# Finite Element Methods for Nonlinear Static Analysis of Sandwich Plates

**Author(s):** Damin J Siler, 2nd Lieutenant, USAF

**Performing Organization:** Air Force Institute of Technology, WPAFB OH 45433-6583

**Sponsoring Agency:** Mr. William Baron, WL/FIBA, WPAFB OH 45433

**Abstract:** A finite element method, developed for static analysis of composite plates, was enhanced to be used with sandwich plates. The theory considers geometric nonlinearity and transverse shear. Furthermore, a new postprocessor was written to check for initial failure using the maximum stress criteria. It also includes a procedure for evaluating transverse normal stresses by enforcing equilibrium. The code modifications for sandwiches were verified by comparing finite element solutions to closed-form sandwich theories. Both methods showed good correlation. In addition, comparisons between one type of composite plate and a similar sandwich plate found that the sandwich had better specific stiffness for various geometries. Finally, quasi-static models of low-velocity impacts on sandwich plates succeeded in predicting incipient damage due to core crushing in the impact region, but they were inconsistent in estimating the actual load levels for initial failure, based on experiments from other research.

FINITE ELEMENT METHODS FOR NONLINEAR STATIC ANALYSIS OF SANDWICH PLATES

THESIS

Presented to the Faculty of the Graduate School of Engineering of the Air Force Institute of Technology Air University In Partial Fulfillment of the Requirements for the Degree of Master of Science in Aeronautical Engineering

Damin J Siler, B.S. Second Lieutenant, USAF

December 1994

Approved for public release; distribution unlimited
Preface

This thesis is part of an overall research project dealing with sandwich constructions and their usage in structural panels. The research is sponsored by the Flight Dynamics Directorate of Wright Laboratories. Mr. William Baron is the point-of-contact for the sponsor, and Dr. Anthony Palazotto, AFIT/ENY, is the principal investigator.

The successful completion of this thesis was not an entirely individual effort. I would like to thank my advisor Dr. Palazotto for his invaluable guidance, patience and confidence. I would also like to acknowledge Capt. Timberlyn Harrington whose thesis work was directly related to mine and provided essential data for both modeling and comparison purposes. Finally, I would like to thank my parents Dave and Diane, my sister Deawn and the rest of my family for their long-distance support.

Abstract

In this research, a finite element method, originally developed for analyzing the static behavior of composite flat plates, was enhanced so it could also be used with sandwich plates. The governing theory considers geometric nonlinearity and transverse shear effects. Furthermore, a new external postprocessor was written in order to check plate models for initial failure using the maximum stress criteria. It also includes a procedure for evaluating transverse normal stresses by enforcing equilibrium through the thickness.

The programming modifications to allow modeling of sandwich plates were verified by comparing finite element solutions to those from closed-form linear theories for sandwich plates. Results showed good correlation between the numerical and theoretical solutions. In addition, displacement results (using the same program) from previous research for particular composite plates were compared to sandwich plates of similar composition and equal size. The sandwiches were more flexible in absolute terms, but displayed higher stiffness-to-weight ratios than the composites. Finally, low-velocity impact tests were modeled quasi-statically with the finite element code, and the new postprocessor was employed to predict incipient plate damage. Locations and modes of failure were correctly determined, but the predicted load levels for initial failure were inconsistent with experimental results from other research.
1. Introduction

The need for strong, lightweight materials in aerospace structural components has led to a renewed interest in sandwich plates and shells using modern composite materials. These hybrid constructions consist of two dense outer faces that are bonded to a lightweight core. The core usually has little in-plane and flexural stiffness, compared to the faces, but it can have significant transverse strength and acts as a spacer to enhance the bending resistance of the faces. The result is a thicker plate or shell with a higher stiffness-to-weight ratio than the facesheets alone.

Predicting the static response of laminated composite plates is complicated due to effects such as: property variation through-the-thickness, geometric and physical nonlinearity, transverse shear and multiple failure modes. The additional complexity of sandwich constructions further complicates the analysis. Closed-form methods are limited to linear solutions (with many simplifying assumptions) for specific geometries and boundary conditions. Furthermore, experimental testing can give good results for a particular plate, but it can be impractical, in terms of time and money, for analyzing the effects of a wide range of variables. On the other hand, numerical techniques like finite elements (FE) can be applied to plates of different shapes, sizes, compositions, loadings and supports with greater flexibility. The accuracy and practicality of FE methods are dependent on the governing theories, model complexity and a given computer's speed and precision. Therefore, the application of advanced theories and finely-detailed models
is conditioned by the availability of affordable technology that can handle them in a timely manner.

This research employs a finite element method developed for laminated plates and cylindrical shells and enhances it for use with sandwich plates. The governing theory considers geometric nonlinearity (through the von Karman strain-displacement relations) and transverse shear effects. In addition, plate materials are assumed linearly elastic to exclude such effects as plasticity and failure within the solution. A full three-dimensional plate model is reduced to a two-dimensional analysis by describing all displacement variations in the thickness direction relative to those at the mid-plate surface. This assumption ignores transverse normal stresses, but it greatly reduces the solution's complexity.

The main objective of this research was to test the effectiveness of the given finite element method in analyzing sandwich plates. Three cases were considered. First, linear and nonlinear displacement results were obtained for the same sandwich plate models used by Pagano [18] and Whitney [21] in developing closed-form solutions. This provided comparisons to established theories in order to verify the FE algorithms. Second, displacement results (using the same FE code) from previous research by Owens [16,17] for laminated plates were compared to sandwiches of equivalent overall geometry-- in which the core was half the total thickness and the face plies were constructed from the same material as the laminated plates. Finally, an attempt was made to predict initial failure using postprocessed stress calculations and maximum stress failure criteria. Sandwich plates used in experimental work by Harrington [7] were
modeled, so that the FE results could be compared to actual, incipient plate damage from low velocity impacts. In this research, a quasi-static approach was used to simulate the dynamic loading employed in the experiments.

Previous Work

The textbook by Palazotto and Dennis [19] gives a detailed history of the use of finite elements for analyzing flat plates and cylindrical shells. It also describes the past research and theories which led to the development of the FE code (called SHELL) used in this thesis. Dennis [4] wrote the original version of SHELL for the study of large displacements and rotations of shells. Owens [16] used it to analyze composite plates and made comparisons between linear, geometrically nonlinear, classical and nonclassical solutions. He showed, for a given loading, that membrane stiffness due to nonlinear in-plane strain terms becomes significant in thin plates. In addition, the transverse shear flexibility present in nonclassical theories is important for thick plates. Linear and nonlinear solutions become alike for thicker plates as do classical and nonclassical solutions for thinner plates.

Early work in the study of sandwich plates was conducted by Pagano [18]. He developed a linear, three-dimensional elasticity solution for rectangular plates with simply-supported edges. Pagano's results for both composite and sandwich plates further emphasized the limitations of classical laminated plate theory (CLPT) for thick plates due to its neglect of transverse shear. Later work by Whitney [21] yielded an alternative closed-form solution that resembles CLPT with additional contributions for transverse shear. Displacement results from both methods showed good agreement over a wide
range of plate width-to-thickness ratios; although, for thin plates, Pagano’s solution converged closer to CLPT than Whitney’s did.

Both Pagano and Whitney calculated in-plane stresses from strain values and the constitutive relations, but they derived transverse shear stresses from the equilibrium equations in elasticity theory (see the textbook by Sadda [20]). This method provides better accuracy than computing all stresses through the constitutive relations. Engblom and Ochoa [5,6] also used this procedure in developing linear finite element formulations for laminated composite plates. By assuming linear stress distributions through the thickness of each ply, the integral-differential equations of equilibrium can be converted into matrix operations for easy implementation.

On the other hand, SHELL does not satisfy localized equilibrium (although such errors tend to cancel out on a global scale) since it relates all stresses to strains through the constitutive relations. It does this because its consideration of nonlinear strains and higher-order stress distributions prevents it from obtaining transverse stresses within the solution through a linear system of equations that enforce equilibrium. Furthermore, compatibility is satisfied at the nodes but not through the thickness, in general. SHELL could be modified to employ an iterative process in which the postprocessor calculates transverse stresses by enforcing equilibrium and then uses them to alter the strain and displacement solutions until both equilibrium and compatibility are satisfied. However, this would have to be nested within the existing iteration scheme for load or displacement incrementing in SHELL’s nonlinear solution control, thus greatly reducing the code’s speed. Furthermore, such a modification is beyond the scope of this thesis.
Other research related to sandwich plates has been oriented towards studying and predicting failure due to damage brought about by low velocity impacts. McQuillan et al. [14] were among the first to observe that static and dynamic loading had similar failure mechanisms. Experimental work by Kelkar et al. [10] employed this concept to simulate low-velocity impact damage using equivalent quasi-static loads. Low-velocity impacts are representative of physical damage caused by such actions as a dropping a blunt object onto the plate from a short height. In addition, quasi-static means that loads are applied slowly enough to ignore inertial effects, and the plate is assumed to remain in static equilibrium as damage progression alters its equilibrium state. Finite element models using ANSYS (a commercial software package) were developed by Dandy et al. [3] for comparison with Kelkar’s experiments. Both had agreeable results for thick plates but not for thin plates. The ANSYS solver can only consider linear strains, and the large displacements present in the thin plates invalidate this simplification.

Nemes and Simmonds [15] analyzed the impact response of sandwich plates with a foam core. The experimental plates were square, but the finite element models were circular disks of equivalent size. This allowed a complicated three-dimensional model to be reduced to an axisymmetric radial plane-section of the disk. Therefore, each sandwich’s cross-section through the thickness was modeled as a continuum instead of distinct layers. The FE results overpredicted the experimental deflection but produced agreeable transverse shear stresses. In addition, the low stiffness of the foam cores allowed significant relative displacement between the faces. This effect could be reduced
by introducing a honeycomb core with greater transverse normal stiffness, but the voids present in honeycomb cells may invalidate treating it as a continuum.

