do not have a significant effect on lateral separation control[Ref. 8]. In this thesis we focus our attention on the effects of the interaction forces and first-order wave forces on the system response. We employ a sliding mode feedback control law due to its robustness characteristics with regard to unmodeled dynamics and disturbances. The sliding surface is based on the Linear Quadratic Regulator. Partial state measurement is assumed and a Kalman filter is designed to provide an accurate estimate of the unmeasurable states and to minimize the effects of measurement noises. Disturbance estimation and compensation is used in order to ensure the desired steady state accuracy. A schematic block diagram of the control design is shown in Figure 1.2.
Figure 1.2 Automatic Control of Ship Replenishment at Sea
B. THESIS OUTLINE

In Chapter II, the LQR method of sliding mode controller design is developed and simulated at calm sea. Chapter III is concerned with the Kalman filter design. Simulations of the UNREP with open sea effects are presented in Chapter III.
II. MATHEMATICAL MODEL IN THE HORIZONTAL PLANE

A. NONLINEAR STEERING EQUATIONS IN THE OPEN SEA

The UNREP operation at sea is schematically depicted in Figure 2.1 where \( Y \) and \( N \) are the interaction forces and moments. The leading ship keeps its course unchanged and the tracking ship keeps the separation distance constant, normally less than 100 feet (depending on the type of ship).

Figure 2.6 and Figure 2.7 show the interaction forces and moments on the tracking ship due to the interaction effect of the leading ship. The interaction force \( Y(A,B) \) acts through the ship’s center of gravity and the moment \( N(A,B) \) about the center of gravity in the horizontal plane. The two curves used in this study are for a typical Mariner ship at a nominal speed of 15 knots and for different relative positions. In applying these curves to the leading ship, the interaction force and moment need to be changed to \(-Y(-A,B)\) and \(-N(-A,B)\), respectively. For each figure, the curves for \( B=50 \) ft and \( B=100 \) ft were determined from experimental model testing results[Ref.6][Ref.8], and the curves in between were determined by interpolation. The data were also extrapolated up to \( B=150 \) ft. \( A \) and \( B \) are continually read by the simulation program as input data to a two dimensional interpolation
routine which calculates the base line interaction forces and moments acting on the ship.

The coordinate system used in this study follows the standard system from Principles of Naval Architecture [Ref. 11]. In practice, the leading ship keeps constant heading, while the tracking ship maintains a constant lateral separation distance. Different configurations and the directions of variations of the interaction force and moment as the tracking ship moves from -524 ft to 524 ft are shown in Figure 2.2.

The primary concern for UNREP simulation is related to the space coordinates (longitudinal and lateral separation distance, yaw angle, and yaw rate). So the equations of motion are first expressed in ship velocity coordinates (u, v) and then transformed to space coordinates (x, y) (Figure 2.3). The transformation equations are

\begin{align}
\dot{x} &= u \cos \psi - v \sin \psi \\
\dot{y} &= u \sin \psi + v \cos \psi
\end{align} \tag{2.1}

\begin{align}
\dot{y} &= u \sin \psi + v \cos \psi \tag{2.2}
\end{align}

The ship's coordinates are assumed to be at the ship's center of gravity \((x_c=0, y_c=0)\).

* Note: LS: Leading Ship.

TS: Tracking Ship.
Figure 2.3 Position of Center of Gravity of Ship at Time $t_0$ in Space Axes

* Note:

$v$: Velocity vector tangent to instantaneous ship path.
B. MANEUVERING MATHEMATICAL MODEL

The nonlinear maneuvering equations of motion and the hydrodynamic interaction forces and moments that act on the ship's hull are modeled for 15 knots nondimensional forward speed. In an UNREP control simulation, the ability to manually or automatically control the rudder and propeller speed must be present. Only rudder input is considered here, and the ship forward speed is assumed constant by the propulsion control. The basic mariner study ship characteristics are presented at Table 2.1.

* The ship’s coordinate system is assumed to be at the ship’s center of gravity (x_G, y_G = 0).
The goal of this study is to present an alternative way of steering control based on sliding modes. For this reason the simulation does not concentrate on the derivation of ship dynamic and hydrodynamic effects, but on the results of control and observer feedback. Only the tracking ship is the major consideration, and we assume a reliable lateral distance measurement. The ship hydrodynamic maneuvering model for the study ship consists of the nonlinear equations of motion in the horizontal plane (sway and yaw). The hydrodynamic coefficients are presented in Table 2.3, and the nondimensional equations of motion are:

SWAY EQUATION:

\[(m-Y_N) \dot{\psi} + (mx-Y_t) \dot{r} = F_2(u, ν, r, δ)\]  \hspace{1cm} (2.3)

YAW EQUATION:

\[(mx-N_v) + (I_z-N_t) \dot{r} = F_3(u, ν, r, δ)\]  \hspace{1cm} (2.4)

where

\[F_2(u, ν, r, δ) = Y_N ν^*(Y_t - mu_1) r + Y_δ δ + Y_α n + Y(A, B) + f_1 + f_2\]  \hspace{1cm} (2.5)

and

11
\[ F_3(u, v, r, \delta) = N_v + (N_x - mx_{u_0}) r + N_\delta \delta + N_n n + N(A, B) + n_1 + n_2 \quad (2.6) \]

Y(A, B) nondimensional hydrodynamic interaction force caused by leading ship.

N(A, B) nondimensional hydrodynamic interaction moment caused by leading ship.

f_1, n_1 first-order component of random sea.

f_2, n_2 second-order component of random sea.

Some assumptions were made for simplification without any significant physical effects. First, the ship’s coordinates are assumed to be at the ship’s center of gravity \((x_0, y_0 = 0)\); second, \(Y_n\) and \(N_n\) are small terms also neglected from the simulation; and third, the second-order force and sway moment \(f_2\) and \(n_2\) are not considered in this thesis. This is because the effect of these slowly varying forces and moments is similar to the interaction forces and moments which are analyzed in detail.

1. Rudder Dynamics Model

There are two limiters for modeling rudder dynamics, the first limiter models the rudder saturation limits at \(\pm 0.4\) radians. The second limiter models the proportional band of a variable-displacement pump by limiting its maximum percent stroke, the limits for this nonlinear element have been found to be 0.297 radians for this study case. [Ref.1] [Ref.6]
The lag time and "dead band" in the rudder dynamics when a helm angle is commanded are important aspects of the maneuvering control problem. The rate of change of the rudder angle was assumed to be inversely proportional to the error signal, subject to a maximum rudder rate of 0.0698 rad/sec, and a maximum error input of 0.297 radians.

