**Abstract (Maximum 200 Words)**
The proposal tests the hypothesis that histone deacetylase activity contributes to the transcriptional repression of the methylated estrogen receptor α (ER) gene. It further postulates that inhibition of histone deacetylase (HDAC) and DNA methylation may act together to reactivate the ER gene. Studies to date show that the HDAC inhibitor trichostatin A, can reactivate ER expression in ER-negative breast cancer cell line. Combined treatment with HDAC inhibitors and demethylating agents can synergistically reactivate expression of ER-negative breast cancer cell lines.

INTRODUCTION

This proposal tested the hypothesis that histone deacetylase activity contributes to the transcriptional repression of the methylated estrogen receptor alpha (ER) gene in ER-negative breast cancer cells. It was further postulated that inhibition of histone deacetylation and DNA methylation could act together to reactivate ER expression.

BODY

Technical Objective 1: To determine whether histone deacetylase activity is required for transcriptional silencing of the ER gene.

Because the absence of ER gene expression has been associated with aberrant methylation of its CpG island in a fraction of breast cancers, the contribution of histone deacetylase activity to transcriptional inactivation of the methylated ER gene in a panel of ER-negative human breast cancer cells was tested. Treatment of these cells with trichostatin A, a specific histone deacetylase inhibitor, led to dose- and time-dependent expression of ER mRNA as detected by reverse transcription-PCR without alteration in ER CpG island methylation. Trichostatin A-induced ER re-expression was associated with increased sensitivity to DNase I at the ER locus in MDA-MB-231 cells. These data implicate inactive chromatin mediated by histone deacetylation as a critical component of ER gene silencing in human breast cancer cells. These results were published in Yang et al, Cancer Research 60:6890-4, 2000.

Technical Objective 2: To achieve maximal ER reactivation both in vitro and in vivo through the combination of demethylation and histone deacetylase inhibition.

The combination of a histone deacetylase and a DNA methyltransferase inhibitor was shown to increase ER expression in a synergistic fashion when compared with either treatment alone. The combination led to a 300-400 fold induction in ER transcript. This was associated with ER protein re-expression. Restoration of estrogen responsiveness was demonstrated by the ability of the induced ER protein to elicit estrogen response element-regulated reporter activity from an exogenous plasmid as well as the expression of the ER target gene, progesterone receptor. The synergistic activation of ER occurred concomitantly with markedly reduced soluble DNMT1 expression and activity, partial demethylation of the ER CpG island, and increased acetylation of histone H3 and H4. These data suggest that the activities of both DNMT1 and HDAC are key regulators of methylation-mediated ER gene silencing. These results were published in Yang et al, Cancer Research 61:7025-9, 2001.

KEY RESEARCH ACCOMPLISHMENTS

- Demonstration that an inhibitor of histone deacetylase can reactivate ER expression in ER-negative human breast cancer cells.

- Demonstration that the combination of an inhibitor of histone deacetylase and an inhibitor of DNA methyltransferase can synergistically reactivate ER expression in ER-negative human breast cancer cells over either strategy alone.
REPORTABLE OUTCOMES

As a result of her career development at Hopkins and through this grant, the original PI, Xiaowei Yang, M.D., Ph.D., took a position as a full-time permanent staff scientist at the National Cancer Institute, National Institutes of Health, Bethesda, MD in July 2001. This grant was then transferred to Yi Huang, M.D., Ph.D. who assisted with completion of the work. Because the proposed animal studies were not successful and the remainder of the work proposed had been completed, he began a new project that he continues as a postdoctoral fellow.

Because of a major interest in cancer treatment, Dr. Huang began a study of the effects of novel polyamine analogues in breast cancer cells. He showed that seven different polyamine analogues exhibited growth inhibitory effects against human breast cancer cell lines with IC50 generally less than 1 uM for 96 hr exposure. Evidence of apoptotic cell death was demonstrated by DNA fragmentation assay as well as analyses suggesting that the intrinsic mitochondrial apoptotic pathway was activated in MDA-MB-231 but not MCF-7 cells. These results were presented at the 2002 meeting of the American Association of Cancer Research (Huang et al, Proc AACR 43:90, 2002).

CONCLUSIONS

Administration of a histone deacetylase inhibitor, trichostatin A, can re-activate expression of ER in ER-negative breast cancer cell lines. Adminstration of a combination of histone deacetylase and DNA methyltransferase inhibitors can synergistically reactivate expression of ER in ER-negative human breast cancer cell lines.
Preliminary evidence suggests that new conformationally constrained polyamine analogues and oligoamines can inhibit growth and induce apoptosis in human breast cancer cells.

Transcriptional Activation of Estrogen Receptor α in Human Breast Cancer Cells by Histone Deacetylase Inhibition

Xiaowei Yang, Anne T. Ferguson, Sharyl J. Nass, Dawn L. Phillips, Kim A. Butash, San Ming Wang, James G. Herman, and Nancy E. Davidson

Abstract

Recent findings have established a connection between DNA methylation and transcriptionally inactive chromatin characterized by deacetylated histones. Because the absence of estrogen receptor α (ERα) gene expression has been associated with aberrant methylation of its CpG island in a significant fraction of breast cancers, we tested whether histone deacetylase activity contributes to the transcriptional inactivation of the methylated ER gene in a panel of ER-negative human breast cancer cells. Treatment of these cells with trichostatin A, a specific histone deacetylase inhibitor, led to dose- and time-dependent re-expression of ER mRNA as detected by reverse transcription-PCR without alteration in ERa CpG island methylation. Trichostatin A-induced ER re-expression was associated with increased sensitivity to DNase I at the ER locus in MDA-MB-231 cells. These data implicate inactive chromatin mediated by histone deacetylation as a critical component of ER gene silencing in human breast cancer cells. Therefore, histone deacetylation may be a potential target for therapeutic intervention in the treatment of a subset of ER-negative breast cancers.

Introduction

Interaction between 17β-estradiol and ERα plays an important role in breast carcinogenesis and breast cancer treatment. That estrogen stimulates the growth of certain breast cancers is well established, and hormonal therapy via estrogen depletion or antiestrogen administration is widely used to block the action of estrogen in women with breast cancer. However, patients whose breast cancers lack ER seldom respond to endocrine therapy; therefore, a potential mechanism for hormone resistance is de novo or acquired loss of ER gene expression at the transcriptional level during disease progression (1, 2).