Sandwich plate failure modes due to impacts and static indentations were investigated by Lagace and Williamson [12]. As predicted, both types of loadings had similar damage responses. They tested sandwiches with graphite-epoxy laminate faces and Nomex honeycomb cores, which are similar to those used in this thesis. Initial damage occurred under the applied load from core crushing or buckling near the top face. As a consequence, this face experienced local fiber, matrix and delamination failure because the core could no longer support it. Thicker faces reduced the extent of damage by stiffening the indentation responses. On the other hand, thicker cores increased the chances of buckling more than they enhanced the faces' bending stiffness.

In summary, the majority of research dealing with sandwich plates has been limited to experimentation and linearized solutions. This thesis goes one step further by employing a finite element method that includes geometric nonlinearities. The goal is to validate it as an accurate and practical tool for static displacement and initial failure analysis.
II. Theoretical Considerations

Sandwich Plate

Figure 2.1 contains the geometry and coordinate systems used for modeling sandwich plates. Both X-Y-Z ($X_1$-$X_2$-$X_3$) and L-T-Z represent orthogonal systems. The longitudinal and lateral directions correspond to the principal material directions of an orthotropic ply. A ply's orientation angle $\theta$ is the angle from X to L (or from Y to T). All plates used in this research were symmetrical about their midsurfaces ($z=0$).

![Figure 2.1: Sandwich Plate Geometry and Coordinate Systems](image-url)
**Governing Equations**

A plate is assumed to be in a state of plane stress. As a result, all transverse normal stresses $\sigma_{xz}$ are zero, and plate behavior can be described by displacements and rotations at and relative to the midsurface. Transverse normal strains $\varepsilon_{zz}$ are nonzero in general, but they are consequences (due to Poisson effects) of the other strains and do not affect the stress state. Transverse shear strains $\varepsilon_{xz}$ and $\varepsilon_{yz}$ are assumed to have parabolic distributions in the Z-direction. This can be done since the plane stress assumption decouples the in-plane and transverse shear constitutive relations. It also satisfies the boundary conditions of zero transverse shear on the top and bottom plate surfaces (none of the prescribed loading in this research imposed surface shears).

![Figure 2.2: Plate Displacement Degrees-of-Freedom](image)

Each point within the plate's midsurface has seven degrees-of-freedom as shown in Figure 2.2. Displacements $u$, $v$ and $w$ are translations in the $X$, $Y$ and $Z$ directions. The terms $w_{1}$ and $w_{2}$ are physical slopes of the midsurface in the $X$-$Z$ and $Y$-$Z$ planes, while $\psi_{1}$ and $\psi_{2}$ are rotations due to bending alone in those respective planes. Transverse shearing in a single plane is described by the algebraic sum of the two rotations.
Translational displacements away from the midsurface are evaluated through the following plate kinematics:

\[
\begin{align*}
    u_1(x, y, z) &= u + z\psi_1 + z^3 k(\psi_1 + w_1) \\
    u_2(x, y, z) &= v + z\psi_2 + z^3 k(\psi_2 + w_2) \\
    u_3(x, y, z) &= w
\end{align*}
\]

\[k = -4 / (3h^2)\]  

(2.1)

Furthermore, nonlinear strain and displacement are related through the von Karman plate equations [19] (linear plate solutions disregard all nonlinear terms):

\[
\begin{align*}
    \varepsilon_{xx} &= u_{1,11} + \frac{1}{2} w_{11}^2 \\
    \varepsilon_{yy} &= u_{2,22} + \frac{1}{2} w_{12}^2 \\
    \varepsilon_{xy} &= u_{1,22} + u_{2,11} + w_{11} w_{12} \\
    \varepsilon_{yz} &= (1 + 3z^2 k)(w_{1,2} + \psi_1) \\
    \varepsilon_{xz} &= (1 + 3z^2 k)(w_{1,1} + \psi_1)
\end{align*}
\]

(2.2)

All ply materials are assumed linearly elastic and at least orthotropic. The assumption of plane stress allows the need for only six elastic constants: \(E_{LL}, E_{TT}, G_{LT}, G_{TZ}, G_{LZ}\) and \(v_{LT}\). The constitutive relations for stress and strain are:

\[
\begin{align*}
    \begin{bmatrix}
    \sigma_1 \\
    \sigma_2 \\
    \sigma_6 
    \end{bmatrix}^K &= \begin{bmatrix}
    \bar{Q}_{11} & \bar{Q}_{12} & \bar{Q}_{16} \\
    \bar{Q}_{12} & \bar{Q}_{22} & \bar{Q}_{26} \\
    \bar{Q}_{16} & \bar{Q}_{26} & \bar{Q}_{66}
    \end{bmatrix}^K
    \begin{bmatrix}
    \varepsilon_1 \\
    \varepsilon_2 \\
    \varepsilon_6
    \end{bmatrix} \\
    \begin{bmatrix}
    \sigma_4 \\
    \sigma_5 
    \end{bmatrix}^K &= \begin{bmatrix}
    \bar{Q}_{44} & \bar{Q}_{45} \\
    \bar{Q}_{45} & \bar{Q}_{55}
    \end{bmatrix}^K
    \begin{bmatrix}
    \varepsilon_4 \\
    \varepsilon_5
    \end{bmatrix}
\end{align*}
\]

(2.3)

where \(K\) is the ply number and \(\bar{Q}_{ij}^K\) are the components of that ply material’s elastic stiffness matrix—reduced for plane stress and transformed into the \(X\) and \(Y\) directions.
The numerical subscripts represent a simplified indexing of the stress and strain tensor components:

\[
\begin{bmatrix}
\sigma_1 & \sigma_6 & \sigma_5 \\
\sigma_6 & \sigma_2 & \sigma_4 \\
\sigma_5 & \sigma_4 & \sigma_3
\end{bmatrix} = 
\begin{bmatrix}
\sigma_{xx} & \sigma_{xy} & \sigma_{xz} \\
\sigma_{xy} & \sigma_{yy} & \sigma_{yz} \\
\sigma_{xz} & \sigma_{yz} & \sigma_{zz}
\end{bmatrix}
\]

\[
\begin{bmatrix}
\varepsilon_1 & \frac{1}{2} \varepsilon_6 & \frac{1}{2} \varepsilon_5 \\
\frac{1}{2} \varepsilon_6 & \varepsilon_2 & \frac{1}{2} \varepsilon_4 \\
\frac{1}{2} \varepsilon_5 & \frac{1}{2} \varepsilon_4 & \varepsilon_3
\end{bmatrix} = 
\begin{bmatrix}
\varepsilon_{xx} & \varepsilon_{xy} & \varepsilon_{xz} \\
\varepsilon_{xy} & \varepsilon_{yy} & \varepsilon_{yz} \\
\varepsilon_{xz} & \varepsilon_{yz} & \varepsilon_{zz}
\end{bmatrix}
\]

(2.4)

**Finite Element Solution**

This research employed rectangular plate elements with four nodes and 28 degrees-of-freedom (seven per node as in Figure 2.2). The geometry of an individual element and the representation of its global, local and natural coordinates are shown in Figure 2.3. Displacements within the given element are interpolated from the nodal displacements through appropriate shape functions. The displacement field for w

![Figure 2.3: Four-Node Plate Element Geometry and Coordinate Systems](image-url)
requires $C^1$ continuity (as defined in the textbook by Cook et al. [2]), therefore Hermitian shape functions are used for nodal displacements $w$, $w_1$ and $w_2$:

$$w(x, y) = \begin{bmatrix} H_1 & H_2 & H_3 & H_4 \end{bmatrix} \begin{bmatrix} q_1 \\ q_2 \\ q_3 \\ q_4 \end{bmatrix}$$

$$H_K = \begin{bmatrix} \frac{1}{8}(1 + \xi K \xi)(1 + \eta K \eta)(2 + \xi K \xi + \eta K \eta - \xi^2 - \eta^2) \\ \frac{1}{8} \Delta x \xi K (1 + \xi K \xi)(\xi K \xi - 1)(1 + \eta K \eta) \\ \frac{1}{8} \Delta y \eta K (1 + \xi K \xi)(\eta K \eta - 1)(1 + \eta K \eta) \end{bmatrix}^T$$

(2.5)

$$q_K = \{ w \ w_1 \ w_2 \}_K^T$$

where $K=1$ through 4 represent the local node numbers for an element found at global position $(x,y)$. The other displacement fields only need $C^0$ continuity and employ Lagrangian shape functions:

$$\begin{bmatrix} u(x, y) \\ v(x, y) \\ \psi_1(x, y) \\ \psi_2(x, y) \end{bmatrix} = \begin{bmatrix} N_1 & 0 & 0 & \cdots & N_4 & 0 & 0 & 0 \\ 0 & N_1 & 0 & 0 & \cdots & 0 & N_4 & 0 \\ 0 & 0 & N_1 & 0 & \cdots & 0 & 0 & N_4 \\ 0 & 0 & 0 & N_1 & \cdots & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} q_1 \\ q_2 \\ q_3 \\ q_4 \end{bmatrix}$$

(2.6)

$$N_K = \frac{1}{4}(1 + \xi K \xi)(1 + \eta K \eta)$$

$$q_K = \{ u \ v \ \psi_1 \ \psi_2 \}_K^T$$

The complex formulation of SHELL’s finite element solution is fully described in the textbook by Palazotto and Dennis [19]. In a nonlinear model, the code allows either load or displacement incrementing for solution control. For each increment, it uses a Newton-Raphson iteration scheme to converge to a solution which minimizes potential energy. All plates modeled in this research used some form of distributed or multi-nodal
loading. Therefore, load control was employed in each nonlinear case, since
displacement control would require an assumed shape relation between the prescribed
nonzero degrees-of-freedom. In this research, no iteration convergence problems arose
using load-control.

Every case study in this research considered square plates with simply supported
glines (u and v translations were free). Since all ply orientations were either 0 or 90
degrees, it was only necessary to generate FE meshes for a single quadrant of each plate
by prescribing bi-axial symmetry. Figure 2.4 shows the displacement boundary
conditions that were applied to each square quarter-plate.