The system gain can be defined as:

\[ k_r = \frac{\text{Maximum rudder rate}}{\text{Maximum error input}} = \frac{0.0689}{0.298} = 0.234 \text{ /sec} \]

We nondimensionalize this system gain as:

\[ k_r' = k_r \frac{L}{u_i} = 0.234 \times 527.8 \text{ ft}/(15 \times 1.689) \text{ ft/sec} = 4.89 \]

Where

\[ L = \text{ship length} = 527.8 \text{ ft} \]
\[ u_i = \text{ship forward speed} = 15 \text{ knots} = 15 \times 1.689 \text{ ft/sec} \]

This again was taken approximately equal to 5 in this study; and \( \tau_r = \frac{1}{k_r'} \) is defined as the nondimensional rudder system time constant.

The rudder "dead band" was set to \( \pm 0.5 \text{ deg} \). An analog diagram of the rudder dynamics is shown in Figure 2.4 [Ref.8], which includes the response of the rudder system to step commands. The equivalent rudder dynamics are described by a first order lag, see Figure 2.5, where
\[ \delta = -\frac{1}{\tau_r} \delta + \frac{1}{\tau_r} \delta_c \] (2.7)

\( \tau_r \) is the rudder dynamics time constant, and \( \delta_c \) is the commanded rudder angle.

2. State Space Representation

The mathematical model consists of the previous sway and yaw equations of motion

\[ (m-Y_v) \dot{v} + (mx_g-Y_r) \dot{r} = Y_v \dot{v} + (Y_r - mu) r + Y(\delta) + f_t \] (2.8)

\[ (mx_g-N_v) \dot{v} + (I_x-N_r) \dot{r} = N_v \dot{v} + (N_r - mx_g u) r + N(\delta) + n_t \] (2.9)

and the rudder dynamics

\[ \delta = -\frac{1}{\tau_r} \delta + \frac{1}{\tau_r} \delta_c \] (2.10)

The lateral separation rate can be calculated from the components of lateral direction of ship forward speed \( (u) \) lateral speed \( (v) \), and heading angle \( (\psi) \)

\[ \dot{y} = u \sin \psi + v \cos \psi \] (2.11)
With the small angle assumption we can linearize this equation as:

\[ \dot{\psi} = \psi + \nu \]  

(2.12)

where the dimensionless forward speed is one.

The last kinematic relation is between the ship heading \( \psi \) and heading rate \( \dot{\psi} = r \). The first-order wave force \( f_i \) and moment \( n_i \) in (2.8) and (2.9) vary much rapidly compared to the dynamics of the ship and for control/observer design, they can be effectively modeled as white noise components. This is, however, not true for the interaction forces and moments \( Y(A,B) \) and \( N(A,B) \). These vary at approximately the same rate as the ship dynamics since they depend on the relative separation between the two ships. They are best modeled as colored noise components: the response of a first-order shaping filter driven by white noise

\[ T_N \dot{N} = -N + W_N \]  

(2.13)

\[ T_Y \dot{Y} = -Y + W_Y \]  

(2.14)

where the dimensionless time constants \( T_N \) and \( T_Y \) are equal to \( 1 \) (i.e. the time that it takes to travel one ship length).
Collecting the above equations we get a seven order system in state space form. The control input is the commanded rudder angle $\delta_c$ and the augmented state vector contains the actual rudder angle $\delta$, heading angle $\psi$, sway velocity $v$, yaw rate $r$, lateral separation distance $y$, and the two components of the interaction force $Y$ and moment $N$. In a compact vector notation, the complete state space system is written as follows.

$$\dot{x} = Ax + B_1 \delta_c + B_2 w_1 + B_3 w_2$$  \hspace{1cm} (2.15)

where

$$x = \begin{bmatrix} \delta \\ \psi \\ v \\ r \\ y \\ N \\ Y \end{bmatrix}$$  \hspace{1cm} (2.16)

$$w_1 = \begin{bmatrix} \nu_x \\ \nu_y \end{bmatrix}$$  \hspace{1cm} (2.17)
\[ W_2 = \begin{bmatrix} n_1 \\ f_1 \end{bmatrix} \]  

(2.18)

\[ A = [a_{ij}], \quad i=1-7; \quad j=1-7. \]  

(2.19)

\[ B_1 = \begin{bmatrix} 1 \\ \tau_r \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} \]  

(2.20)

\[ B_2 = \begin{bmatrix} 0 & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & 1 \\ 0 & 0 \end{bmatrix} \]  

(2.21)

\[ b_{4z} = -\frac{N_\psi - mX_G}{F_4} \]  

(2.38)

\[ F_4 = (N_\psi - mX_G) (Y_\tau - mX_G) - (N_\tau - I_Z) (Y_\psi - m) \]  

(2.39)

\[ a_{52}, a_{53} = 1, \]

\[ a_{66}, a_{77} = -1, \]

\[ \tau_r = 0.2, \]

All other terms in the matrices are zero.
*Note:*

Maximum rudder error signal $\pm 0.29$ rad (17 degree).

$k = 0.2$/sec.

Maximum rudder rate $0.0698$ rad/sec (3.5 deg/sec).
Figure 2.5 Equivalent First-order Lag Rudder Dynamics

* Note:

\( K_1 = \frac{1}{\tau_r} \),

\( K_2 = \frac{1}{\tau_r} \),

\( \tau_r = 0.2 \).
C. EXTERNAL FORCES AND MOMENTS

External disturbances that act on a ship during underway replenishment operations are due to several sources. First, the first order wave forces which are rapidly varying forces that depend on the seakeeping qualities of the ship and the particular seaway during operations. Slowly varying wave second order drift forces are important for long term moving and positioning operations while the same is true for current loads. On the other hand, of particular significance to the UNREP problem are the interaction forces and moments caused by the proximity of the two ships. For this reason we concentrate our efforts in the analysis on the control system performance of the two categories of forces: First order wave and interaction.

1. Interaction Force and Moment

These forces arise mainly due to changes in the flow field between two ships in proximity to one another and are modeled according to the data presented in [Ref.3][Ref.8]. As shown in Figure 2.6 and Figure 2.7 these interaction forces are functions of both the longitudinal and lateral separation distances of the two ships. Furthermore, they are not of consistent signs which makes their effect on path keeping control especially troublesome. For simulation purposes the data of these two figures are used with bilinear interpolation...
for the actual values of longitudinal and lateral ship to ship separation distances.

