GFRP, fiber reinforced polymer, glass fibers, durability, salt fog, accelerated exposure.

The objective of this project was to determine the durability under accelerated salt-fog exposure of six commercially available composites. These composites included glass-reinforced vinylesters, polyesters, phenolics, and an epoxy. Durability was measured mainly in terms of the loss of elastic modulus and flexural strength after exposure. In order to accelerate aging, the specimens were subjected to temperatures of 95°F (35°C), 120°F (49°C), and 160°F (71°C) for one, two and three months each while exposed to a salt-fog spray. A previous project had determined that among the common marine exposures, salt-fog was a major cause for degradation of composites used in the retrofit of the Navy’s waterfront infrastructure. Flexural tests were performed, along with dynamic mechanic analyses and scanning electron microscopy. Once the aging effects were determined, a time-temperature superposition analysis was performed in order to extrapolate the results and estimate the degradation over longer time periods. Analysis predictions indicate losses of 35% or more in flexural strength over a 5-year period. To enable predictions beyond 5 years, additional and longer lasting testing would be necessary. Suggestions were made on how to introduce these findings in the design of composite material structures.
EXECUTIVE SUMMARY

The objective of this project was to determine the durability under accelerated salt-fog exposure of six commercially available composites. These composites included glass-reinforced vinylesters, polyesters, phenolics, and an epoxy. Durability was measured mainly in terms of the loss of elastic modulus and flexural strength after exposure. In order to accelerate aging, the specimens were subjected to temperatures of 95°F (35°C), 120°F (49°C), and 160°F (71°C) for one, two and three months each while exposed to a salt-fog spray. A previous project had determined that among the common marine exposures, salt-fog was a major cause for degradation of composites used in the retrofit of the Navy’s waterfront infrastructure. Flexural tests were performed, along with Dynamic Mechanic Analyses and Scanning Electron Microscopy. Once the aging effects were determined, a time-temperature superposition analysis was performed in order to extrapolate the results and estimate the degradation over longer time periods. Analysis predictions indicate losses of 35% or more in flexural strength over a 5-year period. To enable predictions beyond 5 years, additional and longer lasting testing would be necessary. Suggestions were made on how to introduce these findings in the design of composite material structures.

1. INTRODUCTION

Composite materials are being used in the rehabilitation and repair of Naval structures exposed to the marine environment. The use of composites for rehabilitation presents the following advantages: they possess high tensile strength, they are light, composites can be easily bonded to concrete, and they have superior corrosion resistance when compared to traditional construction materials, such as steel and aluminum. However, in order to evaluate the true cost of a specific type of composite, its durability must also be evaluated. The U.S. Navy waterfront infrastructure is subjected to various environmental exposures, including moisture, salt, hot and cold temperatures, and UV radiation. In a previous project, the Naval Facilities Engineering Service Center (NFESC) studied the effects of laboratory simulated marine climates on the mechanical properties of several commercial composites [1, 2] and found that, of all the previous exposures, seawater immersion and salt-fog exposure caused the greatest deterioration of the flexural and tensile strengths of the composites. In order to address the issue of long-term durability under salt-fog conditions, it was suggested that accelerated testing be conducted on the same fiber reinforced composites [3].

2. LITERATURE REVIEW

Knowledge of long-term behavior of composites is required for safe and economical design. The difficulty in predicting the long-term performance of composites arises from the fact that in laboratory tests only short-time results are often obtained. Therefore it is necessary to extrapolate data from short tests to obtain long-term predictions. Several experimental procedures have been used to accelerate the weathering of composites under a variety of aggressive environments. Most of them are based on increasing the intensity of the weathering agent in the expectation that it will accelerate the aging of the material without changing the degradation mechanism. Porter and Barnes [4] have used high alkaline bath and elevated temperature to accelerate alkaline corrosion of E-glass/vinylester composites. Bank, et al. [5] exposed pultruded glass/vinylester rods to several aggressive conditionings for up to 224 days. These conditions included deionized water with high temperature, ammonium hydroxide solutions, pre-strain, and high humidity. This list does not include accelerated testing performed under creep or fatigue loading. Chajes, et al. [6] studied the effect of freeze/thaw or wet/dry cycles in a calcium chloride solution of composites made with aramid, E-glass, and graphite fibers.