Figure 2.4: Boundary Conditions of Square Quarter Plate
Code Enhancements

SHELL required some modifications before being used with sandwich plates. The most critical change was to allow multiple sets of elastic properties. Without this, the faces and core could not be represented as different materials. Furthermore, the typically large variation between face and core thickness commanded the need to define a separate thickness for each ply. Otherwise, it would be necessary to divide all plies into a common uniform thickness, which could cause severe redundancies. Finally, SHELL now gives the user the opportunity to generate a secondary output file for use with a newly written (as part of this research) and separately executed postprocessor program, called FAILURE. Appendix A provides a more detailed explanation of these and other enhancements to SHELL and includes the new structure of its input deck.

FAILURE was written for the purpose of predicting the initial failure regions and modes of rectangular plates (with certain modeling restrictions) using the maximum stress criteria. SHELL’s own postprocessor could have been altered for this task. In fact, FAILURE utilizes some of the same subroutines (with minor modifications). However, a separate program has several advantages. First, the same plate model can be rechecked for failure using different parameters and criteria values without having to re-execute SHELL to obtain the same displacement solution before postprocessing (a valuable feature for code debugging and validation of the methodology, since it has not been tried before with this FE theory). Second, the code’s structure does not need to conform to that of SHELL. Therefore it gives the user more flexibility in adding or changing program features. On the other hand, the secondary output file generated by SHELL (which
contains all preprocessor and solution data needed by FAILURE) is usually as large as its regular output file. Hence, using it with a set of complex FE models requires a computer with plentiful storage space. Appendix B includes the entire FAILURE code, the structure of its additional user-defined input deck and some of its other features.

Since postprocessor results are based on the assumption of perfect linearly elastic materials, FAILURE is invalid for predicting failure beyond the point of initiation (even with a more sophisticated failure theory than maximum stress). In addition, SHELL’s basic design does not allow elastic property variation from element-to-element (a necessary feature for localizing the effects of failure within the solution). Hence, the implementation of progressive failure into the FE solution would require massive amounts of code alteration.

Initial Failure Criteria

FAILURE is designed to report failure when averaged stresses within a given element exceed user-defined maximum magnitudes. For a laminated plate, element stresses are calculated at 12 discrete points per ply-- the four outermost Gauss points (see Figure 2.5) at the upper, middle and lower surfaces of each ply (the FE solution uses 5x5

![Diagram of Single-Element Outer Gauss Points for Stress Calculation](image-url)

Figure 2.5: Single-Element Outer Gauss Points for Stress Calculation
Gauss quadrature for numerical integration [2,19]). Therefore, at a given Gauss point, 
each ply’s stress distribution through the thickness is characterized by three values per 
component at known Z-coordinates. This provides sufficient data to obtain an average 
stress state by calculating parabolas that fit each component’s discrete quantities and then 
finding a mean value for each continuous function (the area under the curve divided by 
the ply thickness). This is a better method because it is equivalent (for the assumed shape) 
to the arithmetic average of an infinite number stress values (per component) instead of 
just three. Figure 2.6 graphically demonstrates how ply stresses are averaged.

![Figure 2.6: Ply Stress Averaging Through the Thickness](image)

Average stress components are given in X-Y-Z coordinates, so they must be 
transformed to match the directions of the material failure criteria. For an orthotropic ply, 
the stresses are transformed into the L-T-Z system by the following matrix operation:

\[
\begin{bmatrix}
\sigma_{LL} & \sigma_{LT} & \sigma_{LZ} \\
\sigma_{LT} & \sigma_{TT} & \sigma_{TZ} \\
\text{sym} & 0 & 0
\end{bmatrix}
= \begin{bmatrix}
c & s & 0 \\
-s & c & 0 \\
0 & 0 & 1
\end{bmatrix}
\begin{bmatrix}
\sigma_{xx} & \sigma_{xy} & \sigma_{xz} \\
\sigma_{yx} & \sigma_{yy} & \sigma_{yz} \\
\text{sym} & 0 & 0
\end{bmatrix}
\begin{bmatrix}
c & -s & 0 \\
0 & 0 & 1
\end{bmatrix}
\]  

(2.7)
where $c=\cos \theta$ and $s=\sin \theta$. On the other hand, stresses for an isotropic ply are converted to principal stresses by evaluating the eigenvalues of the stress tensor--as shown in the textbook by Sadda [20]. The resulting characteristic polynomial is cubic and its roots are solved through a closed-form technique found in the mathematics handbook by Korn and Korn [11]. Seven possible modes of failure were given to orthotropic materials and three were given to isotropic materials. These modes and their maximum stress criteria are listed in Table 2.1.

</table>

FAILURE also includes a procedure for checking delamination at the ply interfaces due to transverse shearing. Since the constitutive relations (Equation 2.3) cause stress discontinuities, in general, across the interface between unlike plies, the values of $\sigma_{xz}$ calculated on each side of the interface are usually different. This also holds true for $\sigma_{yz}$. The arithmetic mean stress at the interface for each component is used for checking delamination. FAILURE reports shear delamination for a given element and
interface if (at any Gauss point) the magnitude of either mean value exceeds defined maximums.

**Estimation of Transverse Normal Stresses**

Although SHELL’s theory assumes all transverse normal stresses are zero, FAILURE includes a routine which estimates $\sigma_{zz}$ by enforcing equilibrium. Neglecting body forces, the equation of equilibrium in the Z-direction is:

$$\sigma_{xz,x} + \sigma_{yz,y} + \sigma_{zz,z} = 0$$

(2.8)

The shear stress gradients in Equation 2.8 are related to displacement gradients of $w$, $\psi_1$ and $\psi_2$ by taking partial derivatives of Equations 2.2 and 2.3:

$$\begin{bmatrix} \sigma_{yz,y} \\ \sigma_{xz,x} \end{bmatrix}^K = \begin{bmatrix} \bar{Q}_{44} & 0 & \bar{Q}_{45} & 0 \\ 0 & \bar{Q}_{45} & 0 & \bar{Q}_{55} \end{bmatrix}^K \begin{bmatrix} \varepsilon_{yz,y} \\ \varepsilon_{xz,x} \end{bmatrix}$$

(2.9)

for ply $K$

$$\begin{bmatrix} \varepsilon_{yz,y} \\ \varepsilon_{yz,x} \\ \varepsilon_{xz,y} \\ \varepsilon_{xz,x} \end{bmatrix} = \left(1 + 3z^2k\right) \begin{bmatrix} w_{,22} + \psi_{,22} \\ w_{,21} + \psi_{,21} \\ w_{,12} + \psi_{,12} \\ w_{,11} + \psi_{,11} \end{bmatrix}$$

(2.10)

$$k = -4 / (3h^2)$$

The displacement gradients in Equation 2.10 are related to nodal displacements through derivatives of the shape functions in Equations 2.5 and 2.6. Since these gradients are also used in other strain terms, SHELL’s stress calculation subroutine (which is modified for use with FAILURE) already contains code for determining their values. Furthermore, the
assumed parabolic distribution of transverse shear strains forces each ply’s transverse shear stresses, and their in-plane gradients, to be parabolic functions of Z:

\[
\begin{align*}
\sigma_{x'y'}(x, y, z) &= kA(x, y)z^2 + kB(x, y)z + kC(x, y) \\
\sigma_{xz}(x, y, z) &= kD(x, y)z^2 + kE(x, y)z + kF(x, y)
\end{align*}
\] (2.11)

where \(z\) is located within a given ply \(K\). The parabola coefficients for a particular ply and Gauss point are obtained by curve fitting the discrete values of \(\sigma_{x'y'}\) and \(\sigma_{xz}\) at the ply’s upper, middle and lower ply surfaces.

Equation 2.8 forces \(\sigma_{zzz} = 0\) at a plate’s top and bottom surfaces, \(z = \pm h/2\), because \(\sigma_{y'z}(x, y, \pm h/2) = \sigma_{xz}(x, y, \pm h/2) = 0\) from Equations 2.2 and 2.3. In other words, since the transverse shear stresses are zero everywhere on those surfaces, their in-plane gradients must also be zero on those surfaces. In addition, the finite element solution assumes that all prescribed transverse loading occurs on the top surface. Therefore, the bottom of the plate is free of transverse normal stresses: \(\sigma_{zz}(x, y, h/2) = 0\). By combining Equations 2.8 and 2.11 and integrating in the Z-direction, the calculation of \(\sigma_{zz}\) becomes:

\[
\sigma_{zz}(x, y, z_n) = \sum_{k=1}^{n} \left[ \int_{z_{k-1}}^{z_k} \left( \frac{1}{2} (kA + kD)z^2 + \frac{1}{2} (kB + kE)z + (kC + kF) \right) dz \right]
\]

\[
= \sum_{k=1}^{n} \left[ \frac{1}{3} (kA + kD)z^3 + \frac{1}{2} (kB + kE)z^2 + (kC + kF)z \right]_{z_{k-1}}^{z_k}
\] (2.12)

where \(K=1\) denotes the top ply and \(K=n\) is the ply located at \(z = -z_n\). The bounds \(z_{k-1}\) and \(z_k\) are the Z-coordinates of ply \(K\)’s upper and lower surfaces, except when \(K=n\). In that case \(z_k = -z_n\). Note that the use of \(-z_n\) arises because the Z-axis is positive downward through the plate. Integrating in the positive Z-direction imposes an initial value of \(\sigma_{zz} = 0\)
at the top of the plate \((z = -h/2)\). Equation 2.12 includes sign changes that alter the constant of integration (and thus translates the function \(\sigma_{zz}(z)\) for a fixed \(x\) and \(y\)) in order to enforce the boundary condition of \(\sigma_{zz} = 0\) at the bottom of the plate \((z = h/2)\). Code testing verified that Equation 2.12 calculates negative (compression) values of \(\sigma_{zz}(x, y, -h/2)\) in plate regions subjected to a compressive transverse pressure on the top surface.