One possible mechanism for loss of ER in ER-negative breast cancers is cytosine methylation of the ER CpG island in the 5′ regulatory region of the gene (3). Indeed the ER gene CpG island is extensively methylated in ER-negative breast cancer cells, and ~50% of unselected primary breast tumors but remains unmethylated in normal breast tissue and many ER-positive tumors and ER-positive cancer cell lines (4, 5). The functional importance of this finding is demonstrated by the fact that treatment of ER-negative human breast cancer cells with the demethylating agent, 5-aza-2′-deoxycytidine, allowed re-expression of ER mRNA and functional ER protein (6). Recent studies indicate that silencing of a gene by methylation involves the generation of an inactive chromatin structure characterized by deacetylated histones. An abundant chromosomal methyl CpG-binding protein, MeCP2, was the first protein identified to link methylated DNA and a HDAC-containing transcriptionally repressive complex for gene silencing. Subsequently, several MBD proteins have been identified that, similar to MeCP2, couple methylated DNA to HDAC (7, 8). More recently, the well-known maintenance methyltransferase, Dnmt1, was found to interact physically with HDAC through its N terminus, thereby forming a transcriptionally inactive chromatin structure that represses transcription (9, 10). All of these findings demonstrate the important role of HDAC in transcriptional regulation. The HDACs deacetylate lysine groups of histones H3 and H4, allowing ionic interactions between positively charged lysines and negatively charged DNA, which result in a more compact nucleosome structure that limits transcription. The availability of specific HDAC inhibitors such as TSA (11) permits the study of the role of HDAC in silencing a variety of tissue-specific methylated genes (7, 12).

Here, we have tested whether loss of ER expression in some breast cancers is associated with transcriptional repression through HDAC activity on the methylated ER gene. Our data demonstrate that specific HDAC inhibition by TSA treatment can reactivate ER transcription in the presence of the methylated DNA. The activated gene transcription is associated with increased sensitivity of the ER promoter to DNase I treatment. These data suggest that inactive chromatin mediated by HDAC is critical to ER gene silencing.

Materials and Methods

Cell Lines, Reagents, and TSA Treatment. Human breast cancer cells (MCF-7, MCF-7/T47D, and MDA-MB-231) were grown in DMEM supplemented with 10% fetal bovine serum and 2 mmL-glutamine. TSA was purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan), dissolved in absolute ethanol at a stock concentration of 1 mg/mL, and stored at −20°C. DNAse I was purchased from Pharmacia Biotech (Phar- macia Biotech, NJ). Cells (MAD-MB-231, MCF-7, T47D, or MCF-7/Ad5) were seeded at a density of 6 × 104 cells/100-mm tissue culture dish (8 × 105 cells/cm2). After 24 h of incubation, the culture medium was changed to different concentrations of TSA- or vehicle (ethanol)-containing medium. Either total cellular RNA or genomic DNA was isolated after 0, 24, 48, or 72 h of TSA exposure.

RNA Isolation and RT-PCR Analysis of ER Expression. Total cellular RNA was isolated from cell lines with TRIzol reagent according to the recommendations of the supplier (Life Technologies, Inc., Rockville, MD). RNA (3 μg) was reversibly transcribed by Moloney murine leukemia virus reverse transcriptase (Life Technologies) using Oligo(dT)15 primer (Promega Corp., Madison, WI) in a final volume of 50 μL. Four μL of synthesized cDNA (2 μL, derived from 150 ng of initial RNA) was used for PCR amplification of ER and the constitutively expressed housekeeping gene β-actin (13). Specific sense and antisense PCR primers were used for the amplifications throughout the seventh
intrion of ER and the first intron of β-actin genes, yielding 470 and 400 bp of PCR products respectively, were described previously (6). PCR products were resolved by 2% agarose gel electrophoresis and visualized by ethidium bromide staining.

**Quantitative Competitive PCR Analysis of ER Reactivation.** A quantitative assay was performed to determine the level of ER mRNA in TSA- and vehicle-treated MDA-MB-231 cells as compared with the expression levels in the known ER-positive MCF-7 and T-47D cells using the method of Wang and Rowley (14). This assay involves coamplification of a wild-type target cDNA (wER) of unknown amount and a competitive template (cER) in known amounts. A truncated competitive template was generated with a sense primer containing a 22-bp deletion (primer 2) and the same antisense primer (primer 3) as the wild-type (Fig. 2A). After amplification, the competitive template was separated, gel purified, and quantified by Spectrophotometer DU 640 (Beckman, CA). Thus, target wild-type and known amounts of competitive templates can be coamplified with the pair of wild-type primers (primers 1 and 3) and differentiated by size. Because the most accurate results are obtained when wild-type and competitive templates are amplified at nearly equivalent concentrations, resulting in the signal ratio of wER:cER equivalent to 1, we first performed an initial titration in log and then in 2-fold dilutions to determine the approximate concentration of the wild-type ER cDNA in our experimental samples. RNAs under comparison were simultaneously reversely transcribed to achieve equal efficiency for reverse transcription. The PCR reactions were carried out with 0.5 μM of wild-type sense and antisense primers for 35 cycles. The wild-type and competitive PCR products were fractionated on 2.5% agarose gel, stained with ethidium bromide, and scanned by Densitometer (EagleSight Software of Eagle Eye II Imaging System; Stratagene, La Jolla, CA). The ratio between wild-type and control templates was determined and used to calculate the amount of target wild-type cDNA because the input of competitive template is known.

**Genomic DNA Isolation and MSP Analysis of ER Cpg Island.** DNA was isolated by standard phenol-chloroform extraction. Isolated DNA was subjected to modification by sodium bisulfite to convert unmethylated cytosines but not methylated cytosines to uracil as described previously (15). Methylation status of the bisulfite-modified DNA at the ER locus was characterized by methylation-specific PCR using a method described previously (5).

**DNase I Sensitivity Assay.** This assay was performed according to the method of Keshet et al. (16) using cells from TSA- or vehicle-treated MDA-MB-231 and MCF-7 cells (1 × 10^8 cells each) with the following modifications. The isolated DNA was digested with EcoRI, the recognition sites of which flank the ER promoter region to yield a 3.1-kb fragment that was separated by 1% agarose gel electrophoresis. DNAs blotted on nylon membrane were probed with a PCR-amplified, 561-bp DNA fragment corresponding to the ER Cpg island (Fig. 4A). The sense and antisense oligonucleotides used to amplify the fragment are 5’-AGACGGCCTAATTGAGTGAGG-GCC-3’ and 5’-GGGAAAACCCCCCAGG-3’. The amplified DNA was cloned into pCR2.1-TOPO vector (Invitrogen, CA) according to the manufacturer’s protocol. Colonies containing amplified DNA sequence, determined by MiniPrep (Promega Wizard Mini-Prep kits), were grown and purified. The purified plasmids were sequenced via automated sequencing (Johns Hopkins Sequencing Core Facility). The specific ER Cpg probe was prepared from sequence-confirmed plasmid and labeled with bio-16-DUTP (Boehringer Mannheim, IN) by PCR using the above-mentioned primer set. The 3.1-kb DNA band containing the ER promoter region was visualized by chemiluminescence using a streptavidin-conjugated, alkaline phosphatase-catalyzed substrate, CD-P-star. The band signals that reflect the resistance to DNase I were quantified by densitometry (Stratagene), and the cumulative DNase I sensitivity was calculated as follows. The band density at each DNase I concentration was divided by the density of the control band and then multiplied by 100%. This value was subtracted from 100% to yield the percentage of DNase I sensitivity. The sum of the percentage of DNase I sensitivity at each dose was considered to be the cumulative DNase I sensitivity.