2. First-Order Irregular Wave Effects

The nondimensional first-order irregular sway force and yaw moment are functions of the regular wave encounter frequency. The Pierson-Moskowitz energy density spectrum is used here as a computer input to characterize the sea state. The nondimensional force and moment can be expressed as [Ref. 8]

$$Y'(t) = \int \cos(\omega_e t - \varepsilon_f(\omega_e)) \sqrt{2S_x(\omega_e)} |H_y(\omega_e)|^2 d\omega_e \quad (2.40)$$

$$N'(t) = \int \cos(\omega_e t - \varepsilon_m(\omega_e)) \sqrt{2S_x(\omega_e)} |H_n(\omega_e)|^2 d\omega_e \quad (2.41)$$

where

- $Y'(t)$ is first-order irregular sway force.
- $N'(t)$ is first-order irregular yaw moment.
- $\omega_e$ frequency of encounter.
- $S_x(\omega_e)$ Pierson Moskowitz energy density spectrum.
- $\varepsilon_f(\omega_e)$ phase angle for sway force.
- $\varepsilon_m(\omega_e)$ phase angle for yaw moment.
- $|H_y(\omega_e)|, |H_n(\omega_e)|$ the linear transfer functions at the frequency of encounter for the sway force excitation and yaw moment excitation.
\[ |H_y(\omega)|^2, |H_n(\omega)|^2 \] are the response amplitude operators (RAO) for the sway force and moment at the frequency of encounter.

The data from Table 2.4 [Ref. 8] were used to determine the response amplitude operators and were nondimensionalized with respect to the series 60 model. For use with the maneuvering model of this thesis a further nondimensionalization step is required.

For the nondimensional sway force:

\[ H_y(\omega_e) = F(\omega_e) \times \frac{M_m g}{\frac{1}{2} \rho L_s^2 u^2} \]  

(2.42)

For the nondimensional yaw moment:

\[ H_n(\omega_e) = Y(\omega_e) \times \frac{M_m g \xi}{\frac{1}{2} \rho L_s^3 u^2} \]  

(2.43)

where \( L_s \) is the mariner-type ship length.

\( L_m \) is the series 60 model length.

\( M_m \) is the displacement of series 60 model.

The frequency of encounter is function of the absolute wave frequency \( \omega \), the ship speed, the ship-to-wave angle \( \theta \), and the heading angle \( \psi \), see Figure 2.8. The equation is
The Pierson-Moskowitz Energy Density Spectrum $S_x(\omega)$ is used to characterize the sea state. This is calculated for a given significant wave height and for a fully developed, wind-driven sea. The characteristics of the wind speed and the corresponding significant wave height are shown in Table 2.2. A model for Pierson-Moskowitz Spectrum is

$$S_x(\omega) = \frac{\pi g^2}{\omega^5} e^{\beta \left( \frac{\omega}{\omega_0} \right)^4}$$

(2.43)

where

- $\alpha = 8.1 \times 10^3$
- $\beta = -0.74$
- $g = 32.174 \text{ ft/sec}^2$
- $\omega$ = frequency of the wave in rad/sec
- $V$ = wind speed in ft/sec

The corresponding Pierson-Moskowitz Spectrum at the frequency of encounter is

$$S_x(\omega_e) = S_x(\omega) \left(1 - \frac{2\omega}{g} u \cos(\theta - \psi) \right)^{-1}$$

III. CONTROL DESIGN

A. CONTROL METHODOLOGY

The method for conducting the Underway Replenishment at Sea maneuver requires the supply ship to maintain a fixed speed and heading. The conning officer of the receiving ship drives it alongside, and the measurement is the visual estimation of the relative distance from the seaman's eye. There are some basic measurement methods and sensor equipments which are utilized on the ship and can give very accurate distance measurement. The information can be fed into the computer which processes the data and automatically maneuvers the receiver ship to the desired position.

A fixed straight line and a zero point were used as the course and the center of gravity of the leading ship, and they are the references for driving the tracking ship to a position of 100 ft from this line, and from -524 ft to 524 ft with respect to this point. The controller is at the tracking ship (receiving ship). When the tracking ship approaches the leading ship (supply ship), the controller of the tracking ship will be aware of the excitation due to the interaction forces and moments from the leading ship. The dynamics of the tracking ship will converge to the sliding surface which is chosen in order to drive the ship to the desired position.
At the station keeping process, after the tracking ship and leading ship are alongside, a constant speed which is a normalized speed is considered for both ships. Also constant interaction forces and moments are exerted at this stage, which will cause a steady state error. Feedforward control is used for eliminating this error.

The feedforward control is mainly used for compensating the error of the ship lateral distance at steady state. The feedback control law is based on stability requirements, while the feedforward part is based on the desired steady state accuracy. Since the feedforward control is a function of the interaction force and moment, when the latter are zero, the former is also zero. Therefore, in general we can write

\[ \text{Control input}(\delta_c) = \text{Feedback Control}(\delta_{fb}) + \text{Feedforward Control}(\delta_{ff}) \]

During the control design stage the first-order wave force and moment and measurement noise are not considered, and perfect and complete state measurements are assumed. Then a kalman filter is designed for observing the unmeasurable states and the noise filter.

Figure 3.1 presents a block diagram of the optimal control design for the ship replenishment maneuver.
Figure 3.1 The Sliding Mode Control Design for Ship Replenishment at Sea
B. SLIDING SURFACE DESIGN FOR THE FEEDBACK CONTROL

1. Reduction of Order

In sliding mode control, the equivalent system must satisfy not only the n-dimensional state equations but also m-dimensional algebraic equations. This indicates that there exist only \((n-m)\) independent equations on the sliding surface and \(m\) poles are located at the origin, where \(n\) is the number of states and \(m\) the number of control parameters (1 in our case) [Ref.10] [Ref.12].

Consider the state equation

\[
\dot{x} = Ax + Bu
\]  
(3.1)

where states and matrices refer to the mathematical model described in Chapter II.

The first state equation of (3.1) describes the rudder dynamics:

\[
\delta = \frac{1}{\tau} \delta + \frac{1}{\tau} \delta_c
\]  
(3.2)

and the rest describe \(\psi, v, r, y, Y,\) and \(N.\)

The system of equations (3.1), (3.2) can be rewritten as:
In this form
\[
x_1 = [\delta].
\]
\[
x_2 = \begin{bmatrix} \psi \\ \nu \\ \zeta \\ y \\ y \\ N \end{bmatrix}
\]

A_{11} = \{1/r\} 1 by 1 matrix.
A_{12} = 0 1 by 6 matrix.
A_{21} = Equivalent control 6 by 1 matrix.
A_{22} = Equivalent state 6 by 6 matrix.