Durability testing of fiber reinforced polymer (FRP) composites is already required by several building codes. For instance, such testing is required for seismic upgrades by the California Department of Transportation (CALTRANS) [7, 8] and the International Conference of Building Officials (ICBO) [9], both of which require exposures to salt water. Such exposures have resulted in material property reduction factors that are included in the various international codes for design with composites for infrastructure applications, in particular in Japan [10],
Canada [11, 12], and the United States [13, 14]. For example in the United States, glass bars in concrete exposed to earth and weather must use an environmental exposure reduction factor of 0.7 [13], and FRP systems under exterior exposure must use a reduction factor of 0.65 [14].

3. BACKGROUND

For the analysis in this project a procedure known as the time-temperature superposition (TTS) equivalence or method of reduced variables, based on the Arrhenius model, was used [3]. The TTS principle has been used extensively for the extrapolation of results in time. The method has been successfully used for failure mechanisms that depend on chemical reactions, diffusion processes, or migration processes. The TTS principle is based on the assumption that the processes involved in molecular relaxation or rearrangements in visco-elastic materials occur at accelerated rates at higher temperatures, and that there is a direct equivalence between time (the frequency of measurement) and temperature. Therefore, the time over which these processes occur can be reduced by conducting the measurement at elevated temperatures and transposing (shifting) the resultant data to lower temperatures. The result of this shifting is a “master curve” where the material property of interest at a specific temperature can be predicted over a broad time scale. The TTS does not, however, take into account the effect of sustained load. Interesting applications are found in stress corrosion of borosilicate glass rods, for E-glass fibers [15], and for zero stress aging of glass fibers embedded in concrete [16]. Recently, Iyer, et al. have used it to model creep and creep-rupture of unidirectional composite laminates with good results [17].

4. TESTING PROGRAM

As mentioned, the testing program is a continuation of a previous one recently completed by NFESC in which seven GFRP specimens were tested under several types of marine exposure [1, 2]. In the current phase, only salt-fog exposure was considered since it was found to result, along with seawater immersion, in the fastest composite deterioration. The time-temperature equivalence principle was used in order to extrapolate the short-term behavior.

4.1. Specimens

Six composites were tested:
- Two glass-reinforced vinylesters (here called I and II): two commercial formulations containing epoxy vinylester made with bisphenol-A and styrene.
- Two glass-reinforced polyesters (here called I and II): two commercial resin formulations made with isophthalic acid, maleic anhydride, and common glycols.
- One glass-reinforced phenolic: commercial resin made with phenol and formaldehyde (product is a waterborne, styrene-free, phenolic resole).
- One glass-reinforced epoxy (epoxy-polyamide): A commercial resin made with bisphenol-A epoxy and aromatic amine curing agents.

The nominal dimensions of each composite piece were 10 x 0.5 x 0.125 in. (254 x 12.5 x 3.2 mm), except for the phenolic, which was thinner (0.093 inch or 2.4 mm). These six pultruded glass reinforced thermoset plastic composites are readily available for use in waterfront applications. The composite strips were all made by one company that purchased the resins and fiberglass matting and prepared 6-inch (152.4 mm) wide pultruded strips. The strips had 7 plies of 3-ounce (85 g) and 2 plies of 0.5-ounce (14.2 g) continuous strand E-glass mat, with 8 plies of 113 yield E-glass rovings for the laminate design of the epoxy, polyester, and vinylester specimens. The glass content of the epoxy, polyester, and vinylester composites was 42.5% by weight. However, the rovings made up 28% of the total glass weight. Rovings were unidirectional and run in the long direction. Continuous strand mat was in random orientation. The stitched mat was a combination of 0º and 90º rovings. The phenolic laminates were different due to the chemical method of preparing phenolics (condensation). Phenolic composite coupons had a 60% glass content by weight. The sheeting was cut into 0.5-inch (12.7-mm) strips in the longitudinal direction and the edges were sealed with a UV veil varnish.