**Results and Discussion.** A growing body of data demonstrates the importance of histone acetylation and deacetylation and corresponding structural alteration of chromatin in gene transcriptional regulation (7, 8, 10). The ER-negative cell line, MDA-MB-231, the ER Cpg island of which is densely methylated, was used as a cell model to test whether HDAC activity contributes to repression of ER expression in ER-negative breast cancer cells. TSA, a specific and potent HDAC inhibitor, was used as a pharmacological tool. Exposure of MDA-MB-231 cells to increasing concentrations of TSA led to induction of ER mRNA synthesis in a dose-dependent manner (Fig. 1A). A detectable level of ER mRNA, as demonstrated by a RT-PCR product with predicted 470-bp size, was noted after treatment with 50 ng/ml (160 nM) TSA for 48 h, and ER transcript was clearly present after 100 ng/ml (330 nM) TSA for the same duration. A time course analysis showed that a weak signal could be seen after 24 h of 100 ng/ml TSA treatment, whereas ER transcript was readily observed after 48 or 72 h (Fig. 2B). Multiple experiments were done to achieve optimal conditions for TSA induction of ER mRNA in MDA-MB-231 cells. These showed that maximal ER reactivation was achieved with 100 ng/ml TSA for 48 h using an initial seeding density of 8 × 10^3 cells/cm^2. Higher inoculating cell densities reduced ER transcript signal (data not shown).

To ascertain whether HDAC activity could play a role in repression of ER expression more generally, the dose response and time course studies described above were extended to other ER-negative human breast cancer cell lines with methylated ER Cpg islands. As shown in Fig. 1C, TSA treatment led to re-expression of ER mRNA in all three ER-negative cell lines tested. Optimal ER gene re-expression was observed after treatment of MDA-MB-231 cells with 100 ng/ml (330 nM), Hs578T cells with 400 ng/ml (13.2 μM), and MCF-7/AdR with 25 ng/ml (82.5 nM) TSA for 48 h. Therefore, TSA treatment consistently induced ER re-expression in the panel of ER-negative cell lines, supporting a role for HDAC in ER gene silencing.

A quantitative competitive PCR assay was used to assess the magnitude of TSA-induced ER mRNA transcript in MDA-MB-231 cells. Fig. 2A shows the design of the primer sets used, and validation of the quantitative competitive PCR is shown in Fig. 2B. As shown in Fig. 2C, a 5-fold increase in ER transcript was obtained after TSA exposure in MDA-MB-231 cells (100 ng/ml for 48 h). This effect was specific for the methylated ER promoter because TSA treatment (50 or 100 ng/ml for 48 h) of ER-positive, unmethylated MCF-7 cells had

no effect on the level of ER mRNA expression using the same quantitative assay (data not shown). However, TSA treatment of MDA-MB-231 cells did not restore ER mRNA expression to the levels seen in cell lines with endogenous ER expression, as shown in Fig. 2C. Quantitative assay suggested that the level of ER transcript seen with TSA treatment of MDA-MB-231 cells represented about 1 and 10% of that seen in the ER-positive MCF-7 and T-47D cell lines, respectively. Several possibilities might account for this:

(a) It is possible that only partial reactivation is seen because only a fraction of cells responded to the treatment. Indeed, a similar pattern of partial reactivation was seen in MDA-MB-231 cells exposed to a demethylating agent, 5-aza-dC, in our previous study (6).

(b) It has been shown that a component of the repression mediated by MeCP2 transcriptional repression domain is partially HDAC independent; mSin3A could retain some ability to repress transcription, even in the absence of associated HDACs (7).

(c) Simultaneous inhibition of several components in the methylation-associated repressive complexes might be necessary to achieve maximal reactivation of the repressed genes (12).

The ability of TSA to reactivate ER expression raised the question of whether the ER CpG island remained methylated. Our previous studies with 5-aza-dC demonstrated that ER re-expression was associated with demethylation of the ER CpG island. However, a parallel study of the progesterone receptor in progesterone receptor-negative human breast cancer cells showed that the ligand-bound ER could overcome methylation-related repression of the progesterone receptor, even in the continuing presence of a methylated progesterone receptor CpG island (17). We therefore examined the methylation status of the ER CpG island in TSA-treated MDA-MB-231 cells using a sensitive MSP assay that allowed examination of methylation status across the ER CpG island (Fig. 3A). As shown in Fig. 3A, the ER CpG island was completely methylated across the entire CpG island in MDA-MB-231 cells treated with vehicle or TSA (100 ng/ml for 48 h). A single primer set, ER 5, was used to confirm this finding in the other TSA-treated, ER-negative human breast cancer cells, Hs578T and MCF-7/AdrR (Fig. 3C). As expected, the unmethylated ER-positive, MCF-7 cells demonstrated an unmethylated pattern using all four primer sets that span the ER CpG island. In summary, TSA treatment of ER-negative breast cancer cells can lead to re-expression of ER mRNA without an apparent alteration in the methylation status of the ER CpG island.

Because acetylated histones are generally associated with transcriptionally active chromatin whereas deacetylated histones are often found in conjunction with an inactive chromatin state (18), we next studied whether HDAC inhibition could alter chromatin structure at the ER gene locus. Because nucleosome susceptibility is one of the characteristics of active chromatin (19), we used a DNase I sensitivity assay to examine chromatin conformation of the ER gene in ER-negative MDA-MB-231 cells in the presence or absence of the HDAC inhibitor, TSA. Cells were treated with 100 ng/ml of TSA for 48 h, a treatment course shown previously to result in optimal re-expression of ER mRNA. Equal amounts of purified nuclei from control and TSA-treated MDA-MB-231 cells were exposed to increasing concentrations of DNase I as described in "Materials and Methods." Nuclei isolated from ER-positive MCF-7 cells served as a DNase I accessible control. As expected, the ER locus in MCF-7 cells was a highly DNase I sensitive region, whereas the ER locus in control MDA-MB-231 cells was relatively resistant to DNase I digestion (Fig. 4B). TSA treatment of MDA-MB-231 cells resulted in an ~2-fold increase in DNase I sensitivity (Fig. 4C), suggesting that inhibition of HDAC activity leads to a more open chromatin conformation, even in the presence of CpG island methylation.