Plate symmetry, with respect to the midsurface, forces all transverse shear stress profiles in the \(Z\)-direction (and their in-plane gradients) to be symmetric about \(z = 0\). Hence, integrating Equation 2.8 generates \(\sigma_{zz}\) profiles, for a fixed \(x\) and \(y\), that are the superposition of an antisymmetric function of \(z\) and a constant (a line normal to \(z = 0\)). As a consequence, the three \(\sigma_{zz}\) boundary conditions on the top and bottom plate surfaces \((\sigma_{zz}(x, y, \pm h/2) = \sigma_{zz}(x, y, h/2) = 0)\) cause each profile to resemble a cubic polynomial with a maximum magnitude at the top surface of \(\sigma_{zz}(x, y, -h/2)\). However, for a laminate, each ply is usually associated with a different cubic polynomial because the coefficients in Equation 2.11 change from ply to ply. Therefore, the actual profiles generated from Equation 2.12 are continuous but piecewise smooth at the ply interfaces. Figure 2.7 displays a typical \(\sigma_{zz}\) profile for a sandwich plate region subjected to a transverse pressure on the top surface.

Testing of the FAILURE code revealed a numerical problem associated with directly calculating \(\sigma_{yz}\) and \(\sigma_{xz}\) from nodal displacements. The use of Lagrangian shape functions-- with only \(C^0\) continuity-- for \(u\), \(v\), \(\psi_1\) and \(\psi_2\) (Equation 2.6) cause in-plane discontinuities in all stress fields. The effects are usually less significant for \(\sigma_{xx}\).
\( \sigma_{xy} \) and \( \sigma_{xy} \) because their corresponding strains have more \( w, w_1 \) and \( w_2 \) terms (Equations 2.1 and 2.2) which tend to minimize the variations across adjacent elements.

![Graph of \( \sigma_{zz} \) Distribution for Sandwich Plate under Transverse Pressure](image)

Figure 2.7: Shape of \( \sigma_{zz} \) Distribution for Sandwich Plate under Transverse Pressure

However, transverse shear strains can fluctuate severely in the direction normal to the transverse plane-- the X-direction for \( \varepsilon_{yz} \) and the Y-direction for \( \varepsilon_{xz} \). Therefore, the fluctuations amplify when calculating \( \sigma_{yzx} \) and \( \sigma_{xzy} \) from Equation 2.9 because they require transverse strain gradients in both X and Y-directions. This resulted in highly varied and inaccurate estimations of \( \sigma_{zz} \). Fortunately, a simple averaging of the \( \sigma_{yzx} \) and \( \sigma_{xzy} \) values obtained at an element’s outer Gauss points greatly reduced these fluctuations. Using the Gauss point labeling as shown in Figure 2.5, the eight stress
gradient values for a given element and ply surface (upper, middle or lower) are combined into four average values.

\[
\begin{align*}
1\sigma_{xz,x}^{av} &= 3\sigma_{xz,x}^{av} = \frac{1}{3}(1\sigma_{xz,x} + 3\sigma_{xz,x}) \\
2\sigma_{xz,x}^{av} &= 4\sigma_{xz,x}^{av} = \frac{1}{4}(2\sigma_{xz,x} + 4\sigma_{xz,x}) \\
1\sigma_{yz,y}^{av} &= 2\sigma_{yz,y}^{av} = \frac{1}{2}(1\sigma_{yz,y} + 2\sigma_{yz,y}) \\
3\sigma_{yz,y}^{av} &= 4\sigma_{yz,y}^{av} = \frac{1}{4}(3\sigma_{yz,y} + 4\sigma_{yz,y})
\end{align*}
\]

(2.13)

When the calculated stress gradients were replaced by these averages, sample plates with a uniform transverse pressure obtained peak \(\sigma_{zz}\) values (from Equation 2.12) that typically ranged between 65 and 85 percent of the applied pressure. These estimates were better than expected, since \(\sigma_{zz}\) is related to the nodal displacement through third-hand calculations (strain-displacement equations, constitutive relations and equilibrium in the Z-direction).

One problem with Equation 2.12 is that it prevents satisfaction of a fourth boundary condition, \(\sigma_{zz}(x, y, -h/2) = 0\), when a region of the top surface is free of transverse loading. It will generally calculate a nonzero value because a cubic polynomial is fully constrained by four boundary conditions, and allowing \(\sigma_{zz}(x, y, \pm h/2) = \sigma_{zz}(x, y, \pm h/2) = 0\) causes zero transverse normal stress throughout the thickness. The only way this can occur is if \(\sigma_{yz}(x, y, z) = -\sigma_{xz}(x, y, z)\) for a particular \(x\) and \(y\).

However, the previously mentioned research by Engblom and Ochoa [5,6] may provide a means of masking the problem. They obtained \(\sigma_{xz}\) and \(\sigma_{yz}\) through the equations of equilibrium in the X and Y-directions and also utilized Equation 2.8 to calculate \(\sigma_{zz}\). The resulting thickness profile of \(\sigma_{zz}\) for a stress-free top surface
resembled a sine wave. Hence, one possibility is to map the curve obtained from Equation 2.12 to a sine wave with an equivalent area under the curve, as shown in Figure 2.8. The area calculated from Figure 2.7 (and other curves based on Equation 2.12) is \((h/2) \cdot \sigma_{zz}(x, y, -h/2)\) because its antisymmetric shape has the same area as a triangle formed by the Z-axis, \(z = -h/2\) and the line connecting \(\sigma_{zz}(x, y, h/2)\) and \(\sigma_{zz}(x, y, -h/2)\).

Also note that Figure 2.8 fails to satisfy the boundary conditions of \(\sigma_{zz} = 0\) at \(z = \pm h/2\). A more complicated mapping function— one that permits additional constraints— could solve this problem, but for simplicity the regions of small stress gradients near the top and bottom plate surfaces are assumed negligible with respect to the entire thickness. FAILURE does not presently include any mapping technique since the structure of SHELL’s secondary output file does not contain information on the location of nodal loads used to generate a displacement solution. Thus, FAILURE cannot tell where mapping should be used. The task of interpreting the meaning of the \(\sigma_{zz}\) calculations is left to the user.

![Figure 2.8: Sine Mapping Function](image)
III. Pagano/Whitney Sandwich Plate Models

Closed-Form Solutions

Both Pagano [18] and Whitney [21] obtained linear solutions for simply-supported square sandwich plates that are subjected to sinusoidal pressures. Each face sheet was a single \([0^\circ]\) ply of an unidentified composite material, and the core was some type of transversely isotropic material. The thickness of a single face was one-tenth that of the core \((h_f = h_c / 10\) and \(h = 2h_f + h_c\)). The face and core materials had the following relevant elastic properties (converted to SI units):

\[
\begin{align*}
\text{Face:} & \quad E_{LL} &= 172.3 \text{ GPa} \quad E_{TT} = 6.985 \text{ GPa} \\
& \quad G_{LT} = G_{LZ} = 3.447 \text{ GPa} \quad G_{TZ} = 1.379 \text{ GPa} \\
& \quad v_{LT} = 0.25
\end{align*}
\]

\[
\begin{align*}
\text{Core:} & \quad E_{XX} = E_{YY} = 275.8 \text{ MPa} \\
& \quad G_{XY} = 110.3 \text{ MPa} \quad G_{XZ} = G_{YZ} = 413.7 \text{ MPa} \\
& \quad v_{XY} = 0.25
\end{align*}
\]

Pagano [18] develops his elasticity solution for a generally loaded plate, but the results for these particular plates are given numerically at selected locations. However, he also includes a CLPT solution algorithm that can be conveniently applied to these cases. For the square quarter-plate notation shown in Figure 3.1, the pressure distribution \(q(x,y)\) on the top surface of the plate is:

\[
q(x, y) = q_0 \cos(\pi x / a) \cos(\pi y / a)
\]
where \( q_0 \) is the peak pressure at the plate’s center \((x=y=0)\). The transverse displacement field \( w(x,y) \) for a simply supported plate can be approximated with a similar sinusoidal distribution:

\[
    w(x, y) = w_c \cos(\pi x / a) \cos(\pi y / a)
\]

where \( w_c \) is the deflection at the plate’s center. For a symmetric plate, Pagano’s CLPT solution for \( w_c \) becomes:

\[
    w_c = \frac{q_0}{(D_{11} + 2(D_{12} + 2D_{66}) + D_{22})(\pi / a)^4}
\]

where \( D_{11} \), \( D_{22} \), \( D_{12} \) and \( D_{66} \) are components of the bending stiffness matrix and are integral functions of the constitutive relations in the \( Z \)-direction (as defined in the textbook by Agarwal and Broutman [1]).
Whitney's plate solution for the same load and displacement distributions as

Equations 3.3 and 3.4 is the following expression [21]:

\[
W_c = \frac{q_0 a^2}{\pi^2 D} (A_1 A_4 - A_2^2)
\]

\[
D = A_1 A_4 A_6 + 2 A_2 A_4 A_5 - A_4 A_5^2 - A_3 A_6^2 - A_2 A_6^2
\]

\[
A_1 = D_{11} + D_{66} + G_{xz, core} h a^2 / \pi^2
\]

\[
A_2 = D_{12} + D_{66}
\]

\[
A_3 = G_{xz, core} h a / \pi
\]

\[
A_4 = D_{66} + D_{zz} + G_{yz, core} h a^2 / \pi^2
\]

\[
A_5 = G_{yz, core} h a / \pi
\]

\[
A_6 = (G_{xz, core} + G_{yz, core}) h
\]

(3.6)

Finite Element Modeling

The enhanced version of SHELL was used to obtain linear and nonlinear displacement solutions for the aforementioned sandwich structure. Five plates with the same thickness and variable widths were considered in order to compare the static responses for thin and thick plates. A constant value of \( h = 12.192 \) mm was assumed, and the aspect ratios (\( S = a / h \)) for the five plates were 10, 20, 30, 40 and 50. The meshes for each quarter-plate model consisted of \( N \)-by-\( N \) square elements of equal size (\( \Delta x = \Delta y = a / 2N \)). The appropriate mesh resolution for each plate was obtained through convergence studies of meshes ranging from 12-by-12 to 24-by-24. Furthermore, the maximum pressure applied to each plate was \( q_0 = 6985 \) kPa.