4.2. Apparatus

The salt fog chamber (by Auto Technology) is a 20-ft³ (0.566-m³) cyclic corrosion chamber used in the automotive industry for cyclic salt fog, drying and humidity tests, as well as other cyclic tests, following ASTM B 117 [18]. In the salt fog cycle, the salt solution is atomized into a fine mist. Hot, humid air is created by bubbling compressed air (usually at 15 psi or 103.4 KPa) through a tube (bubble tower, or humidifying tower) that is about 3/4 full of hot (usually 118°F/48°C) deionized water (see Figure 1).

The salt solution is moved from the 60-gallon (0.227 m³) holding tank to the nozzle by a gravity feed system using a float switch and plastic solenoid. When the hot, humid air and the salt solution mix at the nozzle, the latter is atomized into a corrosive fog. The chamber is usually heated during this cycle at 95°F (35°C) by the chamber heaters. The chamber temperature is set by the user, and controlled by a Programmable Logic Controller. Fog distribution is controlled by the

Figure 1. Auto Technology salt-fog chamber.
Uni-Fog dispersion system. The salt solution can be replaced by other solutions to create a corrosive fog with differing properties.

Dynamic mechanic analysis (DMA) testing was performed using a TA Instruments DMA-2980. DMA measures the flexural storage modulus (stiffness) and damping (energy dissipation) properties of materials. A sinusoidal deformation force is applied to a material sample as it sits in a clamped configuration (e.g. three-point bending) inside a furnace. The sample deformation that occurs under the applied force is measured as the furnace cycles through a temperature program input by the operator.

For the composite specimens tested, a three-point bending mode was utilized, conforming to ASTM D 4065 [19] and ASTM D 5023 [20]. Composite strip specimens taken from the salt-fog chamber at specified sampling times were cut into 2.36-in (60-mm) lengths for placement in the DMA clamps. Four replicate samples were tested for each type of composite material and each exposure. The DMA furnace was programmed to heat the sample from 95°F (35°C) to approximately 320°F (160°C), or as required to extend past the glass transition phase of the material. The heating rate was set at 3.6°F/minute (2°C/minute). The frequency of the sinusoidal force was set at 1.0 Hz. The flexural storage modulus (E’) and the flexural loss modulus (E”) were plotted against temperature for each sample. The temperature at the peak of the E” curve is taken to be the glass transition temperature, Tg. Data from the exposed specimens were compared to data of control specimens for each type of composite tested.

Specimens were carefully observed under a scanning electron microscope (SEM) for signs of deterioration along with their corresponding control surfaces. Comparisons were made between the control surfaces and the three-month exposed surfaces in order to appreciate signs of deterioration. The SEM observations can help insure that the same degradation mechanism exists during the 3-month testing, a necessary condition for the TTS to be valid.

4.3. Accelerated Aging Temperature

Each test for a specific temperature was performed over 3 months for a total program duration of 9 months. Given the temperature range (95 to 160°F, or 35 to 71°C) where the chamber can operate, the temperatures used to accelerate aging were:

- 95°F (35°C)
- 120°F (48.9°C)
- 160°F (71.1°C)

These temperatures are below the glass transition temperature of the selected thermosets (see Table 1), thus avoiding the change in the degradation mechanism that may occur at that point. A maximum temperature of 0.8 Tg has been suggested for accelerating the degradation process [21]. Others recommend that accelerating temperatures be kept at least 10 to 15°C below the Tg of the matrix. As a result tests are often conducted at 60°C, 80°C, and sometimes even higher temperatures [21, 22].