Recently, the interaction between DNA methylation and histone deacetylation linked by methyl-binding proteins (MBDs), or the direct interaction of Dnmt1 with HDAC as well as other corepressors, has

DNA methylation in breast cancer

X Yang, L Yan and N E Davidson

Breast Cancer Program, The Johns Hopkins Oncology Center, Johns Hopkins University School of Medicine, Baltimore, Maryland 21231, USA

Abstract

Like all cancers, breast cancer is considered to result in part from the accumulation of multiple genetic alterations leading to oncogene overexpression and tumor suppressor loss. More recently, the role of epigenetic change as a distinct and crucial mechanism to silence a variety of methylated tissue-specific and imprinted genes has emerged in many cancer types. This review will briefly discuss basic aspects of DNA methylation, recent advances in DNA methyltransferases, the role of altered chromatin organization and the concept of gene transcriptional regulation built on methylated CpGs. In particular, we discuss epigenetic regulation of certain critical tumor suppressor and growth regulatory genes implicated in breast cancer, and its relevance to breast cancer diagnosis, prognosis, progression and therapy.

Introduction

Cytosine methylation and CpG islands in mammals

In vertebrate genomes, methylation of DNA occurs on cytosine residues of the CpG dinucleotides in DNA (Bird 1980). This epigenetic alteration in DNA is heritable but does not alter nucleotide sequence, in contrast to genetic changes (Feinberg 2001). Thus, unlike genetic changes, epigenetic modifications are potentially reversible (Baylin et al. 2001). About 3–6% of cytosines are methylated in mammals. Approximately 70–80% of CpG sites in the human genome are methylated (Vanyushin et al. 1970, Antequera & Bird 1993, Bird 1995). Cytosine residues in newly synthesized DNA are methylated by DNA-cytosine methyltransferase-1 (DNMT1) (Bestor 1988, Bestor & Verdine 1994). This enzyme transfers a methyl group from the methyl donor, S-adenosylmethionine, to nascent DNA using a hemimethylated DNA template in order to maintain DNA methylation patterns during cell division in mammals. CpG dinucleotides are not randomly distributed throughout the genome. Rather they are frequently clustered into CpG islands, regions that are rich in CpG sites. These islands extend about 0.5–3 kb, occur on average every 100 kb in the genome and are often found in the promoter area of genes (Cross & Bird 1995). Indeed, approximately half of all genes in the human (~45 000 genes) contain CpG islands (Antequera & Bird 1993). DNA methylation plays a role in such diverse functions as gene imprinting (Fonse et al. 1997, Reik & Walter 1998), X-chromosome inactivation (Heard & Avner 1994, Heard et al. 1997), normal development (Li et al. 1993, Weiss & Cedar 1997), repression of gene transcription (Keshet et al. 1985, Cedar 1988, Chan et al. 2000), and the suppression of parasitic DNA sequences (Yoder et al. 1997). It is believed to exercise its critical role in gene expression via several routes. First, methylation of a CpG island is associated with loss of transcription of the target gene. Secondly, 5-methylcytosine (5meC) residues are susceptible to deamination to thymine, resulting in a transition mutation (Schmutte & Jones 1998). Thirdly, it is possible that inappropriate hypomethylation could be linked to dysregulated gene induction (Muller et al. 2001).

DNMTs

To date, three members of the Dnmt gene family have been identified. Direct sequence analysis has revealed that the Dnmt gene family is highly conserved among eukaryotes, suggesting a central role of these proteins for development (Bestor 2000).

DNMT1 is the best known and studied member of the DNMT family. It is primarily a maintenance methylase, that is, it reproduces DNA methylation patterns from hemimethylated DNA during cell division (Bestor 1988). However, there is some evidence that DNMT1 may also have de novo methylase activity, at least in in vitro systems.
Yang et al.: DNA methylation in breast cancer

(Laeyoun & Smith 1995, Pradhan et al. 1997). Dnmt1 gene knockout mice die in mid-gestation with reduced levels of DNA methylation (Li et al. 1992), disrupted imprinting and ectopic X-chromosome activation (Li et al. 1993), indicating that maintenance of DNA methylation is pivotal for development.

The human DNMT1 gene is located at human chromosome 19p13.2 (Yen et al. 1992) and encodes a 200 kDa protein whose methyltransferase catalytic domain is located at the C-terminus of the protein. The large N-terminal portion of DNMT1 targets to replication foci through proliferating cell nuclear antigen (PCNA) (Chuang et al. 1997). Recent studies have identified new functions for this domain. First, its amino acid (653–730) sequence contains a CXXC motif that interacts directly with histone deacetylases (HDACs), which act to remove acetyl tails from histones in the nucleosome to generate a transcriptionally inactive chromatin structure (Fukuoka et al. 2000). Secondly, through its first 120 amino acids, it binds to a transcriptional co-repressor, DMAP1, that represses transcription independent of HDAC activity (Kountz et al. 2000). Lastly, amino acids 416–913 of the N-terminus of DNMT1 interact with the retinoblastoma protein, Rb (Robertson et al. 2000). Thus, the N-terminal portion of DNMT1 alone or in collaboration with other co-repressors and recruited HDACs significantly suppresses transcription in vitro.

A large body of data demonstrates that DNMT1 activity is elevated in neoplastic cells and this increased activity is associated with increased cell proliferation (El-Deiry et al. 1991), tumorigenesis (De Marzo et al. 1999) and tumor progression (Issa et al. 1993). For example, overexpression of DNMT1 can transform NIH-3T3 mouse fibroblast cells (Wu et al. 1993), and inhibition of this enzyme by antisense constructs can induce global DNA demethylation and revert the malignant phenotype (Ramchandani et al. 1997). In addition, fos-mediated transformation of normal fibroblasts is associated with increased DNMT1 expression and total methylation content in the genome (Bakin & Curran 1999). Finally, it is also reported that elevation of DNMT1 is an essential component of transformation induced by SV40 large T antigen via the Rb pathway (Slack et al. 1999).