SHELL cannot automatically consider the sinusoidal load distribution in Equation 3.3. Therefore it was necessary to calculate individual nodal loads. This was accomplished by integrating the product of Equation 3.3 and the Hermitian shape
function $H_{K1}$ (associated with the nodal displacement $w$ in Equation 2.5 and converted into global coordinates based on Figure 2.3) across each element's area for every local element node $K$. The nodal loads for an entire mesh were calculated by adding the contributions of each adjacent element for a given node. Note that this method ignores coupled loads obtained from the other shape functions in Equation 2.5, but it should be a good approximation of the distributed load for meshes with a relatively large number of elements. MATLAB™ [13] and Mathematica™ [22] (commercial mathematical software packages) were employed to perform the integrations and other computations. The accuracy of its nodal load calculations was verified by checking for load symmetry about each quarter-plate's plane of symmetry (x=y) and by comparing the sum of all nodal loads to the total force from a continuous distribution (integrating Equation 3.3 across the entire area of the quarter-plate yields a total load of $q_0a^2/\pi^2$).

Convergence Study

As shown in Table 3.1, 12x12 meshes converged well for $S=10$ and 20 while 20x20 meshes were satisfactory for $S=30$, 40 and 50. Deviations under 5% are considered good for the plate elements used by SHELL.

Results and Discussion

Figures 3.2 and 3.3 plot the nonlinear FE deflection of each plate at its center \( w_c \) due to varying peak load pressures. The two thickest plates, S=10 and 20, exhibit very linear behavior up to \( q_0 = 6985 \) kPa. On the other hand, geometric nonlinearities become evident in the curves for S=30, 40 and 50 when \( q_0 \) is greater than 500 kPa. At the highest load, the value of \( w_c \) for the thinnest plate (S=50) is about 15 times greater than its thickness. By comparison, a linear FE solution (from Table 3.2) for S=50 would predict a maximum deflection that is 58 times greater than the plate thickness, which obviously violates the assumption of small displacements for linear behavior.

In order to obtain deflection results from CLPT and Whitney’s solution (Equations 3.5 and 3.6), the bending stiffness matrix must be determined for each sandwich plate. SHELL’s preprocessor calculates these numbers and can be commanded to display them in the output file. For these plates, the matrix does not change since face and core thickness are held constant. The relevant values (in N-m=10^6 kPa-mm^3) are: \( D_{11}=13215.7 \), \( D_{22}=551.238 \), \( D_{12}=137.810 \) and \( D_{66}=272.014 \). In addition, both Pagano
and Whitney nondimensionalized their displacement results with the following expression:

$$
\bar{w} = \frac{100w_x E_{TT \text{ face}}}{q_0 S^4 h}
$$

(3.7)

Table 3.3 lists the nondimensional displacements from CLPT, Pagano’s elasticity solution, Whitney’s solution and both linear and nonlinear FE methods. Figures 3.4, 3.5 and 3.6 plot these values versus the corresponding aspect ratio. The linear FE solution produced deflections similar to both Pagano and Whitney (albeit slightly stiffer for thick plates). Furthermore, all linear cases converged to the CLPT solution as plates became thinner. The differences for thick plates can be attributed to variations in how each theory considers transverse shear effects (or neglects them in the case of CLPT). As bending effects become dominant for large aspect ratios, each linear theory produces nearly identical results. The divergence between linear and nonlinear FE results as S is increased is due to a coupling between bending and membrane stiffness that is not present in the linear case.

IV. Sandwich Plate Versus Composite Plate

Finite Element Modeling

In order to demonstrate some of the advantages of sandwich plates in terms of stiffness-to-weight ratios, nonlinear displacement solutions for thin and thick sandwiches were obtained from SHELL and compared to solutions (also using SHELL) by Owens [16,17] for similar composite plates. His six plates were [0\(_2/90\)]\(_s\) laminates of a transversely-isotropic graphite-epoxy composite. Each ply was 1.016 mm thick, thus h=6.096 mm. All plates were square and their widths were varied to produce aspect ratios (S=a/h) of 10, 20, 30, 40, 50 and 60. He computed nonlinear finite element solutions for simply-supported edges and uniform transverse pressures.

In this research, each sandwich plate had the same overall geometry as the plates modeled by Owens and were subjected to the same loads and boundary conditions. Each face sheet was made of the same graphite-epoxy material in a [0/90\(_{12}\)] lay-up so that both faces comprised half of a plate’s total thickness. The other (central) half was a honeycomb core made of Nomex\textsuperscript{TM} (specifically classified as HRH-10-1/8-9.0) [8]. Figure 4.1 compares the geometry of both types of plates. The walls of the core’s hexagon-shaped cells run parallel to the Z-axis, and the voids between the cells give it negligible in-plane stiffness compared to the facesheets. The relevant elastic and density properties of the face and core materials are:

\[
\begin{align*}
\text{Face:} & \quad E_{LL}=137.9 \text{ GPa} & \quad E_{TT}=3.447 \text{ GPa} \\
& \quad G_{LT}=G_{LZ}=1.724 \text{ GPa} & \quad G_{TZ}=0.6895 \text{ GPa} \\
& \quad \nu_{LT}=0.25 & \quad \rho_f=1.6 \text{ g/cm}^3 \text{ (from [1])}
\end{align*}
\]
Core: $E_{LL}=E_{TT}=G_{LT}=0$

$G_{LZ}=120.6 \text{ MPa}$

$\nu_{LT}=0.5$

$G_{TZ}=75.84 \text{ MPa}$

$\rho_c=0.14417 \text{ g/cm}^3$  \hspace{1cm} (4.2)

Figure 4.1: Composite and Sandwich Quarter-Plate Geometry

Just like the plates in the Pagano/Whitney case study, the quarter-plate FE models for these sandwiches used an N by N mesh of square elements, and each mesh was refined to establish convergence. Furthermore, each plate geometry was solved twice to obtain results for core orientations of $[0^\circ]$ and $[90^\circ]$. This was done to see if aligning the core’s stiffest transverse plane with either the longitudinal or lateral directions of the outer face plies caused significant differences. Finally, the maximum uniform load applied to each plate was 6985 kPa, for which SHELL automatically generated the equivalent nodal forces.
Convergence Study

Displacement convergence at the plate center for the highest applied pressure was tested for three of the six plate geometries. The results are listed in Table 4.1. It was found that 12x12 meshes were acceptable for S=20 (and S=10 since it has a stiffer response). Similarly, 20x20 meshes converged reasonably well for S=30, 40, 50 and 60.

Results and Discussion

Figures 4.2 through 4.7 display the deflection of each sandwich plate’s center as a function of applied pressure, and Figures 4.8 and 4.9 combine the first six graphs into a family of curves for easier comparison. The thickest plates, S=10, behaved very linearly over the entire pressure range, and the S=20 plates were linear up to about q₀=2000 kPa and then showed a very shallow nonlinear deviation. On the other hand, the thinner plates’ deflections became highly nonlinear at pressures less than 1000 kPa. In addition, a [90°] orientation of the core caused the plate to be slightly more flexible for S=10 and 20, but for thinner plates, the curves were almost identical. In fact, Figures 4.5, 4.6 and 4.7 show only the results for a [0°] core to avoid redundancy. For a square plate with the same kind of support on every side, rotating the core through a right angle has the same
effect as rotating both faces instead of the core. It is important to keep in mind that modifying the orientation of the same core or faces should have very different consequences if the whole plate was rectangular or had multiple types of edge supports.

Owens published deflection results [17] in a nondimensionalized form for selected pressures (which are also nondimensionalized) as a function of aspect ratio. The nondimensional forms of plate center deflection and applied pressure are:

\[
\bar{w} = \frac{10w_c E_{\text{1.1 face}}}{q_0 S^4 h}
\]

\[
\bar{q} = 10^4 q_0 / E_{\text{1.1 face}}
\]  

(4.3)

While \(\bar{q}\) is directly proportional to \(q_0\), the \(S^4h\) term in \(\bar{w}\) serves to cancel-out geometric effects on \(w_c\) for CLPT solutions. Deflection results from the previous chapter (Figures 3.4 through 3.6) showed that \(\bar{w}\) was a horizontal line-- unaffected by changes in \(S\)-- for the CLPT case. Furthermore, the weight of each plate can be considered by multiplying \(\bar{w}\) by a ratio of the plate’s overall density to the density of the face material \(\rho_f\). The composite plates obviously had densities equal to \(\rho_f\), so its nondimensional displacements were unchanged. On the other hand, the core accounts for half of each sandwich plate’s volume. Therefore, the sandwich plates had an overall density equal to the average of the core and face densities. From the data in Equations 4.1 and 4.2:

\[
\rho_s = \frac{1}{2}(\rho_f + \rho_c) = 0.872 \text{ g/cm}^3 = 0.545\rho_f
\]

(4.4)

The resulting nondimensional variable \(\bar{w}_\rho = \bar{w} (\rho_{\text{plate}} / \rho_f)\) can be used as an indicator for comparing two plates’ stiffness-to-weight ratios.
Figures 4.10 through 4.17 compare the nondimensional nonlinear displacements of each composite plate and its corresponding sandwich plate (the same value of $S$) at four nondimensional load levels. Each consecutive pair of figures plots $\overline{w}$ and $\overline{w}_p$ versus $S$ for a given $\overline{q}$. In Figures 4.10, 4.12, 4.14 and 4.16, the sandwich constructions were up to 85% more flexible than the composites. This is because the core material provides little bending stiffness (none for this FE modeling) and offers less resistance to transverse shear than the composite’s additional face material in the central plies. Hence, the outer faces of each sandwich must compensate by bending more. Also note that thick sandwiches gain flexibility at a greater rate than the composite plates as $S$ is reduced.

On the other hand, stiffness contributions due to bending and transverse shear from plies near the midsurface (either face or core material) have less significance in thinner plates. This caused the sandwich and composite curves to converge sharply at first and then become nearly parallel as $S$ increased and bending in the outer faces became dominant. In addition, higher loads increased the rate at which the sandwich and composite curves converge and decreased the ultimate (large $S$) curve deviation.