4.4. Tests Performed

Any accelerated test method is based on a set of measurements made periodically during the duration of the test to note changes in properties of the material. A set of tests was performed for each of the three temperatures listed above. Three sets (3) of each type of the exposed specimens were removed each month for the 3-month period and tested for:

- Flexural strength and modulus of elasticity following ASTM D 790 [23]. The test specimens were supported at two points distanced 2.5 in. or 63.5 mm (support span) and loaded in a conventional “three point loading” configuration. Actual width and thickness dimensions were measured before proceeding with the test. Elastic moduli of the specimens were obtained by flexing the specimen at 73°F (23°C).

- Elastic storage moduli and glass transition temperatures were obtained by DMA (ASTM D 5023 [19]).

Flexural strength and stiffness data for 95°F (35°C) at 0 days (control), 28 days, and 12 months were available in the previous NFESC test program [1, 2]. They were made part of the results obtained here. For these composites, while decreases in tensile strength are mainly affected by fiber degradation, decreases in flexural strength are more affected by matrix and interface degradation. Previous testing showed that salt fog exposure of these composites would affect their flexural strength to a greater degree than tensile strength [1, 2], so the current testing was focused on flexural strength losses.

5. DEGRADATION MECHANISMS

The mechanism governing water attack on bulk glass is a combination of leaching and etching. Silicon hydroxide (SiOH) is formed as a by-product at the interface between the glass and the water. This gel layer is less dense than the original glass structure and will transport water and alkalies more readily, thus accelerating the degradation process. The addition of alumina to the glass will increase the resistance of the glass to water attack, but will actually decrease the resistance of the glass to alkalies. E-glass contains alumina and, therefore, this alkali effect should be evident. However, since the water attack eventually evolves into an alkali
attack, the addition of alumina to the glass could possibly be expected to not influence the long
term overall degradation resistance of glass.

It has been shown that in the case of E-glass fibers in vinylester, the glass fibers were the
critical component [15] and that the maximum moisture content of the composite was insensitive
to the temperature of the environment but highly sensitive to the moisture content of the
environment. Other research work indicated that the temperature of the bath would not affect the
tensile strength, but the moisture content would.

Moisture has been shown to act as a plasticizer in cured thermosets, generally resulting in
a reduced stiffness modulus and glass transition temperature [24]. Water acts as a plasticizer by
cauing physical swelling of the polymer, which can lead to increased internal stresses and micro
cracking in the material [25, 26]. Plasticization disrupts Van-der-Walls bonds in the polymer
chains [27, 28].

Effects of moisture sorption are potentially reversible, but may also lead to irreversible
permanent effects, e.g. when hydrolysis of the molecular bonds occurs [24]. A distinction
between water absorption and hydrolysis needs to be made, since they are separate phenomena
[29]. Water absorption refers to the reversible physical uptake of water by the material, whereas
hydrolysis is the irreversible chemical degradation of the polymer by absorbed moisture. Water
absorption into a hydrolysis-sensitive polymer leads to hydrolysis.

The rate of water diffusion into the polymer is related to the polymer structure and
temperature [29, 30]. The rate is lowered by the presence of nonpolar functional groups (i.e.
hydrophobic groups), by branching of the polymer (steric hindrance), and by cross-linking in the
polymer. The cross-linkages reduce the voids in the polymer where water may penetrate and
react [30].

In the presence of electrolytes in the water, such as sodium and chloride ions from salt,
diffusion is generally decreased, unless the electrolyte reacts with the polymer molecule [29].
Studies comparing epoxy, polyester, and vinyl ester GFRPs have indicated that distilled water
aging over 18 months differs significantly from sea water aging in terms of weight gain (water
absorption) of polyesters [31]. The use of distilled water seems to have an accelerating effect on
water absorption. The vinyl ester and epoxy showed similar increases after one to three months
at 50ºC in distilled water [31]. Differentiations between plasticization or alkali attack and
chloride attack are not clear; that is, deterioration in the presence of chloride ions may not be
attributable to chloride when water absorption is occurring or when alkali solutions are present
[32].