However, increased DNMT1 expression is apparently not an obligatory feature of malignant cells (Eads et al. 1999). Somatic knockout of DNMT1 expression in human colon cancer cells is not a lethal event. Further, total genomic methylated CpG content was reduced by only about 20% and certain gene-specific CpG island methylation patterns were maintained (Rhee et al. 2000). These findings, together with the observation that embryonic stem (ES) cells from DNMT1 knockout mice are still capable of de novo methylation, suggest the possible existence of other DNMTs (Li et al. 1992, Lei et al. 1996).

One such DNMT, Dnmt2, was isolated by several groups (Okano et al. 1998). However, its catalytic domain lacks DNMT activity in the human and it is not discussed further.

Two isoforms of the DNMT3 enzyme family, de novo DNMTs 3a and 3b (Dnmt3a and 3b) were recently isolated in the mouse (Okano et al. 1999). They methylate CpG dinucleotides of unmethylated and hemimethylated DNA in vitro. The two genes are expressed at high levels in ES cells and relatively low levels in adult somatic tissues. Human DNMT3a has been mapped to chromosome 2p23 whereas DNMT3b maps to chromosome 20q11.2 (Robertson et al. 1999, Xie et al. 1999).

Disruption of both Dnmt3a and Dnmt3b in mice by gene targeting blocks de novo methylation in ES cells and early embryos, but has no effect on maintenance of an imprinted methylation pattern (Okano et al. 1999). However, methylation capability is retained after inactivation of either Dnmt3a or 3b, indicating some redundancy in the function of these two de novo methylases. Dnmt3b appears to be critical for the methylation of a particular compartment of the genome; loss of DNMT3b catalytic activity by gene mutation in the syndrome of immunodeficiency, centromeric instability and facial anomalies causes demethylation of only specific families of repeated sequences and CpG islands on the inactive X-chromosome (Hansen et al. 1999). Human DNMT3a is ubiquitously expressed but DNMT3b is expressed at low levels except in testis, thyroid and bone marrow. Overexpression of both DNMT3b and DNMT3a appears to characterize multiple types of human tumors (Xie et al. 1999). Four spliced forms of DNMT3b with altered enzymatic activity were expressed in a tissue-specific manner (Robertson et al. 1999). Future study will be needed to elucidate the possible roles of DNMT3 family members in tumorigenesis, de novo tissue-specific gene methylation and transcriptional regulation in somatic tissues.

Altered CpG island methylation, chromatin organization and transcriptional regulation

Much experimental evidence has documented the association of CpG island methylation and gene transcriptional inactivity but only recently have the underlying mechanisms of transcriptional silencing by methylation been partially clarified. One possible mechanism of transcriptional repression is the direct interference by methylation with the binding of sequence-specific transcription factors, such as AP-2, E2F and NFkappaB to DNA (Hermann & Doerfler 1991). A second possibility is that methylated CpG sequences recruit transcriptional co-repressors like mSin3A, DMAP1, TSG101 or Mi2, thereby contributing to transcriptional repression. Finally, chromatin structure is emerging as an important and more generalized mechanism to silence a variety of methylated tissue-specific and imprinted genes by HDAC family members. The deacetylation of lysine groups

www.endocrinology.org

116
of histones H3 and H4 allows ionic interactions between positively charged lysines and negatively charged DNA, resulting in a more compact nucleosome structure that limits gene activity. The discovery of the family of methyl-CpG-binding proteins provides a mechanistic linkage between DNA methylation and histone deacetylation as mediators of gene transcription. To date, six methyl-CpG-binding proteins including MeCP2, MBD1, MBD2a, MBD2b and MBD3 have been identified in vertebrates (Nan et al. 1998, Wade et al. 1998, Ng et al. 1999, 2000, Snape 2000). The common functional features for these proteins are that they bind to methyl-CpGs in DNA and frequently associate with members of the HDAC family, which currently includes eight distinct members (Ng & Bird 2000). That these processes might collaborate to regulate gene expression is demonstrated by a recent study, showing that multiple hypermethylated genes, such as MLH1, TIMP-3, CDKN2B and CDKN2A, could be robustly reactivated by a combination of DNMT1 and HDAC inhibition, suggesting that DNMT1 and HDAC are both essential in the silencing process in these colon cancer cells (Cameron et al. 1999). The above observation was confirmed by a very recent study that the known DNA methylation machinery protein, DNMT1 itself, is implicated in forming transcriptionally repressive complexes with HDAC as well as other co-repressors (Rountree et al. 2000).

**DNA methylation patterns in normal tissues and cancer**

Cell type and tissue-specific methylation patterns are established during early development, in part through the action of the de novo Dnmt3a and 3b (Okano et al. 1999). The sperm genome is extensively methylated while the oocyte genome is not. After fertilization, genes are demethylated and then remethylated before implantation. As the embryoblast differentiates, tissue-specific genes are demethylated in a tissue-specific fashion while housekeeping genes remain demethylated from fertilization through organogenesis (Bestor 1998).

CpG islands are generally unmethylated in normal adult tissues with the exception of transcriptionally silent genes on the inactive X-chromosome and imprinted genes like the H19 gene (Tremblay et al. 1995). Conversely, most neoplastic tissues demonstrate whole genomic hypomethylation and local promoter hypermethylation in certain critical tumor suppressor and growth regulatory genes (Baylin et al. 1998). The mechanism responsible for this type of pattern remains largely unclear. It is believed that the cell cycle checkpoint gene p15, p21WAF1/CIP1, may play a role in methylation regulation (Baylin et al. 1998). Since p21 competes with DNMT1 binding to PCNA, loss of p21 function may increase DNMT1 at replication sites (Chuang et al. 1997). In addition, mutation of another cell cycle gene, Rb, may play a role as Rb mutation in its A/B pocket domain might disrupt the function of the transcriptionally repressive protein complex that involves Rb, DNMT1 and HDAC. Mistargeting of DNMT1 could then result (Robertson et al. 2000). Together, these observations are beginning to shed light on the paradox of global hypomethylation, increased CpG island hypermethylation, and increased DNMT1 activity in tumor cells.

**DNA methylation and genetic instability**

DNA methylation changes may ultimately lead to the genetic instability characteristic of cancer in several ways. First, 5mCs serve as sites of transition mutations by the hydrolytic deamination of 5mC to thymine. For example, such mutations frequently occur in the well-known p53 tumor suppressor gene (Magewu & Jones 1994). Similar point mutations characterize the mutations found in several other important genes like Rb, and c-H-ras-1 (Ghazi et al. 1990).