The linear switching surface parameters are
\[
K = [K_1, K_2]
\]

The switching surface can be written as
\[
\rho(x) = K_1 x_1 + K_2 x_2
\]

where K_1 = 1 and K_2 is a 1 by 6 matrix which is computed by the LQR method for the equivalent system as described later.

The equivalent control is based on the system
\[ \dot{x}_2(t) = \left[ I - A_{21}(K_2A_{21})^{-1}K_2 \right] A_{22} x_2(t) \]  \hspace{1cm} (3.6)

\[ x_2 = -K_2^{-1}K_1 x_1 \]  \hspace{1cm} (3.7)

with \( x_2 \) viewed as the state and \( x_1 \) as the control input.

By substituting (3.6) into (3.7), the reduced order dynamics can be rewritten into the form:

\[ \dot{x}_1 = [A_{11} - A_{12}K_2^{-1}K_1] x_1 \]  \hspace{1cm} (3.8)

Having found \(-K_2^{-1}K_1\), the switching surface and control law is completely defined.

2. LQR Method for Determination of the Sliding Surface

The control law design is based on the following: A 5 degree of rudder for path control is used when the heading deviates 5 degrees from zero or the ship reaches a lateral offset of 10.43 m (one quarter of beam). From the linear quadratic regulator theory the control should minimize the quadratic performance function:

\[ J = \frac{1}{2} \int (x^TQx + u^TRu) \, dt \]  \hspace{1cm} (3.9)

where \( Q \) is a positive semidefinite matrix weighting on the states, and \( R \) is a positive definite control weight.
The two weights $Q$ and $R$ can be obtained from the criteria mentioned above and can be evaluated as follows:

Weighting on heading angle $\psi$:

$$q_{22} = \left(\frac{5}{57.3}\right)^2 = 131.332$$  \hspace{1cm} (3.10)

Weighting on side distance $y$:

$$q_{55} = \left(\frac{10.43}{290}\right)^2 = 772.463$$  \hspace{1cm} (3.11)

Weighting on rudder angle $\delta$:

$$q_{11} = \left(\frac{6}{57.3}\right)^2 = 131.332$$  \hspace{1cm} (3.12)

Weighting on commanded rudder $\delta_c$:

$$r_{11} = \left(\frac{5}{57.3}\right)^2 = 131.332$$  \hspace{1cm} (3.13)

The equivalent system is:

$$\dot{X}_2 = A_{22}X_2 + A_{21}X_1$$  \hspace{1cm} (3.14)

The Riccati equation is:

$$A_{22}^TK_2 + K_2A_{22} - K_2A_{21}Q^{-1}A_{21}^TK + Q = 0$$  \hspace{1cm} (3.15)
The equivalent control is then given by:

\[ x_1 = -Q^{-1}A_2^TK_2x_2 \]  \hspace{1cm} (3.16)

3. System Dynamics and Switches

a. Theory of Switching Control

Switching control has been successfully applied to nonlinear processes such as the "Bang-Bang" control and is widely used in optimal control. Systems with switched control law represent differential equations with discontinuous right hand side. A problem arises in that the conventional existence-uniqueness theory for ordinary differential equations is not valid. A discontinuous differential equation is defined on \( \mathbb{R}^n \) as follows: [Ref.10] [Ref.11]

Let \( S \) be defined as \( \{ x : \rho(x) = 0 \} \), where \( \rho \) is a function from \( \mathbb{R}^n \) to \( \mathbb{R} \), and \( S \) is \( (n-1) \) dimensional which represents the switching boundary. The switching dynamics are then defined:

\[
\begin{align*}
\dot{x} &= f^+(x) : x = \rho(x) \geq 0 \\
\dot{x} &= f^-(x) : x = \rho(x) \leq 0
\end{align*}
\]  \hspace{1cm} (3.17)

where \( f^+ \) and \( f^- \) are smooth functions from \( \mathbb{R}^n \) to \( \mathbb{R} \) and are not matched on \( S \) so that the dynamics are discontinuous at \( S \). The mechanism of the switches are operated as \( \rho(x) \) changes sign which implies that the state trajectory passes through the surface and across it.
From the ideal switching law, existence of a sliding mode requires infinitely fast switching. But in actual systems imperfections exist in the facilities responsible to the switching control such as delay, hysteresis, saturation, etc., which force the switches with a finite frequency. The ideal switching can still be considered as long as the frequency of the switching is much higher than the dynamic response of the system. This regularization of the switching dynamics is schematically depicted Figure 3.2 and Figure 3.3.

The value $\rho$ represents the switching variable: when $\rho > 1$, the dynamics are described by $+r$, and when $\rho < -1$, they are described by $-r$, where $r$ is chosen as 1. A linear relation of $x$ and $\rho(x)$ within this saturation region is described by the switching function.

Existence of the sliding mode requires stability of the state trajectory to the sliding surface $\rho(x)=0$ and asymptotic stability within the region of attraction which is the region between $+\Delta$ and $-\Delta$. 
b. The Lyapunov Function

The second method of Lyapunov provides a characteristic function for analyzing the existence of the sliding mode. The Lyapunov function \( v(t,x,p) \) is continuously differentiable with respect to all of its variables and satisfies the following conditions: [Ref.12]

- \( v(t,x,p) \) is positive definite with respect to \( p \).
- The total time derivative of \( v(t,x,p) \) for the system has a negative supremum for all \( x \in \Omega \) except for \( x \) on the switching surface where the control inputs are undefined.

The structure of the function \( v(t,x,p) \) is determined by the ease which one can compute the switching parameters, such as pole placement, Root locus, LQR, or other
state space control theory, for application of variable structure control design. For all single input system a suitable Lyapunov function is \( v(t,x) = 0.5\rho^2(x) \), which is a function of \( \rho \) depending on the control and has a negative derivative function with respect to time

\[
\frac{1}{2} \frac{d\rho^2}{dt} = \rho \frac{d\rho}{dt} < 0 \tag{3.18}
\]

In the domain of attraction the state trajectory converges to the surface and is restricted to the surface for all subsequent times. The feedback gains associated with the optimal design are computed from Linear Quadratic Regulator theory. The weighting matrices for control and state associated with the cost function are obtained from (3.10) to (3.13).

4. Feedback Control Law

The method of determination of the switching surface \( \rho(x) = 0 \) is by Lyapunov function. The stability function guarantees that a sliding mode exist at every \( t \geq t_0 \), where \( t_0 \) is the time when the state trajectory intercepts the surface.