In general, vinyl esters are the most resistant to water absorption in comparison to
epoxyes and polyesters [25, 32]. A study of GFRPs in deionized water and seawater at elevated
temperatures revealed that epoxy and vinyl ester shear properties losses were largely recoverable
after drying, whereas permanent damage occurred in the polyester composites after 18-month
exposures [31]. All polyesters are hydrolyzable, but aromatic polyesters are more resistant than
aliphatic polyesters [29].

The most common type of epoxy is a bisphenol-A epoxy. Its resin structure (uncured) is
given in Figure 2. The end groups are called “oxirane” groups. These groups react with a
“hardener”, typically an amine, to cure and cross-link the epoxy.
Although epoxies are known for their toughness and chemical resistance, the deleterious effects of hot and humid environments on epoxy polymers have been documented for decades and are well known [33]. As early as 1973, epoxy-graphite composites were examined for water absorption effects [34]. In this study, significant creep at room temperature, in addition to diminished rigidity, was observed.

Epoxies that are room-temperature cured are more likely to be under-cured than are epoxies cured at elevated temperatures [30]. Under-cured epoxies have reactive oxirane groups. This manifests itself in a “post-cure” when the under-cured epoxy is subsequently exposed to heat during service exposure. Post-curing causes an increase in cross-linking and thus an increase in strength of the molecular structure. A cross-linked amine-cured epoxy is represented in Figure 3.

Post-curing and plasticization can be considered as competing phenomena within the polymer during exposure to moist, hot conditions. In hydrolysis of an epoxy polymer, the oxirane epoxy groups react with water and are consumed [26]. The more under-cured the polymer, the higher the degree of plasticization [35].

Vinyl ester are now commonly used for GFRP and CFRP composites because they bond well to glass fibers and other fiber reinforcements, they process easily, and they resist a wide range of chemicals throughout the pH range [29]. Uncured vinyl ester resins can be considered as a type of acrylic polymer [36]. Cured vinyl esters, however, are thermosets. They are typically produced by reacting epoxy resins with methacrylic acids dissolved in styrene monomer. Their performance tends to fall between that of epoxy and that of unsaturated polyester. An example of a vinylester resin (uncured) is given in Figure 4.
Compared to unsaturated polyester resins, vinyl esters have better chemical resistance. Nearby functional groups shield the ester linkages (weak in comparison to carbon-carbon bonds) from acid and base-induced hydrolysis [36]. When ester groups are hydrolyzed, usually in basic solutions, the process is often referred to as “saponification” because the reaction is analogous to the process used to convert fats to soaps. In the presence of a base such as sodium hydroxide, the carboxylic acid becomes a salt.

\[
\begin{align*}
\text{R-COOR'} & + \text{OH}^- \rightarrow \text{R-COO}^- + \text{R'}\text{OH} \\
\text{Ester Group} & \quad \text{Hydroxide ion} & \quad \text{Carboxylic ion} & \quad \text{Alcohol}
\end{align*}
\]

Glass fibers are relatively impervious to water, but are deteriorated by alkali solutions and chloride ions [25]. The corrosion mechanism of glass fibers by alkali solutions is given below [37, 38].

\[
\begin{align*}
\text{-Si-O-Si-} & + \text{OH}^- \rightarrow \text{-Si-OH (solid)} + \text{-Si-O- (solution)}
\end{align*}
\]

This mechanism is known as hydroxylation and dissolution, where both a solid and a liquid by-product are formed. Hydroxylation occurs at pH values above 10 and is rapid initially, then slows as the solid by-product forms over the surface of the glass [15]. In concrete, a notching of the glass fibers occurs caused by the growth of calcium hydroxide crystals. This reduces the cross-sectional area of fiber available to resist tensile forces [15]. Aramid fibers are less susceptible to alkali environments than glass fibers [32]. Like carbon fibers, they are insensitive to chloride ions. Their susceptibility to water absorption and swelling, however, precludes their use in marine environments [25].