When the nondimensional deflections of the sandwich plates were scaled-down to consider their lighter weights, the resulting plots (Figures 4.11, 4.13, 4.15 and 4.17) suggested equal or better stiffness-to-weight ratios than those of the composite plates for a wide range of aspect ratios. The $\overline{w}_p$ versus $S$ curves also indicate that the range of $S$ in which the particular sandwich outperforms the composite is bounded due to merging or crossing of the curves. Near $S=10$, the curves intersected due to the steeper increase in
flexibility that is present in thick sandwiches. Furthermore, the sandwiches have lower axial stiffness for response to nonlinear membrane and flexural coupling, which may cause the curves to intersect again beyond S=60. The apparent advantages demonstrated by these sandwich plates, in terms of specific stiffness, may not hold true for all sandwich and composite plate constructions, but the specific case illustrates the potential benefits of using sandwich plates.

V. Sandwich Plate Incipient Damage Predictions

Finite Element Modeling

The preceding displacement solutions for various sandwich plates were obtained with SHELL under the assumption of perfect, linear elastic materials. However, an actual sandwich may experience some kind of initial failure well before any geometric nonlinearities take effect. Once this occurs, any solution SHELL generates beyond that point is invalid due to the presence of physical nonlinearities which the present code cannot consider. Therefore, FAILURE was written for the purpose of attempting to predict where, when and how a plate initially fails (using the maximum stress criteria presented in Chapter 2). Sample plate models were tested to verify the accuracy of its numerical and logical procedures (compared to manual calculations and expected output). Hence, the next step was to check the validity of its methodology by modeling actual plates and comparing FAILURE’s results to what really happens. As previously mentioned in Chapter 1, a low-velocity impact for a composite plate has been found to have internal failure characteristics that can be predicted with a quasi-static response [10,12,14]. Thus, experimental impact studies on sandwich plates by Harrington [7] provided a means for applying the FAILURE program.

In Harrington’s work, simply-supported square plates (a=127 mm) were subjected to impact loads at their center by the dropping of a spherical-nose punch from a series of heights. Four cases of plate and load combinations were considered for finite-element modeling, and these are listed in Table 5.1. The 4 and 16-ply facesheets were made of
AS4/3501-6 graphite-epoxy lamina with a thickness of 0.127 mm per ply. The 4-ply faces had [0/90]₄₉ lay-ups, while the 16-ply faces had [0/90]₄₈ arrangements. Each plate’s core was 12.7 mm thick and made of an HRX-10-1/8-9.0 Nomex™ honeycomb material [8]. Furthermore, two 0.254 mm thick adhesive layers of epoxy bonded each face to the core. For convenient referencing, the plates with 4 and 16-ply faces are denoted as Sandwich A and B, respectively. In addition, the numbering of the cases, one through four, in Table 5.1 corresponds to the radii of plate indentation (R) from smallest to largest. For each case, the peak load (Pₚ) equals the maximum instantaneous force acting on the plate within the experimental impact time history, and it is assumed quasi-static for FE analysis.

Table 5.1: Plate and Loading Cases

The elastic properties of the face, core and adhesive layers have the following relevant values:

\[
\begin{align*}
E_{LL} &= 119.3 \text{ GPa} \\
E_{TT} &= 9.098 \text{ GPa} \\
G_{LT} &= G_{LZ} = 5.398 \text{ GPa} \\
G_{TZ} &= 4.319 \text{ GPa} \\
v_{LT} &= 0.25
\end{align*}
\]

\[
\begin{align*}
E_{LT} &= E_{TT} = G_{LT} = 0 \\
G_{LZ} &= 120.6 \text{ MPa} \\
G_{TZ} &= 75.84 \text{ MPa} \\
v_{LT} &= 0.5
\end{align*}
\]
Adhesive (assumed isotropic): \[ E = 3.447 \text{ GPa} \]
\[ \nu = 0.35 \] \hspace{1cm} (5.3)

In addition, the following maximum stress values were known or assumed:

Face:
\[ \sigma_{LL_{\text{max}}} = 2.016 \text{ GPa} \]
\[ \sigma_{LL_{\text{min}}} = -1.398 \text{ GPa} \]
\[ \sigma_{TT_{\text{max}}} = 56.96 \text{ MPa} \]
\[ \sigma_{TT_{\text{min}}} = -246.7 \text{ MPa} \] \hspace{1cm} (5.4)
\[ \sigma_{LT_{\text{max}}} = \sigma_{LZ_{\text{max}}} = 177.9 \text{ MPa} \]
\[ \sigma_{TZ_{\text{max}}} = 142.3 \text{ MPa} \]

Core:
\[ \sigma_{ZZ_{\text{min}}} = -14.55 \text{ MPa} \] \hspace{1cm} (5.5)
\[ \sigma_{LZ_{\text{max}}} = 177.9 \text{ MPa} \]
\[ \sigma_{TZ_{\text{max}}} = 142.3 \text{ MPa} \]

Adhesive: \[ \sigma_{\text{max uniaxial}} = 108.8 \text{ MPa} \] \hspace{1cm} (5.6)

Face Ply Interface: \[ \sigma_{XZ_{\text{max}}} = \sigma_{YZ_{\text{max}}} = 142.3 \text{ MPa} \] \hspace{1cm} (5.7)

FAILURE is not presently designed to directly use the core’s transverse compressive strength (\( \sigma_{ZZ_{\text{min}}} \) from Equation 5.5) as a failure condition. This is because the user-defined Z-coordinate at which \( \sigma_{ZZ} \) is calculated may or may not be the location of maximum compressive \( \sigma_{ZZ} \) within the core. However, the reported \( \sigma_{ZZ} \) values, if appropriate, can be manually used to check for initial failure due to crushing of the core.

The impact punch was assumed to create an ellipsoidal pressure distribution on each plate’s top surface within its radius of indentation. This type of loading is similar to that obtained from Hertz contact stresses for isotropic materials [9]. Wu and Yen [23] also observed the presence of ellipsoidal distributions for composite plates in contact with
rigid spheres. The ellipsoidal pressure \((q)\) as a function of impact force \((P)\) and radial distance from the center of the plate \((r)\), has the following expression:

\[
q(r) = q_0 \left(1 - \frac{r^2}{R^2}\right)^{1/2}
\]

\[
r(x, y) = \left(x^2 + y^2\right)^{1/2}
\]

\[
P = \int_0^{2\pi} \int_0^R q(r) r \, dr \, d\theta = \frac{2}{3} \pi q_0 R^2
\]  

(5.8)

Note that the pressure is a peak value of \(q_0\) at the center of the plate \((x = y = r = 0)\) and goes to zero along the indentation radius \((r = R)\). Also note that \(P\) refers to the impact force on the entire plate, while \(q_0\) has the same pressure for both full and quarter-plate models. The load distribution parameters for each FE case are listed in Table 5.2 when \(P = P_p\).

<table>

</table>

These pressure distributions must be converted to discrete nodal loads in order to use SHELL. The method employed in Chapter 3 (pp. 3-3 and 3-4) was also used here by substituting Equation 5.8 for Equation 3.3 when integrating the product of the pressure and shape functions. Figure 5.1 shows three mesh arrangements that were used in the elliptical pressure zones. All plate centers were located at the node in the lower-left corner of each mesh. It was necessary to approximate the circular indentation zone with
rectangles because FAILURE is limited to rectangular meshes. As a consequence, those elements which lie along the arc had to be integrated over a partial area when calculating their nodal loads. In order to minimize the number of elements requiring partial integration, the mesh lines in Figure 5.1 were designed so they intersected the arc at nodes. The 3x3 mesh was employed in each FE case, and the other two were only used in case 4 as part of the convergence study.

![Figure 5.1: Quarter-Plate FE Meshes in Impact Zone (L_ij are element labels)](image)

Figures 5.2 through 5.9 display the entire mesh for each quarter plate model. Again, the center of each plate is the lower-left corner node. The size of each element can be determined from the element increment lengths (the distances between the nodes) listed in Table 5.3-- which are the same for both the X and Y-directions (defined upwards and to the right respectively) since all plates are square. The four 24-by-24 meshes were the primary models used for checking each case for failure, and the others applied to case four for convergence studies. The 23-by-23 and 22-by-22 meshes were coarser inside the
impact zone, while the 18-by-18 and 12-by-12 meshes were coarser outside the impact zone.

Convergence Study

The 24-by-24 mesh for case 4 (Figure 5.5) underwent two types of refinement to check for convergence of the displacement results (within 5% relative deviation). First, the element spacing in regions outside the load zone was widened to form 18-by-18 and 12-by-12 meshes (Figures 5.8 and 5.9). The profile of plate deflection along the line x=y was compared for each mesh at the peak load. The profiles turned out to be identical (very small numerical deviations could not be identified graphically). This suggests that these plate models were practically insensitive to changes away from the applied load. The profile is not included here, since it does not show anything extraordinary in comparison to a typical profile for a simply-supported plate with a central transverse load.

Second, the mesh arrangement within the load zone for case 4 was modified according to Figure 5.1. This produced the 23-by-23 and 22-by-22 plate meshes shown in Figures 5.6 and 5.7. Calculations for $\sigma_{zz}$ were obtained for each mesh at the top of the plate near the center (where the pressure is highest). The distance from the center of the plate to the closest Gauss points in local elements $L_{11}$, $L_{21}$ and $L_{31}$ (Figure 5.1) varies slightly for each mesh (Gauss point positions are fixed in the natural coordinate system and scaled for each element’s dimensions). However, they are all near enough to the center that the variation in the elliptical pressure distribution is negligible with respect to the peak value. For $q_0=16.20$ MPa, the calculated values, in decreasing order of mesh resolution, were: 16.14, 13.09 and 10.46 MPa. Hence, the 24-by-24 mesh converged to within 0.4% of the actual value.
Results and Discussion

For every finite element case, the plate’s maximum deflection at peak load was very small relative to its geometry. Sandwich A (4 ply face) is the more flexible plate, and for its highest load (case 4) the midsurface deflection at the plate’s center was only 0.71mm—about 5% of its total thickness \(h_A=14.224\ \text{mm}\). Therefore, although each case was solved nonlinearly, its static results were practically linear.