Secondly, epigenetic inactivation of certain critical genes in cancer by promoter methylation may predispose to genetic instability (Herman & Baylin 2000). For instance, methylation of MLH1, a gene involved in mismatch repair, precedes the MIN + phenotype in sporadic colon, gastric and endometrial cancers (Esteller et al. 1999a). Further, there is a striking correlation between mismatch repair, genetic instability and methylation capacity in colon cancer cell models (Lengauer et al. 1997, 1998). In addition, promoter CpG island methylation and resulting inactivation of the detoxifying pi-class glutathione S-transferase (GST) can lead to accumulation of oxygen radicals and subsequent DNA damage. The resulting adenine or guanine mutations are implicated in carcinogenesis in prostate, breast and other tissues (Lee et al. 1994, Henderson et al. 1998, Matsui et al. 2000). Further, a p53-inducible gene, 14-3-3-s is methylated and inactivated in many breast cancers. Loss of its expression may also facilitate the accumulation of genetic damages (Ferguson et al. 2000).

Apart from regional hypermethylation of some critical tumor suppressor genes, genome-wide hypomethylation is an important feature in cancer. This also could contribute to genetic instability (Schmutte & Fishel 1999).

**Methylation of critical tumor suppressor and growth regulatory genes in breast cancer**

A large body of evidence has demonstrated that CpG island hypermethylation is implicated in loss of expression of a variety of critical genes in breast cancer. Some important genes inactivated by methylation in breast cancer are summarized in Table 1 and described below. They fall into several broad categories including cell cycle regulating, steroid receptor, tumor susceptibility, carcinogen

Methylation of cell cycle-related genes in breast cancer

p16/p16INK4A/CDKN2A/MTS methylation and breast cancer

The p16 gene is located on chromosome 9p21. It encodes a cyclin-dependent kinase inhibitor, p16INK4A, that regulates the transition from G1- to S-phase via its effect on Rb phosphorylation (Liggett & Sidransky 1998). The transcription of the p16INK4A gene can yield two distinct transcripts (α or β) that code for two functionally distinct proteins, p16INK4A and p19ARF. These two transcripts share identical second and third exons but have distinct first exons (Sharpless & DePinho 1999). Loss of p16INK4A resulting from homozygous deletion, methylation of p16 promoter or point mutation is a common feature of many cancers. Methylation of the 5’ promoter and exon 1 regions is observed in both human breast cancer cell lines (Table 2) and 20-30% of primary breast cancers (Herman et al. 1995, Woodcock et al. 1999). The methylation phenotype is associated with loss of expression at both mRNA and protein levels although it does not correlate with some important clinical parameters in some relatively small cohort studies. For example, a study of 97 patients with breast cancer showed no association between p16 methylation and overall or disease-free survival (Hui et al. 2000).

Finally, the stepwise inactivation of cyclin D-dependent kinase inhibitor p16INK4A in human mammary epithelial cells (HMEC) is associated with progressive methylation of the p16 promoter CpG island. This allows HMECs to escape from M0 proliferation block, thereby identifying CpG methylation together with p16 silencing as a possible contributor to breast tumorigenesis (Foster et al. 1998).

14–3–3σ gene inactivation by methylation

The 14–3–3σ gene (also known as HME1), is localized at chromosome 1p35, and is a member of a gene family responsible for instituting the G2 cell cycle checkpoint in response to DNA damage in human (Chan et al. 1999). Normally expression of σ is induced in response to DNA damage, and it causes cells to arrest in G2. However, σ protein expression was downregulated in a significant fraction of primary bladder, colon and breast tumors (Celis et al. 1999). Studies of the molecular mechanisms responsible for the reduced expression have implicated hypermethylation of the CpG-rich exon 1 region of the gene, instead of genetic alterations such as loss of heterozygosity (LOH) and intragenic mutations in breast cancer (Ferguson et al. 2000). DNA from HMECs, immortal MCF-10A and HBL100 cells and two breast cancer cell lines, MCF-7 and MDA-MB-231, were unmethylated at the σ locus. In contrast, Hs578t and MDA-MB-435 cells were fully methylated as demonstrated by bisulfite genomic sequencing and methylation specific PCR (MSP) analyses. The use of 5-aza-2’-deoxycytidine (5-aza-dC) to treat the methylated non-expressing lines in vitro led to induction of transcription, further supporting the role of CpG island methylation in its repression. In addition, six DNA samples from microdissected normal mammary epithelial cells demonstrated an unmethylated pattern while 32 samples from microdissected breast carcinomas were methylated. Together, these cell line- and tissue-based studies support a role for methylation in the loss of 14–3–3σ expression in breast cancer.

Methylation of steroid receptor genes in breast cancer

The methylation of three members of the steroid hormone superfamily has been extensively studied in breast cancer models. These include estrogen receptor (ER) α, progesterone receptor (PR) and retinoic acid receptor-β (RARβ).

ERα methylation and hormone resistance

Steroid hormones, particularly estrogen, have long been linked to mammary carcinogenesis (Fishman et al. 1995). The role of estrogen and its catechol metabolite in breast cancer initiation and promotion is a continuing area of controversy (Yager 2000). That 17β-estradiol stimulates the growth of certain breast cancers via functional ER is well recognized, and endocrine therapy is an established and important part of breast cancer management (Ruiz-Cabello et

al. 1995, Davidson 2000). The presence of ER in breast tumors is a predictive marker for response to hormone therapy. However, up to one-third of breast carcinomas lack ER at the time of diagnosis and a proportion of cancers that are initially ER-positive lose ER during tumor progression (Hortobagyi 1998). Genetic alterations, such as homozygous deletion, LOH or ER gene mutation have not been reported to play a major role in loss of ER expression.

However, recent studies have shown that epigenetic alteration appears to play a role in inactivation of the gene (Ottaviano et al. 1994). The ER gene, located at chromosome 6q25.1, has a CpG island in its promoter and first exon regions. As demonstrated by Southern and methylation-specific PCR analyses, the ER CpG island is unmethylated in normal breast tissue and ER-positive tumor cell lines, such as MCF-7, T47-D and ZR75-1; it is methylated in ~50% of unselected primary breast cancers and most ER-negative cancer cell lines, e.g. MDA-MB-231, MDA-MB-435, MDA-MB-468, Hs578t and MCF-7/Adr (Table 2) (Lapidus et al. 1998). The ER CpG island methylation is associated with reduced or absent ER mRNA expression. The use of the methyltransferase inhibitors 5-aza-cytidine (5-aza-C) and 5-aza-dC, led to partial demethylation and restoration of ER mRNA expression, and synthesis of functional ER protein (Ferguson et al. 1995).