The existence of the sliding mode implies that:

- \( d\rho(x)/dt < 0 \).
- \( \rho(x) = Kx = 0 \), where the \( K \) is the surface parameters (feedback gains), and \( x \) is the state vector.
From the chain rule

\[ \dot{\rho}(x) = \frac{d\rho}{dx} \dot{x} = K\dot{x} < 0 \]  \hspace{1cm} (3.19)

we substitute the constraint equation

\[ \dot{x} = Ax + Bu \]  \hspace{1cm} (3.20)

and the definition

\[ \dot{\rho} = -\eta^2 \text{sign}(\rho(x)) \]  \hspace{1cm} (3.21)

where \( \eta \) is the weighting for the switching structure.

This form guarantees the existence of a sliding mode and will operate as the sign of the state trajectory changes.

Combining (3.19), (3.20) and (3.21)

\[ \frac{d\rho(x)}{dx} \dot{x} = -\eta^2 \text{sign}(\rho(x)) \]  \hspace{1cm} (3.22)

where \( d\rho(x)/dx = K \) and substituting (3.22), then the control law is written as

\[ u = -(\frac{d\rho(x)}{dx} B)^{-1} d\rho(x) - Ax - (\frac{d\rho(x)}{dx} B)^{-1} \eta^2 \text{sign}(\rho(x)) \]  \hspace{1cm} (3.23)
There are two parts in this feedback control. They are a feedback structure term for the first part, and the second part is for the switching structure.

In general the steps for the control design are:

- Determining the reduced order dynamical equations governing the system motion on the switching surface.
- Choosing the switching surface parameters $K$ for a linear switching surface $\rho(x) = 0$, so that the system is stable in the sliding surface that has been chosen.
- Augmenting the control law.

5. Switching Surface Design

Generally, the stability of the closed loop system depends on the design of the switching surface. The design of the switching surface depends on the choice of the surface parameters and the dynamics of the system equation.

The switching surfaces are designed such that the state trajectory is restricted to $\rho(x) = 0$, and that stability is guaranteed.

Again from the reduced order dynamics the state equation can be written as:

\[
\begin{align*}
\dot{x}_1 &= A_{11} x_1 + A_{12} x_2 + B_{11} u \\
\dot{x}_2 &= A_{21} x_1 + A_{22} x_2 + B_{21} u
\end{align*}
\] (3.24)
The rudder dynamics, first equation of (3.3), will be responsible for the control phase of the second equation of (3.3), which has an order n-1. The equivalent control gives the equivalent system in the form

$$x_2 = A_{22}x_2 + A_{21}x_1$$

(3.25)

where

- $x_2$ is the (n-1)th-order equivalent state vector.
- $x_1$ is the 1st-order equivalent control input.
- $A_{22}$ is the equivalent state matrix (n-1) by (n-1) matrix.
- $A_{21}$ is the equivalent control matrix (n-m) by m matrix.

The gain $K_2$ results by minimizing the cost function

$$J_2 = \int [x_2^TQ_2x_2 + x_1^TR_2x_1] dt$$

(3.26)

where

$$R_2 = [q_{11}]$$

(3.27)

$$Q_2 = diag([q_{22}^2 0 0 q_{55}^2 0 0])$$

(3.28)
The weighting factors are as indicated by (3.10), (3.11), and (3.12), (3.13).

Since \((A_2, A_2)\) is controllable, it is possible to effectively use classical feedback control techniques to compute a \(K_2\) and \(K_1\) such that \((A_2 + A_2, K_1 K_2)\) has the desired characteristics. Having found \([K_1, K_2]\), the linear switching surface is:

\[ [K_1, K_2] x = 0. \]  

(3.29)

C. SLIDING SURFACE DESIGN FOR FEEDFORWARD CONTROL

1. Introduction

There are two types of disturbances that were considered in this thesis. These are time varying low frequency disturbances at passing process, and constant disturbances at station keeping process.

A steady state error in the station keeping process indicates that feedback control is not enough. The compensation is achieved by feedforward control.

The design objective is to eliminate the steady state error. Prediction of disturbance and cancellation process is done by the feedforward control generated at time \(t\). The disturbances were assumed to be the same at one time step before \((t-\Delta t)\) and one time after \((t+\Delta t)\)
\[ \Delta Y = Y(t+\Delta t) - Y(t) \]
\[ \Delta N = N(t+\Delta t) - N(t) \]  

(3.30)

And

\[ \Delta Y = Y(t) - Y(t-\Delta t) \]
\[ \Delta N = N(t) - N(t-\Delta t) \]  

(3.31)

By the assumption that \( \Delta t \) is small and we have slowly varying interaction forces and moments as the tracking ship passes the leading ship. The differences will approach to zero

\[
\lim_{{\Delta t \to 0}} \Delta Y = 0 \\
\lim_{{\Delta t \to 0}} \Delta N = 0
\]  

(3.32)

2. The Feedforward Control Law

The steady state Conditions are:

\[ \dot{r} = 0 \]
\[ \dot{\psi} = 0 \Rightarrow r = 0 \]
\[ \dot{\psi} = 0 \Rightarrow \psi = -r \]  

(3.33)
The separation distance is assumed to be $y=0$, which is the desired position in which the tracking ship will be located.

We substitute (3.33) into the state equations and we get

$$a_1 \delta + b_1 v = c_1$$

(3.34)

$$a_2 \delta + b_2 v = c_2$$

(3.35)

where

$$a_1 = Y_b (N_x - mX_G\delta) - \Xi_6 (Y_v - m)$$

(3.36)

$$b_1 = Y_v (N_x - mX_G) - N_v (Y_v - m)$$

(3.37)

$$c_1 = -(Y \omega f_1) (N_x - mX_G) + (Y_v - m) (N + n_1)$$

(3.38)

$$a_2 = Y_b (N_x - I_z) - \Xi_6 (Y_v - mX_G)$$

(3.39)

$$b_2 = Y_v (N_x - I_z) - N_v (Y_v - mX_G)$$

(3.40)

$$c_2 = -(N_t - I_z) (Y \omega f_1) + (Y_v - mX_G) (N + n_1)$$

(3.41)
Simultaneous solutions of (3.34) and (3.35), provide the state variables at steady state. The results are:

\[
\delta_s = \frac{(c_1 \times b_2) - (c_2 \times b_1)}{(a_1 \times b_2) - (a_2 \times b_1)} \tag{3.42}
\]

\[
v_s = \frac{(c_1 \times a_2) - (c_2 \times a_1)}{(b_1 \times a_2) - (b_2 \times a_1)} \tag{3.43}
\]

\[
\psi_s = -v_s \tag{3.44}
\]

The results of these algebraic equations provide the amount of the control needed.