Table 5.4 lists the incipient failure results for each case, in which all maximum stresses except transverse core compression were considered (Equations 5.4 through 5.7).

Table 5.4: Initial FE Sandwich Failure Ignoring Core Compression

In each case, the initial failure occurred near or beyond the peak impact force. Tension fracture of the face’s matrix material on the bottom of the plate is a possible failure mode for a standard laminated composite, but it is not realistic for these kinds of sandwiches. The lower surface of the top face is more likely to fail that way as a progressive mode...

5-12
when core damage from indentation removes the top face’s localized support in the Z-direction. It occurs on the bottom face for sandwich B because SHELL’s plate kinematics (Equation 2.1) prevents describing indentation. The top and bottom faces (for a fixed x and y) must have the same w-translation as the midsurface. Transverse shear failure of sandwich A’s core is a possible mode in later stages, but core crushing is more likely to occur first.

Before examining the core for transverse compression failure, it was necessary to see if Equation 2.12 was successful in obtaining values of $\sigma_{zz}$ in the impact zone that were close to the applied pressure (Equation 5.8) on the top surface (or at least close to $q_0$ near the plate’s center). Table 5.5 compares the known pressures to the calculated stresses.

For cases 2 through 4, the stress results were very good, but case 1 underpredicted the applied pressure by a large margin. There is an inverse correlation between the error and radius of the pressure zone (the indentation radius). Since pressure must drop from a peak value to zero within this zone, its gradient may be too high in case 1 for the employed mesh. However, finer meshes were not generated because the predominantly manual
process used to calculate the nodal loads limited the practicality of finer meshes. Mathematica™ [22] was used for the complex integrations, but due to difficulties in automating the entire process, each element’s nodal loads had to be individually evaluated and manually added to the nodal loads in adjacent elements. Besides, the other three cases provided sufficient data for comparing core crushing predictions.

Table 5.6 lists each case’s calculated value of $\sigma_{zz}(0,0, -h_c/2)$ at the top of the core and the center of the plate, using Equation 2.12, for the highest load levels. The linear behavior exhibited by all the plates permitted the use of linear interpolation to determine the failure loads at which the FE models predicted core crushing.

Compared to the other initial failure results in Table 5.4, crushing of the core within the impact region occurred at substantially lower fractions of the maximum load for each case, except 4. Furthermore, although case 4 did not show failure from any mode until the peak load was exceeded, both tables predicted some kind of core failure (either crushing or shearing) at nearly the same load level. Hence, through the use of an analytical method that assumed zero transverse normal stresses in determining the static response, it was still possible to detect transverse compression of the core as the primary
mode (or one of several modes) in which these types of sandwich plates initially fail. Regardless of the projected load levels, the mode agrees with Harrington’s experimental findings which showed incipient indentation damage, at least partially due to core crushing, within the impact zone for sandwiches with 4 and 16-ply faces.

In Figures 5.10 through 5.13, the FE load levels at predicted core failure have been superimposed, for their respective cases, onto the actual time histories of impact loading from Harrington’s experiments. Actual initial failure is usually represented by the first sharp drop in load (in excess of noise on the curve), which signifies a sudden shift in a plate’s equilibrium state due to a reduction in stiffness. For the 16-ply face sandwiches (type B) in cases 1 and 3, such drops were clearly evident at loads of about 2500 N for both Figure 2.10 and 2.12. The FE failure load in case 1 underestimated the onset of failure by about 50%, but case 3 provided a very close estimate of the actual failure load.

For the 4-ply face sandwiches (type A) in cases 2 and 4, the actual failure loads were not clearly distinguishable from the noise present in Figures 5.11 and 5.13, although moderate spikes between 500 and 1000 N may or may not be due to failure. The sandwich A plates experienced more data noise than the sandwich B plates because they were more flexible and thus subjected to greater momentum transfer during the impact. In addition, sandwich A displayed the same phenomenon as sandwich B in the finite element results-- a near doubling of the projected first-core-crushing load for the case with the higher applied load. One would expect the loads that cause initial internal failure to remain constant for different applied loads on the same plate (as they clearly do for
sandwich B). This inconsistency between the finite element and experimental results suggests that maximum stress may not be the best choice of failure criteria. Although the primary mode was core crushing, other stress components may contribute to the initial failure. The maximum stress criteria isolate the stresses and do not permit coupling to affect the failure predictions.

Another source of inconsistency in the failure results could be the FE modeling of the pressure distribution. Cases 2 and 4 had larger impact forces than cases 1 and 3, respectively, but their larger indentation radii (the assumed constant radii of the impact zones) spread out the loading so that the peak pressures actually dropped for higher total loads, as shown in Table 5.2. In the former cases, the values of $q_0$ were roughly cut in half, which explains the doubling of the projected load for initial internal failure. In an actual impact, both total load and contact area vary with time, and the right combination produces a peak pressure high enough to initiate failure in the core. This type of nonlinear behavior cannot be modeled with SHELL; therefore, the good results that occurred in case 3 were most likely a coincidence brought about by nearly having the right mesh size to produce the actual failure load.

VI. Conclusions

In this thesis a geometrically nonlinear finite element program, created for static analysis of composite plates and shells, was enhanced so that it could be used to study sandwich plates. Furthermore, a new, separate postprocessing unit was created in order to detect initial failure in a plate using the maximum stress criteria. The program was also given the capability of estimating the transverse normal stresses within a plate by enforcing equilibrium through its thickness. Three case studies were investigated for the following purposes:

1. To validate the sandwich plate enhancements to the FE code by comparing its displacement results to those of established linear solutions for a particular sandwich plate problem.

2. To compare the stiffness and stiffness-to-weight characteristics of regular composite plates to those of sandwich plates for different load intensities and aspect ratios.

3. To simulate low-velocity impact tests on sandwich plates with a quasi-static FE solution and attempt to predict incipient plate damage using the maximum stress criteria.
Linear solutions for simply-supported sandwich plates, under a sinusoidal transverse pressure, showed good agreement with Pagano's exact elasticity solution and Whitney's laminated plate solution for both thick and thin plates. For thin plates, all three methods converged to the CLPT solution. The code enhancements related to sandwich plates only affected the formulation of the constitutive relations in the preprocessor. Since they do not change for either a linear or nonlinear solution of the same plate, the modified code can be considered valid for sandwich plates using either solution method.

Comparisons between a graphite-epoxy composite and a sandwich with similar facesheets, a honeycomb core and the same overall geometry, show that the sandwich is more flexible (especially for thick plate). The differences in stiffness become smaller for thin plates as bending in the outer faces dominate the response. When the lighter weight of the core material is taken into account, the sandwich plate demonstrates a significantly higher stiffness-to-weight ratio than the composite for both thick and thin plate within certain bounds. If specific stiffness is the primary criterion in selecting a material, a sandwich construction may be a better choice than a laminated composite of similar construction.

The procedure for calculating $\sigma_{zz}$ was shown to be capable of highly accurate estimates of transverse pressures on the top surface of a plate, provided the FE mesh in these areas were properly refined. Therefore, the method was partially successful in extracting a three-dimensional stress state from a two-dimensional solution. In addition, for the case of sandwich plates subjected to low-velocity impact loads, the use of quasi-
static FE modeling and the maximum stress criteria was successful in detecting core crushing in the impact zone as one of the primary modes of incipient damage. However, inconsistencies in the predicted load levels for initial failure suggest the need for a more complex criteria that considers stress coupling. Although the presence of time-dependent nonlinearities, like momentum transfer and variable contact areas, also contributed to preventing the quasi-static models from making good predictions of when initial failure occurred, this quasi-static approach was at least able to identify where and how it occurred.

</tbody>
</table>
The code required three major modifications for use in this research:

1. Enhance the preprocessor to allow sandwich constructions
2. Restore load and displacement control options to the nonlinear solver
3. Generate a secondary output file for use with a separate initial-failure check program

Since the entire SHELL code is very large, only those components requiring extensive changes are listed at the end of this appendix. The other components remain unaltered or needed minor corrections in its nonexecutable statements (i.e. altering common variable blocks to make them consistent with the rest of the program). The new structure for SHELL's input deck is also included just before the code listings.

Sandwich Construction

The previous version of SHELL could model an isotropic material or a symmetric laminate consisting of plies of the same orthotropic material at different orientations. It also required each ply to have the same uniform thickness. The input deck for a laminate contained: the number of plies, the ply thickness, the orthotropic elastic properties and each ply's orientation. In order to model sandwich constructions, the code was altered to allow multiple sets of elastic properties and variable ply-to-ply thicknesses (although still uniform across a single ply). The new input deck for a laminate includes: the number of plies, the number of materials, an indicator for uniform or variable ply thickness, each material's orthotropic elastic properties, and each ply's orientation, material reference number, and thickness (or a single thickness value if uniform). Note that a sandwich
containing isotropic materials can be modeled as a laminate by treating their elastic properties as orthotropic but numerically consistent with isotropic.

The use of multiple elastic property sets was implemented into the code by converting the single-value variables for $E_{LL}$, $E_{TT}$, $G_{LT}$, $G_{LZ}$, $G_{TZ}$ and $v_{LT}$ into one-dimensional arrays. Since plies can be at different orientations, the preprocessor was already designed to calculate a separate set of constitutive relations for each one. Therefore, all that was needed was a way to index the correct element in each elastic property array (corresponding to the ply's material reference number). This was done by creating a material-stacking-sequence (MSS) array similar to the preexisting orientation angle array. As the code cycles through each ply, it reads a new material number and angle and uses the former to load the proper elastic constants.