Restored ER function was documented by eliciting estrogen response element-driven promoter activity from an exogenous plasmid as well as expression of the ER-responsive gene, PR.

In order to study de novo ER gene methylation in vitro, DNMT1 activity levels were measured in a panel of breast cancer cell lines. Expression of DNMT1 at both RNA and protein levels in ER-negative breast cancer cell lines is significantly elevated in ER-negative breast cancer cell lines compared with their ER-positive counterparts (Ottaviano et al. 1994). Detailed studies showed that DNMT1 expression was tightly correlated with S-phase fraction in ER-positive cells, while ER-negative cells expressed DNMT1 throughout the cell cycle, suggesting its expression is dysregulated in ER-negative breast cancer cells (Nass et al. 1999). The data also showed that DNMT1 and p21 expression are inversely correlated in the breast cancer cell lines examined. Studies using DNMT1 antisense constructs showed that decreased expression of DNMT1 protein is linked to increased p21 protein expression. Since p21 competes with DNMT1 for targeting to PCNA, the increased p21 may lead to inhibition of DNA replication and methylation in these tumor cells (Chuang et al. 1997).

A related question is whether an inactive chromatin structure mediated by HDAC is involved in ER gene silencing. In fact, inhibition of HDAC by HDAC inhibitor (A, trichostatin TSA) induced ER transcript by 5-fold in a panel of well-characterized ER-negative MDA-MB 231, Hs578t and MCF-7/Adr cell lines. This transcriptional reactivation was associated with increased sensitivity to DNaseI at the ER locus without alteration of the methylated CpG sites, suggesting that open chromatin structure is associated with ER expression even in the presence of ER CpG island methylation (Yang et al. 2000). Our findings identified a role for both DNA methylation and histone acetylation in the regulation of ER gene transcription.

PR gene methylation

The PR gene, located at chromosome 11q13, also has a CpG island in its first exon (Lapidus et al. 1996). The PR gene encodes two isoforms, hPRa (79 kDa) and hPRb (90 kDa), which differ in both their N-terminal sequences and biological activities. The hPRb transcript is preferentially induced by ER while the hPRa is not. Since ligand-bound ER is a major transcriptional activator of hPRb gene expression, the presence of PR is indicative of functional ER. PR gene methylation has been demonstrated by Southern analysis in ~40% of PR-negative breast tumors and several PR-negative breast cancer cell lines (Table 2). A possible functional role for PR CpG island methylation is suggested by the observation that treatment of PR-negative MDA-MB-231 cells with 5-aza-dC in the presence of estrogen led to partial demethylation of the PR CpG island.
Yang et al.: DNA methylation in breast cancer

and re-expression of PR gene. Co-treatment with both 5-aza-dC and a pure anti-estrogen, ICI 182,780, prevented PR reactivation, suggesting that demethylation alone is not sufficient to reactivate PR expression. Rather it appears that ER-mediated chromatin remodeling is essential and sufficient to activate PR gene expression even in the presence of a methylated PR CpG island (Ferguson et al. 1998).

**RARβ2 gene methylation**

RARα, -β and -γ and retinoid X receptors-α, -β and -γ are also members of the nuclear receptor superfamily (Minucci & Pelicci 1999). All six of these receptors are ligand-activated transcription factors (Chambon 1996). The RARβ gene, located at chromosome 3p24, appears to play an important role in limiting the growth of certain tumor types, including breast, lung and others. RARβ2 expression is often reduced or lost in breast cancer cells and they become resistant to induction by all-trans-retinoic acid (ATRA) (Swisschelm et al. 1994, Jing et al. 1996, Widschwendter et al. 1997). DNA methylation of the RARβ promoter is believed to be one of the factors linked to RARβ2 downregulation in breast cancer (Widschwendter et al. 2000). RARβ promoter methylation has been demonstrated by Southern and methylation-specific PCR analyses in several RARβ2-negative human breast cancer cell lines and about one-third of unselected primary breast cancer specimens (Sircia et al. 2000). It is not observed in normal breast tissue or HMECs. There is no apparent correlation with ER status. As with other methylated genes, treatment of RARβ2-negative cell lines with 5-aza-dC can partially re-induce RARβ2 transcripts. Of note, the HDAC inhibitor TSA can also reactivate RARβ2 expression in the presence of a methylated promoter, implicating inactive chromatin conformation as another possible regulatory process.

**GSTP1 inactivation by methylation and its predisposition to genetic instability**

Glutathione (GSH) and its corresponding cytosolic GSTs are involved in the detoxification pathway of xenobiotics and chemotherapeutic agents (Daniel 1993). They catalyze intracellular detoxification reactions by conjugating chemically reactive electrophiles to GSH, inactivating electrophilic carcinogens (Mannervik et al. 1985). The GSTs, encoded by several different genes at different loci, have been classified into α, μ, π and θ families. The π-class GST, encoded by the GSTP1 gene, on chromosome 11, is of particular importance in breast cancer (Cairns et al. 1992, Gilbert et al. 1993). In cultured breast cancer cell lines an inverse relationship between GSTP1 and ER gene expression has been reported, i.e. GSTP1 was expressed in ER-negative but not in ER-positive lines (Table 2) although the underlying mechanism is unclear (Jhaveri & Morrow 1998). Treatment of the GSTP1-negative cell line MCF-7 with 5-aza-dC could induce mRNA expression and de novo synthesis of π-class protein. MSP-based studies of human tissues demonstrated that GSTP1 promoter methylation is associated with gene inactivation in about 30% of primary breast carcinomas (Esteller et al. 1998). The detection of GSTP1 methylation correlates with PR expression but there was no correlation with other clinical parameters such as the age at onset, histological type and grade, tumor size, nodal metastasis, DNA ploidy or ER status (Esteller et al. 1998). It is postulated that methylation-associated inactivation of GSTP1 can result in adenine or guanine mutation by estrogen metabolites-DNA adduct formation and lead to genetic instability (Cavalieri et al. 1997).