3. **Switching Surface Design For Feedforward Control**

As mentioned above rudder angle, heading angle, and lateral separation rate are depend on the interaction forces and moments at steady state. If constant disturbances act on the ship then these three states will not go to zero and a steady state error will be presented. An appropriate compensation input will be found to eliminate this error.

The steady state switching surface is:

\[
\rho_s(x) = K_1 \delta_s + K_{11} \psi_s + K_{12} v_s + K_{15} N + K_{16} Y \tag{3.45}
\]
4. Augment of Automatic Control Law

A subsliding surface was designed for this feedforward control input. (An subscript s indicates that the states are for feedforward calculation)

Substitute the feedforward control switching surface (3.45) into the control law and augment the reference input as

\[
\delta_r = -(KB)^{-1}KAX_s - (KB)^{-1}\eta^2 \text{sign}(\rho_s) \tag{3.46}
\]

where

\(\delta_r\) is the feedforward control rudder input.

\(\rho_s\) is the switching surface for feedforward control at steady state condition.

\(\eta\) is the weighting factor for switching control.

\[
X_s = \begin{bmatrix} \delta_s \\ \Psi_s \\ V_s \\ 0 \\ 0 \\ N \\ Y \end{bmatrix} \tag{3.47}
\]

\(x_s\) is the state vector at steady state.

The augmented control law for tracking design is completed and the schematic block diagram is shown in Figure 3.4.
Figure 3.4 The Configuration of the Feedforward Control
* Note for Fig 3.4:

\[ B_1 = (N_x - m x_0) Y_0 - (Y_0 - m) N_x \]  
\[ (3.48) \]

\[ B_2 = (N_y - I_y) Y_0 - (Y_0 - m) N_y \]  
\[ (3.49) \]

\[ A_1 = (N_x - m x_0) Y_0 - (Y_0 - m) N_y \]  
\[ (3.50) \]

\[ A_2 = (N_y - I_y) Y_0 - (Y_0 - m x_0) N_y \]  
\[ (3.51) \]

\[ f_{1,2} \] : 1st-order wave force and moment.
\[ N,Y \] : Interaction forces and moments.
5. Simulation at Calm Sea

a. Introduction

Fortran Program SHIP4QQ.FOR (see Appendix B) was used to simulate the UNREP in the horizontal plane using controller designed by LQR. Simulation is performed with a perfect and full state feedback at this stage. Interaction forces and moments are calculated by the bilinear rule. The surge velocity is simulated as 15 knots. The time step is .005 dimensionless seconds which corresponds to 10 Hz sampling rate. Two data files TABLE1.DAT and TABLE2.DAT contained the data points from Figure 2.6 and Figure 2.7.

b. Simulation Condition Specification

Two types of ship maneuvering processes are considered in this control test. These are the passing maneuver and the station keeping process. The passing maneuver is a process in which the tracking ship is passing the leading ship at constant speed while keeping a desired course. The station keeping process is a process in which interaction forces and moments are constant after both ships are driven alongside, where the same course and speed for the leading and tracking ship are maintained at this stage.

In this chapter, the sea state is considered as a calm sea. Perfect measurements from the sensors are assumed. The initial conditions for the tracking ship are specified as:

- One normalized separation distance, \( y(0) = 1 \).
• Initial heading angle 5 degrees, \( \psi(0)=0.087 \) rad.

• Simulation starts at -4000 ft longitudinal distance, and ends at 8000 ft.

• The leading ship travels twice as fast as the tracking ship during the passing process.

The weighting factor \( \eta \) in the switching structure of the feedback control dominates the sensitivity of the control law, the stability of the state trajectory in the zone of the attraction, and the capability of the design to remain stable under external disturbances. Too small a value indicates that the system may be slow or even unstable, too high a value may cause a chattering problem. The chattering problem will not be discussed here[Ref.14][Ref.12].

D. SIMULATION RESULTS AT CALM SEA

1. Passing Process, \( \eta=1, \Delta=0.12 \)

Results for this case are presented in Figure 3.4. The four graphs in this and all similar figures show clockwise from the upper left corner the interaction force and moment, the actual rudder angle, the tracking ship lateral deviation from the desired position (100 ft), and the ship heading in radians. All variables are presented versus the ship-to-ship longitudinal separation with 0 corresponding to the two ships alongside. It can be seen from the figure that the control objectives are met. The effect of the interaction forces is evident by the rudder activity at about 0 ft longitudinal distance.
2. **Passing Process, \( \eta=1, \Delta=0.06 \)**

The effects of reducing the boundary layer thickness are shown in Figure 3.5. The results are virtually identical to those of Figure 3.4 which means that for the above range of variation, \( \Delta \) has no significant effect. It should be mentioned, though, that this is true under the current assumptions of calm sea and perfect feedback, and it may no longer be the case under the general conditions studied in the next chapter.

3. **Passing Process, \( \eta=8, \Delta=0.12 \)**

The effects of increasing the switching gain \( \eta \) are shown in Figure 3.6. In order to demonstrate this effect, the commanded rudder angle is presented instead of the interaction forces. It can be clearly seen that increasing \( \eta \) results in more control chattering and increased overshoot of the commanded path. Both of these are operationally dangerous and should be avoided in practice.

4. **Passing Process, \( \eta=0.5, \Delta=0.12 \)**

The effects of reducing the value of the switching gain are shown in Figure 3.7. The control response is now very sluggish and the objectives of the underway replenishment maneuver are not met.
Figure 3.5 UNREP Passing Process, No Feedforward, Calm Sea (Prefect Feedback, $\eta=1$, $\Delta=0.12$)
Figure 3.5 UNREP Passing Process, No Feedforward, Calm Sea (Perfect Feedback, $\eta=1, \Delta=0.06$)
Figure 3.7 UNREP Passing Process, No Feedforward, Calm Sea (Perfect Feedback, $\eta=8$, $\Delta=0.12$)
Figure 3.8 UNREP Passing Process, No Feedforward, Calm Sea (Perfect Feedback, $\eta=0.5$, $\Delta=0.12$)
5. **Station Keeping Process, \( \eta=1, \Delta=0.12 \), No Feedforward**

During the station keeping process where the two ships travel alongside for some time, constant interaction force and moment will develop, see Figure 3.8. As a result in the absence of the feedforward term, a nonzero steady state error will be present. Although the feedback control stabilizes the system, it cannot ensure the required steady state accuracy.