6. ANALYSIS OF RESULTS

6.1. Flexural tests

The flexural strength and modulus of elasticity were measured at the end of the 1-, 2-, and 3-month testing durations (details of all results are included in Appendices A through D). The plots of flexural strength and elastic modulus are shown in Appendix C. The values were then averaged for each composite, testing time, and temperature. A summary of results is shown in Tables 2 and 3. It was observed that the shift factors were not constant for different stress levels, therefore the stress-modified \((t, T)\) parameter method was used.

In some cases, flexural strength and stiffness initially increased despite longer exposure to the aging agent. This increase is probably due to an increase in the crosslink density. In the case of epoxy, samples are not fully cured at room temperature and additional crosslinking will take place at higher temperatures. Immersion in liquid media causes plasticization of the resin with a simultaneous reduction in $T_g$ of the polymer.

These values of maximum stress and stiffness were plotted in a logarithmic chart and then shifted onto the 95°F (35°C) curves for each material. These superimposed curves are known as the master curve. It was found that the shifting factors followed a straight line behavior, which is a necessary condition for the TTS to be valid. Later, the master curve thus obtained was moved back to 70°F (21°C). This is the service temperature assumed for the specimens. The resulting master curves obtained are shown in Appendixes A and B. The master curves at 70°F (21°C) span a longer period of time, herein called maximum predictable time (MPT), but not enough to predict the degradation for a service-time length. No data fitting for extrapolation beyond the MPT was attempted due to the unknown nature of future behavior. Table 4 shows the maximum predictable time and the degradation experienced by each material.

6.2. Dynamic Mechanic Analysis

Composite specimens exposed in the salt-fog chamber for 3 months at 95°F (35°C), 3 months at 120°F (49°C), and 2 months at 160°F (71°C) were tested and compared to control specimens for each type of FRP composite. Appendix D contains averaged DMA curves of exposed versus control flexural storage and loss moduli. All specimens were allowed to dry out 1 week or longer before DMA analysis. This was done in an attempt to preclude temporary effects of the moisture exposure and to capture the permanent effects of the exposure on the materials.

Interpretation of DMA curves can be difficult due to the possibility of competing chemical processes in the materials as they are exposed. The analysis of DMA results that is presented below is based on generally observed DMA behavior of thermoset resins exposed to moisture environments.

When a thermoset plastic-fiberglass composite is exposed to a moisture environment, it is generally expected that the material resin will undergo plasticization over a period of time [35, 39]. This is evidenced in the DMA data by the lowering of both flexural storage modulus values, E’, and the glass transition temperature (taken as the temperature at the peak of E”, the loss modulus curve). However, even if a material shows dramatic loss of storage modulus (stiffness), it may only lose a few degrees in T_g value [35].

At higher exposure temperatures, it is increasingly possible for competing reactions to affect the material. One such phenomenon is residual cross-linking or post curing of the polymer. It is not uncommon for manufactured resins to be less than 100% cured. This is not necessarily undesirable or a “flaw” in the manufacturing process. Depending on application, a slight undercure may be desirable and increases the flexibility of the material. In the case of residual cross-linking, the T_g would be expected to increase 2 to 3 degrees, depending on the degree of cross-linking [35]. A fully cured material will typically have a higher storage modulus than an under-cured specimen of the same material [35, 40]. However, the storage modulus may still decrease in a moisture exposure. This is because the more under-cured a material, the more susceptible it is to moisture damage and the greater the degree of plasticization [35, 41]. It is possible, therefore, for the resin to be plasticized and residually cross-linked, i.e. competing reactions and resulting complications in the behavior of the storage and loss moduli.