Enhancing the code to allow variable ply thicknesses was not essential, but it could greatly reduce redundancies in the input deck and calculations throughout the program. For example, a 3-ply laminate with ply thicknesses of 5, 36 and 5 units would otherwise require a 46-ply model with unit thickness per ply. The large variation between face and core thicknesses in typical sandwiches would amplify this redundancy. The old preprocessor used the uniform ply thickness to calculate the through-the-thickness ($Z$) coordinates of each ply at its upper, middle and lower surfaces. A modified method using a ply thickness array (similar in form to the MSS and orientation arrays) is now employed when variable thickness is indicated. The method involves simple step-by-step addition and is too elementary to warrant an in-depth explanation.
Some core materials have negligible stiffness in the in-plane directions. However, setting $E_{LL} = E_{TT} = 0$ in the input deck will cause the program to crash. The error is due to a line that calculates $v_{TL}$ from the relation:

$$v_{TL} = v_{LT} \frac{E_{TT}}{E_{LL}}$$  \hspace{1cm} (A.1)

To prevent division by zero, a precautionary step was added to the code which sets $v_{TL} = v_{LT}$ and skips Equation A.1 whenever $E_{LL} = E_{TT}$.

**Load and Displacement Control**

The original version of SHELL included both load and displacement control methods for the nonlinear solver. A later version included the Riks-Wemper method which allows a better description of a cylindrical shell’s behavior when it undergoes snapping instability [18]. However, this research uncovered the fact that in adding the Riks method the other methods had been removed. Load or displacement control is usually more practical when modeling flat plates because plates do not tend to snap, and the Riks method normally does not increment the loads and/or displacements at regular intervals.

In converting the program to the Riks method, certain parts of the original code were deleted or turned into comments. Fortunately, another finite element program called ISHELL contains a processor unit nearly identical in format to SHELL but features the original load and displacement control instead of the Riks method. The process of enhancing SHELL to include all three methods, involved a line-by-line comparison and
merging of both processor codes. An indicator was added to the input deck to trigger the use or disuse of the Riks method, and many if-then statements were added to the code to skip unwanted operations in either case.

Secondary Output File

In order to execute the separate initial-failure check program FAILURE, certain model-dependent information is needed from SHELL. The required data includes:

1. Model parameters from the input deck (an isotropic or laminate model, a linear or nonlinear solution, the number of elements, plies and materials and the elastic material properties)

2. Preprocessor calculations (the nodal coordinates, nodal connectivity of elements, constitutive relations, z-coordinates and thickness factor for transverse shear)

3. Nodal displacement results (for each increment if solution is nonlinear)

All of the above is written to a separate output file in a format easily read by FAILURE. A new indicator in the SHELL input deck allows the user to decide whether or not to generate the file.

Other Modifications

In addition to the aforementioned code changes, several other nonessential modifications were implemented to enhance the user-friendliness of the software. First, direct keyboard input was added to the beginning of the program to allow user-defined names for the input and output files. This alleviates the task of renaming or relocating old files before running a new model with default filenames. It also allows simultaneous
execution of multiple models on a computer network without the need for extra copies of the program in separate file directories.

Second, the double-precision variables that contain nodal coordinate and displacement values were reformatted. Each value’s scientific notation is now printed to the output files with an “E” (instead of a “D”) to indicate the exponent. This data can be cut-and-pasted into separate files for use with commercial math or graphing software. However, it was discovered that some software packages do not recognize “D” as an acceptable substitute for “E” and will misread the data or generate a syntax error. The modified output format alleviated this problem.

A-9

As of 11/24/94
**COMPUTER PROGRAM SHELL**

**DESCRIPTION OF THE VARIABLES**

- **CON(M,N)**: Constitutive matrix used in stress
- **CONS(M,N)**: Constrained matrix
- **ELD(M)**: Element displacement vector
- **ELP(M)**: Element force vector
- **ELXY(M,N)**: J-th coordinate of element node I (J=1,2)
- **GD(M)**: Global displacement vector
- **GF(M)**: Global force vector; solution vector from 'SOLVE'
- **GSTIFF**: Global stiffness matrix (in banded form)
- **GN**: Global N matrix for bifurcation analysis
- **HT**: Thickness of the plate or shell
- **IBDY(M)**: Array of specified global displacements
- **IBSF(M)**: Array of specified nonzero global forces
- **IDFG(M)**: Array of nodes that have edge loading
- **IFOR(M)**: Array of dof for equivalent force calculation
- **IJREP(M)**: Array of element no. for stress output
- **IEM**: Indicator for the element type:
  - IEM=1, plate element
  - IEM=2, shell element
- **ISLAB**: Maximum number of iterations for an increment
- **ISLAB**: Maximum number of iterations for an increment
- **INTYP**: Parameters for nonlinear incrementation
  - INTYP=0, load incrementation
  - INTYP=1, displacement incrementation
- **KES**: Constant from kinematics
- **KLD**: Constant from kinematics
- **LD**: Indicator for the distributed applied loading
  - LD=0, zero distributed loading
  - LD=1, transverse or normal pressure
  - LD=2, dead weight (shell)
  - LD=3, axial loading

**ANALYSIS PARAMETERS**

- **ANAL(M)**: Analysis parameters
  - ANAL(1)=0.12 for NL. LIN. EIGEN
  - ANAL(2)=0.12 for ARB. ISO. SYM
  - ANAL(3)=1 for Von Karman plate analysis

**INCREMENT CONTROL OPTIONS**

- **NCOUNT**: Increment count
- **NCMAX**: Value of the column-dimension of GSTIF
- **NEDGE**: Number of nodes that have edge loading
- **NFOR**: Number of dof for equivalent force calculation
- **NINC**: Number of increments
- **NMID**: Number of midside nodes
- **NRMAX**: Value of the row-dimension of GSTIF
- **NOD(M,N)**: Connectivity matrix
- **NBDY**: Total number of specified degrees of freedom
- **NBSF**: Total number of specified nonzero forces
- **NPE**: Number of elements per element, 4 or 8
- **NEM**: Number of elements total
- **NNM**: Number of nodes total
- **NKX**: Number of K nodes
- **NY**: Number of Y nodes
- **NN**: Number of nodes
- **NDF**: Number of dof per element, 28 or 36
- **ND*7**: Number of corner nodes
- **NSTRES**: Number of elements to calculate stress
- **PO**: Intensity of the distributed load
- **PHT**: Element indep stiffness matrix
- **RAD**: Radial shell radius, 1/RAD
- **RSTEPS**: Used in bifurcation algorithm
- **STIFF**: Element stiffness matrix
- **VBDO**: Values of the displacements in the array IBDO
- **VBFS**: Values of the specified forces in the array IBSF
- **VFOR**: Values of the calculated equivalent forces
- **VRES**: Values of the array of z-locations used in disp increment NL analysis
- **X*, Y*, Z**: Arrays of X and Y-coordinates of global nodes
- **Z(M,1)**: LOCATES Z VALUES, USED IN STRESS

**SUBROUTINE LIST**

- **MESH**: Automatically forms mesh
- **ELAST**: Calculates elasticity matrices, A-T and AS-FS
- **STIFF**: Calculates element stiffness matrix and force vec
- **SHAPE**: Calculates shape functions at Gauss point (XI, ETA)
- **DIS**: Evaluates disp gradient at Gauss pt (XI, ETA)
- **PK**: Element indep stiffness, k for plate
- **PK1**: Element indep stiffness, n1 for plate
- **PKN**: Element indep stiffness, n2 for plate
- **SK**: Element indep stiffness, k for shell
- **SN1**: Element indep stiffness, n1 for shell

**IN-PLANE SHEAR LOADING**

- **LD=4**: In-plane shear loading

**ARRAY OF SORTED MIDSIDE NODE NUMBERS**

- **MSID**: Array of sorted midside node numbers

Appendix B:

Initial Failure Postprocessor Code FAILURE

FAILURE is a FORTRAN code for use with the updated version of SHELL. It is an enhanced postprocessor designed to predict initial failure of flat plates using maximum stress criteria. It also features a procedure for estimating maximum transverse normal stress magnitudes through a plate's thickness. It is limited to finite element plate models constructed from 28 degree-of-freedom elements in a regular rectangular mesh. Execution of FAILURE requires two input decks. The first is generated by SHELL for a given model, and the second is user-defined. The structure of the second deck and a sample of program output is contained in this appendix (just before the listing of the FAILURE code).

FAILURE consists of the main program and four subroutines: FSTRESS, PARFIT, SHAPE and DIS. The latter two are identical to those used by SHELL (see Appendix A, Table A.1). In addition, FSTRESS is a modified version of SHELL's own STRESS subroutine. The main difference between the two is that FSTRESS does not place stress calculations in temporary variables for immediate reporting to the output file. Instead, it stores the values for a single element and solution increment in arrays, so they can be mathematically manipulated. Finally, PARFIT is a set of linear algebra computations used to curve fit discrete stress and Z-coordinate data to parabolic
distributions. This is needed for stress averaging through a ply's thickness when checking material failure and for evaluating $\sigma_{zz}$ by enforcing equilibrium.

The program gives the user the option of checking for failure in a single element or all of them. The same option applies to load or displacement control increments (one or all) in a nonlinear solution. All criteria stresses should be entered as absolute values since negative stresses are accounted for when the program checks for failure. Furthermore, any of the material or shear delamination failure modes can be turned off by entering a value 0.0 for its maximum stress value.

When the algorithm for evaluating $\sigma_{zz}$ (denoted $\sigma_{33}$ in some parts of the code) is activated, the user must define a single $Z$-coordinate to identify the plate surface (on or between $-h/2$ and $h/2$) at which values are to be calculated. In addition, a nonzero shear-to-moment ratio may be entered in order to limit $\sigma_{zz}$ calculations to elements in which transverse shear stresses are significant compared to in-plane bending stresses. For this particular research, shear-moment ratios were not employed (although they were initially proposed which led to their inclusion in the code).

Vita

Lieutenant Damin J Siler was born on 2 October 1970 in Saginaw, Michigan and grew up in the neighboring town of Merrill. In 1989 he graduated from Nouvel Catholic Central High School in Saginaw and began study at Michigan Technological University. He graduated from there in May of 1993 with a Bachelor of Science in Mechanical Engineering and Summa Cum Laude honors. Upon graduation he also received a reserve commission in the USAF through AFROTC. His first active duty assignment was to attend the Air Force Institute of Technology and pursue a Master of Science in Aeronautical Engineering.