6. **Passing Process, \( \eta=1, \Delta=0.12 \)**

The simulations that follow include the feedforward term in the control law as developed previously. The results are shown in Figure 3.9. Comparing these to Figure 3.4, where feedforward was not included we can see that for the passing process the effects of the feedforward term are very small except for the increased rudder action at 0 ft longitudinal position, as expected.

7. **Passing Process, \( \eta=4, \Delta=0.06 \)**

As seen from Figure 3.10 increasing \( \eta \) and decreasing \( \Delta \) results in more path accuracy and increased control activity. The tighter control law in this case helps however during the station keeping process in the following two figures.

8. **Station Keeping Process, \( \eta=1, \Delta=0.12 \)**

The effect that the feedforward term has on path accuracy is evident by comparing the results of this simulation Figure 3.11, with those at the no feedforward case, Figure 3.8. Although the transient response during the
Figure 3.9 UNREP Station Keeping Process, No Feedforward, Calm Sea (Perfect Feedback, $\eta=1$, $\Delta=0.12$)
Figure 3.10 UNREP Passing Process, Calm Sea (Perfect Feedback, Disturbance Compensation, $\eta=1$, $\Delta=0.12$)
Figure 3.11 UNREP Passing Process, Calm Sea (Perfect Feedback, Disturbance Compensation, $\eta=4$, $\Delta=0.06$)
approach phase is identical, the steady state path deviation becomes much smaller and asymptotically reaches zero.

9. *Station Keeping Process*, $\eta=4$, $\Delta=0.06$

The results of this simulation are shown in Figure 3.12 where we can clearly see the increased rudder action and path overshoot. These result from increasing $\eta$ and decreasing $\Delta$ as in the passing process.
Figure 3.12 UNREP Station Keeping Process, Calm Sea (Perfect Feedback, Disturbance Compensation, \( \eta=1, \Delta=0.12 \))
Figure 3.13 UNREP Station Keeping Process, Calm Sea (Perfect Feedback, Disturbance Compensation, $\eta=4, \Delta=0.06$)
E. REMARKS

A sliding mode controller has been designed for the UNREP which utilized a LQR method. The controller have been proved to be very effective for a time varying disturbance (passing). Disturbance compensation was achieved by means of a feedforward term in the automatic controller.

The results demonstrate excellent tracking and path keeping characteristics in the presence of strong interaction forces and moments without any compromise in the stability and robustness properties at calm seas.

In this control test results all states are measurable, but in reality for a ship operating at sea not all states can be measured. So a Kalman filter design is needed as done in Chapter IV.
IV. KALMAN FILTER

A. INTRODUCTION

1. Disturbances

As was demonstrated in the previous chapter the optimal sliding mode control law was able to guarantee stability and steady state accuracy. For that it required knowledge of all states including the interaction forces and moments. An observer is therefore necessary in order to provide an estimate as accurate as possible of all system states. The first order wave forces can be effectively modeled as white noise components since they vary very rapidly compared to the dynamics of the maneuvering ship. A shaping filter is introduced in order to model the interaction force \( Y \) and moment \( N \) as exponentially correlated noise driven by white noise. In other words

\[
\begin{align*}
\dot{N} &= -\frac{1}{T_N} N + \frac{1}{T_N} W_N \\
\dot{Y} &= -\frac{1}{T_N} Y + \frac{1}{T_N} W_Y
\end{align*}
\]

(4.1)

where \( W_N, W_Y \) are white noise components and \( T_N \) and \( T_Y \) are time constants of the filter which are approximately equal to one (the time that it takes to travel one ship length).
The power spectral density of Y and N is

\[ Q_v = \begin{bmatrix} Q_N & 0 \\ 0 & Q_Y \end{bmatrix} \]  \hspace{1cm} (4.2)

where \( Q_N \) and \( Q_Y \) are estimated using

\[ Q_N = 2\sigma_N^2 T_N \]  \hspace{1cm} (4.3)

\[ Q_Y = 2\sigma_Y^2 T_Y \]  \hspace{1cm} (4.4)

The root mean square values of N and Y denoted by \( \sigma_N \) and \( \sigma_Y \) can be estimated using the typical curves for the interaction forces shown in Figure 4.1. This calculation gives

\[ Q_v = \begin{bmatrix} 1.548 \times 10^{-6} & 0 \\ 0 & 8.97 \times 10^{-8} \end{bmatrix} \]  \hspace{1cm} (4.5)

2. Measurement Noise

The measurable states in this study are heading angle(\( \psi \)), yaw rate(\( r \)), and lateral separation distance(\( y \)).

The output equation is
\[ y_m = \begin{bmatrix} \Psi \\ r \\ y \end{bmatrix} = \begin{bmatrix} 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \end{bmatrix} \delta \]

where \( y_m \) is the output vector, the output matrix

\[
C = \begin{bmatrix} 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \end{bmatrix}
\]

and \( V \) is the measurement noise. The power spectral density \( R_v \) of \( V_n \) can be evaluated using the numerical values in Table 4.1. The weighting matrix \( R_v \) is written in the form

\[
R_v = \begin{bmatrix} r_{v_{11}} & 0 & 0 \\ 0 & r_{v_{22}} & 0 \\ 0 & 0 & r_{v_{33}} \end{bmatrix}
\]  

(4.7)

*Note:*

- $\sigma$: Random standard deviation from the true value (units are degrees for heading angle and yaw rate, ft for $v$).
- $\tau$: The correlation time.
- All values of $R_i$ are in nondimensional values.
B. DESIGN OF KALMAN FILTER

In order to avoid enlarging the plant noises and measurement noises, an optimal stochastic observer is required. The state vector and the covariance error are described as follows

\[
E[x(t_0)] = \bar{x}_0
\]
\[
E[(x(t_0) - \bar{x}_0)(x(t_0) - \bar{x}_0)^T] = p_0
\]

The estimate of the state at \( t_0 \) is assumed to be

\[
\hat{x}(t_0) = \bar{x}_0
\]

The disturbance in the state equations has

\[
E[w(t)] = 0
\]
\[
E[w(t)w^T(\tau)] = Q(\tau) \delta(t-\tau)
\]

The measurement noise has

\[
E[v(t)] = 0
\]
\[
E[v(t)v^T(\tau)] = R(\tau) \delta(t-\tau)
\]

Design of the Kalman Filter is based on the cost function
\[ J = \frac{1}{2} \left[ (x_0 - \bar{x}_0)^T P_0^{-1} (x_0 - \bar{x}_0) \right] \]
\[ + \frac{1}{2} \int_{t_0}^{t} \left[ w^T Q^{-1} w + (y_m - Cx)^T R^{-1} (y_m - Cx) \right] dt \]

(4.12)

where the first term minimizes the error in the initial estimate, the second term minimizes the effect of \( w \), and the third term minimizes the error in the estimate of \( x \).