In addition to the modulus values, the overall shape of the DMA curves gives clues to the material’s degree of cure or residual cross-linking [35]. A curving E’ plot at temperatures below the T_g suggests a lack of cure in the specimen. This is likewise indicated by a broader E” peak. Straight line E’ plots below T_g are indicative of a more fully cured or residually cross-linked specimen. This is likewise indicated by a sharper E” peak. In thermoplastic materials such as polyethylene, the shape of the curves gives indications of the amorphous nature of the material.

A phenomenon known as “vitrification” may also occur at higher temperatures [35]. Vitrification is an early form of decomposition of the polymer where the cross-linkages break down, or the material becomes amorphous. Another phenomenon seen at higher exposure temperatures is hydrolysis decomposition of the resin structure [42]. It is a severe form of plasticization. This would be expected to have a similar effect on the DMA modulus values, but with more dramatic losses.

It has been documented in the literature that a change in the exposure temperature affects the behavior of the composite material [42]. What causes an increase in the glass transition
temperature (embrittlement) of a material at one exposure temperature may cause a softening effect of the resin at another temperature.

For the various composites tested, the following was observed:

**Vinyl Ester I:** These exposed vinyl ester specimens showed a drop in the glass transition temperature (Table 1) for the 95°F and 120°F exposures (106.1 and 101.0°C respectively versus 108°C for the controls). This indicates a plasticizing effect on the material at these temperatures. The storage modulus values below the T_g for all of the specimens are within the range of the controls however. Overall, this vinyl ester appears to not have been significantly affected by the exposures, in terms of its elastic storage modulus.

**Vinyl Ester II:** These exposed vinyl ester specimens showed a decrease in the T_g (Table 1) at 95°F and 120°F exposures, but the 160°F specimens showed an increase over that of the controls (102, 103.7 and 111.4°C versus 105.5°C respectively). This would suggest some residual cross-linking might be occurring at 160°F, while plasticization is occurring at 95°F and 120°F. The 120°F E’ curve below the T_g is at the lower edge of the range of the controls. The stiffness is still reduced in the 160°F exposed specimens, as evidenced by the lower starting E’ values. Plasticization may also be occurring. The “straightening” and “sharpening” of the shape of both the E’ and E” curves of the 160°F exposure indicates the material has residually cured.

**Polyester I:** These exposed isopolyester specimens all showed a decrease in the T_g (Table 1) from that of the control specimens (87.9, 87.9, and 88.5 versus 89.8°C respectively) indicating a plasticizing effect from the exposure. Only the 160°F exposure shows a significant drop in the E’ flexural modulus, however, indicating a significant loss of stiffness at that temperature exposure.

**Polyester II:** These exposed isopolyester specimens showed a decrease in T_g (Table 1) for the 95°F and 120°F exposures from the controls (88.2 and 87.9 versus 94.7°C respectively). The 160°F exposure showed an increase in T_g (97.9°C) indicating possible residual cross-linking. Markedly lower storage modulus values, compared to the controls, were observed for all exposed specimens indicating plasticization. The E’ and E” curves of the 160°F specimens are sharper in appearance, indicating residual curing is also occurring at this exposure temperature.

**Phenolic:** Due to erratic test behavior and a lack of proper numbers of available specimens, this material was discarded from consideration.

**Epoxy:** The 120° and 160°F epoxy amide specimens showed significant loss in storage modulus compared to the controls, indicating a strong plasticizing effect. The glass transition temperature was shifted to lower temperatures (Table 1) for the 95° and 120°F exposures compared to the controls (140.4 and 137.9°C versus 144.2°C) as further evidence of this effect. However the T_g of the 160°F exposure remained about the same as the controls (145°C). Epoxies are known to be especially susceptible to the plasticizing effect.