The Kalman Filter has the familiar form

\[ \frac{d\hat{x}}{dt} = A\hat{x} + B_1 u + L (y_m - C\hat{x}) \]

(4.13)

\[ L = P C^T R^{-1} \]

(4.14)

\( L \) is the time-varying Kalman gain matrix,

\( P \) is the solution of the Riccati differential equation,

\[ \dot{P} = AP + PA^T + B_2 Q B_2^T - PC^T R^{-1} CP \]

(4.15)

\( B_2 \) is the disturbance matrix; and

\( P(t_0) = P_0 \).

At steady state \( P \) is the solution to the algebraic Riccati equation

\[ AP + Pa^T + B_2 Q B_2^T + PC^T R^{-1} CP = 0 \]

(4.16)
In such a case the Kalman filter gain matrix is time-invariant and the Kalman filter is a full order observer with its gains tuned in an optimal way to the system at hand.

C. SIMULATION AT OPEN SEA

1. Introduction

In the following we present results for both the passing and the station keeping process. The sliding mode linear quadratic Gaussian compensator is used along with the feedforward term developed in chapter III. All results are based on UNREP in a random sea of significant wave height of 16 ft. Solid curves in the graphs denote the actual values of the variables while dotted curves correspond to the estimated values from the Kalman filter.

2. Passing Process, $\Delta=0.12$, $\eta=1$

The results of the simulation are shown in Figure 4.1. Convergence to the desired track is achieved. The steady state deviation of the tracking ship from the commanded path is minimal. The steady state use of the rudder angle is also very satisfactory.

3. Passing Process, $\eta=4$, $\Delta=0.06$

The results of the simulation are shown in Figure 4.2. Initial conditions were selected on the desired path so this simulation demonstrates the effects of the passing ship disturbance. The two ships are located beam-to-beam at 0 ft longitudinal distance. The maximum deviation of the tracking ship is $\pm 3$ ft.

Figure 4.4 Tuning Phase—(continued)
Figure 4.4 Position Phase (Steady State)
Figure 4.4 Position Phase - (continued)
4. Station Keeping Process, $\eta=1$, $\Delta=0.12$

The results of this simulation are shown in Figure 4.3. Steady state accuracy is maintained. There appears to exist an error in the estimates of $Y$ and $N$ despite the zero steady state error in the path deviation. This is attributed to the existence of the first order wave force and moment. Since there is no explicit estimation scheme for these, their effect is effectively combined by the observer into an equivalent interaction force and moment which of course differ from the actual.

5. Station Keeping process, $\eta=4$, $\Delta=0.06$

The results of this simulation are shown in Figure 4.4. Compared to the simulation shown in Figure 4.3 we can see the effects of the tighter control law in this case. Both the transient and steady state path deviation are reduced while the rudder activity is slightly increased.

D. CONCLUSIONS AND REMARKS

The sliding mode Linear Quadratic Gaussian compensator was able to adequately control the lateral motion of a surface ship during underway replenishment in an open sea. The feedforward term ensured state path accuracy in the presence of interaction forces and moments as well as first order wave effects. The Kalman filter was able to minimize the effects of the measurement noises and external random disturbances while at the same time it provided the controller with an accurate
estimate of the states needed for control. Different control options were considered with regards to their transient and steady state characteristics. These comparisons provided insight towards appropriate selection of the boundary layer thickness and switching gain of the sliding mode control.

Suggestions for further research include the application of integral control instead of disturbance estimation and compensation for eliminating the steady state path error. Furthermore, the effects of constant disturbances, such as currents, and slowly varying second order wave draft forces should be investigated.
APPENDIX A. SUMMARY FOR COMPUTER PROGRAMS

The complete listing of the computer programs written and used in this thesis are in APPENDIX B and APPENDIX C.

The MATLAB program in APPENDIX B is used for calculating feedback gains and observer gains using the LQR method, which are utilized for sliding surface design and Kalman filter design.

The FORTRAN program in APPENDIX C is a complete listing for PASSING PROCESS simulation. The modified program for the STATION KEEPING PROCESS is not listed here, the only change is the following FORTRAN code logic expression:

\[
\text{if (b.ge.0) b=0.}
\]

APPENDIX C. UNREP SIMULATION PROGRAM: SLIDING MODE CONTROLLER DESIGNED BY LQR METHOD

program shipdynamics

**c** Simulation program for UNREP

**c** Written by LT FU, HSU-SHENG SIMON

**c** The program controls one rudder input with a sliding mode design for path keeping and tracking.

**c** Speed is constant 1 normalized value.

**c** The initial conditions for ship are follows: 1 nondimensional lateral separation distance, -4000 ft longitudinal distance, 0.087 rad heading angle.

**c** The disturbances include interaction forces and moments, and first-order wave sway force and yaw moment.

**c** The observed states: yaw rate, lateral separation rate, interaction forces and moments.

**c** The measurements: heading angle, lateral separation distance, and rudder angle.

**c** The outputs of the program are written to files, these files are then accessed by the MATLAB to generate output graphics.

**c** This program utilized subroutines for different functions that are required:

**c** subroutine locate: find the interaction forces and moments at the real time and use subroutine trlint as interpolation.

**c** subroutine trlint: incorporate with subroutine locate.
subroutine randm : generate random signal.
subroutine trap : Trapzoid integration.
subroutine first : first order wave calculation.

Two data files for interaction forces and moments:
Table1.dat: interaction forces.
Table2.dat: interaction moments.

return
end

subroutine first(psi, ws, time, fl, nl)
c
c This subroutine is used for calculating the sway force
and yaw moment component from first-order wave
excitation.
c
The inputs of the subroutine are:
c
(1) The encounter frequency(wz):
c
wz = w*(w^2)/g*u*cos(theta-psi)
   w is the actual wave frequency.
   theta(θ) is the wave-to-ship angle.
   psi(ψ) is the ship heading.
   g is the acceleration of gravity.
   u is the ship forward speed (15 knots).

(2) The wind speed(ws).
(3) The RAO of sway force and RAO of yaw moment are the function of encounter frequency.

(4) The Pierson-Moskowitz spectrum is the function of wind speed.

The associated force and moment are calculated from Trapizoid Integration and be the outputs of the subroutine.

The phase angles correspond to the sway force and moment are generated by random process (irregular wave) 
(epsf, epsm) from 0 to 2π