**6.3. Scanning Electron Microscopy**

SEM pictures of the epoxy composite were taken after 3-month exposure at 120°F, and shown in Figure 5 and Figure 6 along with their corresponding control surfaces. This material experienced a 36% flexural strength degradation after such exposure. Prior to the examination, all samples were prepared to a half-micron final polish. They were subsequently sputter coated with gold palladium.
The SEM pictures show significant amounts of surface fiber degradation and interface damage, as shown by the dark pits and cracks (Figure 5b). This type of damage was also reported by Grant and Bradley [43]. As previously noted, the damage mechanism is a combination of leaching and etching, probably caused by the formation of SiOH at the interface between the glass and the water.
6.4. Minimum Allowable Values

The data that were obtained under this exposure may be used to determine minimum allowable values for the flexural strength, the ultimate elongation, and the Young’s modulus. For example, CALTRANS has established criteria to determine those minimum values [7]: the Young’s modulus, strength and strain are estimated after exposure to 1,000 hours, 3,000 hours and 10,000 hours (41, 125, and 416 days respectively) to several aggressive environments (the minimum values are estimated as the mean of three tests minus two or three standard deviations). The accelerated technique could be used to shorten the exposure times, or to make those exposure times representative of longer actual environmental exposure conditions. ACI 440 [13] recommends that glass bars in concrete exposed to earth and weather must use an environmental exposure reduction factor of 0.7 – the current results could be used to establish similar or even more severe factors for flexural applications, depending on the structure life expectancy, bar protection, and bar diameter. Alternatively, an expected service life could be proposed, during which the remaining strength after exposure could not be less than a certain percentage of the measured short-term property. While the current results provide a preliminary insight into the expected degradation, additional testing would be needed to allow time extrapolation in the order of the structure’s life expectancy.

7. CONCLUSIONS

A testing program for accelerating aging in GFRP has been conducted under salt-fog exposure. The resulting high degradation raises serious questions about the durability of composites under this simulated marine exposure. The degradation experienced by these specimens did not allow for a long-term evaluation of their behavior. However, the short-term behavior was significant enough to report and to warrant further research into the effect of salt water on composites.

From the laboratory results and the time-temperature superposition technique, more specific conclusions can be drawn:

1. In the short test time, the degradations experienced by most of the materials were significant enough to compromise their long-term flexural strength (losses of 35% or more in less than five years in all cases).

2. Salt-fog exposure seemed to affect the flexural strengths of the composites to a much larger degree than they affected the moduli, an observation previously reported in the literature [44].

3. Phenolics seems to be unfit for this type of exposure due to the significant degradation (~60%) expected in a short time (20 months). Glass reinforced phenolics had an erratic behavior making predictions unreliable. The significant variation in both exposed and unexposed specimen properties also points to difficulties and nonuniformity in the phenolics fabrication process.
4. Glass-reinforced vinylester seems to be the most convenient material for this exposure given the lesser degradation (~35%) over a five-year period. The superior performance of vinylester relative to polyester resin in typical industrial corrosive environments has been well documented [45, 21].

5. With glass-reinforced vinylester, the stiffness degradation is also the least, averaging 25% in roughly the same time.

6. The degradations experienced by the specimens were not enough to extrapolate into service-life expectancy (50-100 years) of concrete structures. Additional testing is needed for longer predictions.

7. Further research is required to determine a procedure to incorporate these results into an effective safety factor.

8. ACKNOWLEDGEMENTS

Funding for this project was provided by the Office of Naval Research under Dr. Ignacio Perez. Professor Arsenio Caceres, from the University of Puerto Rico, was on leave at NFESC under the Navy Summer Faculty Research Program sponsored by the Office of Naval Research and administered by the American Society of Engineering Education.

Dan Polly kindly assisted in the preparation of samples and operation of the SEM for the pictures shown in this report. Specimens and support provided by Dr. Tom Novinson are gratefully acknowledged.