**BRCA1 methylation in sporadic breast cancer**

The BRCA1 gene, located at chromosome 17q21, is a well-known breast cancer susceptibility gene (Miki et al. 1994). Inactivation of BRCA1 expression through antisense oligonucleotides increases the proliferation of normal and malignant mammary cells while overexpression of wild-type BRCA1 suppresses MCF-7 breast cancer cell tumorigenesis in mice. Inherited mutations in the BRCA1 gene account for one-half of inherited breast carcinomas (Friedman et al. 1994). However, in contrast to other tumor suppressor genes, somatic mutations in this gene have not been reported, despite the high degree of LOH at the BRCA1 locus in sporadic breast and ovarian cancer (Merajver et al. 1995). Since BRCA1 transcript and protein are either absent or reduced in sporadic breast cancer, DNA methylation has been proposed as an alternative mechanism to inactivate BRCA1 (Dobrovic & Simpfendorfer 1997, Magdinier et al. 2000). By Southern analysis of the BRCA1 promoter region, methylation was detected in 11% of sporadic breast cancer cases and was inversely correlated with expression of both ER and PR (Cateau et al. 1999). A study with 194 primary breast carcinomas demonstrated that the BRCA1 promoter is methylated in 13% of unselected primary breast tumors (Esteller et al. 2000b). BRCA1 methylation was especially associated with medullary and mucinous subtypes. As expected, BRCA1 was unmethylated in all normal tissues examined as well as in 21 breast cancer cell lines (Table 2). The methylation was present in two breast cancer xenografts with concomitant loss of gene transcript. In this study one allele is lost by LOH and the other is inactivated by aberrant methylation, thereby resulting in biallelic inactivation and loss of functional BRCA1 gene product. Finally, BRCA1 methylation is only observed in breast and ovary cancers but not in tumors of colon or liver or leukemia, supporting a tissue-specific event for the process. Using chromatin immunoprecipitation and endonuclease chromatin accessibility assays, transcriptional repression of BRCA1 by cytosine methylation is also mechanistically linked to histone deacetylation and inactive chromatin structure.
E-cadherin gene methylation and breast tumor progression

The E-cadherin gene, located at chromosome 16q22.1, encodes a cell-surface adhesion protein that is important in maintaining homophilic cell-cell adhesion in epithelial tissues (Ilyas & Tomlinson 1997). Considerable evidence shows that loss of expression and function of E-cadherin protein contributes to increased proliferation, invasion and metastasis in breast cancer (Oka et al. 1992). Classical mutations and deletions clearly play a role in loss of the E-cadherin expression and function (Cleton-Jansen et al. 1994, Risinger et al. 1994). However, several studies demonstrate that epigenetic silencing of the E-cadherin gene by 5' CpG methylation occurs in some human breast cancer cell lines (Table 2) as well as about 50% of unselected primary breast cancers (Graff et al. 1995, Hiraguri et al. 1998). Its loss of expression is associated with tumor metastatic progression and decreased patient survival (Bringuier et al. 1993). Our recent work demonstrated that hypermethylation of the E-cadherin CpG island was evident in about 30% of ductal carcinomas in situ and increased significantly to nearly 60% of metastatic lesions (Nass et al. 2000), suggesting a role for this process in breast tumor progression.

Methylation and inactivation of TIMP-3 gene

TIMP-3 belongs to a family of molecules that inhibit the proteolytic activity of the MMPs (Gomez et al. 1997, 1999). This protein can suppress primary tumor growth via its effects on tumor development, angiogenesis, invasion and metastasis (Uria et al. 1994). Methylation of its 5'CpG island has been associated with the loss of TIMP-3 expression at both transcript and protein levels in several tumor types (Bachman et al. 1999). The TIMP-3 promoter region is methylated in ~30% of human breast cancer cell lines as well as ~30% of primary breast tumors (Bachman et al. 1999). TIMP-3 gene methylation has been associated with its loss of expression as its expression could be restored by 5-aza-dC treatment, again supporting a role for epigenetic mechanism in TIMP-3 gene regulation.

Clinical implications of epigenetic regulation in breast cancer

Recognition of the important roles that DNA methylation and histone deacetylation play in gene expression in malignancy including breast cancer has led to consideration of how these findings can be exploited clinically. Two areas for exploration are the use of methylated markers for detection and prognosis, and the application of DNMT and HDAC inhibitors therapeutically to re-express silenced tumor suppressor and growth inhibitory genes.

Methylated markers for detection and prognosis

One of the tenets of epigenetic regulation is that CpG islands are generally unmethylated in normal adult tissues with rare exceptions. In contrast, as noted earlier, hypermethylation of various gene promoters is a common feature of malignant cells and these changes can occur early in the progression process. For example, about one-third of ductal carcinoma in situ lesions demonstrated methylation of the E-cadherin or ER promoter CpG islands (Nass et al. 2000). The availability of PCR-based strategies to assess methylation changes in minute quantities of biological materials raises the possibility that identification of methylated alleles might serve as a means of molecular risk assessment or detection (Herman et al. 1996). Indeed the ability to detect methylated genes in serum, urine, bronchoalveolar lavage fluid and lymph nodes derived from individuals with various types of malignancies has been described (Esteller et al. 1999b). In some cases methylated changes were also detected in samples banked well before the diagnosis of malignancy, raising the possibility that this type of analysis could facilitate risk assessment or early diagnosis strategies. One potential application in breast cancer would be the assessment of methylated markers using nipple duct lavage fluids or fine needle aspirates of the breast, as it could be hypothesized that their presence would predict a higher likelihood of subsequent breast cancer development. Other applications could include molecular staging of sentinel lymph nodes or bone marrow aspirates. Such studies will first require the development of a panel of methylated markers that would together identify virtually all breast cancers but that are unmethylated in normal tissues (Evron et al. 2001).

Finally, another possible clinical application for gene-specific methylation is prediction of prognosis or treatment outcome in certain cancers (Weinstein 2000). For example, the DNA-repair enzyme O'6-methylguanine-DNA methyltransferase (MGMT) inhibits the ability of alkylating agents to kill tumor cells; loss of its expression by methylation might be expected to sensitize tumor cells to this class of agents. Indeed, methylation of MGMT is correlated with increased overall and disease-free survival and improved response to the alkylating agent carmustine in glioblastoma patients (Esteller et al. 2000a). Therefore, MGMT promoter methylation is a marker of good prognosis and predicts response to chemotherapy for glioblastoma patients.

DNMT and HDAC inhibitors for therapy of breast cancer

Although heritable, epigenetic changes are potentially reversible. Therefore, the prospect of intervening to reverse these changes as a possible means of reverting the malignant
Yang et al.: DNA methylation in breast cancer

phenotype is an attractive one. The availability of DNMT and HDAC inhibitors makes this a testable strategy.

DNMT inhibitors

The classic DNMT inhibitors, 5-aza-C and 5-aza-dC are cytosine analogs that are incorporated into replicating DNA (Jones & Taylor 1980, Jones 1985). The subsequent formation of covalent adducts between DNMT and 5-aza-C-substituted DNA irreversibly inactivates DNMT (Santi et al. 1984, Ferguson et al. 1997). One potential consequence then is the reactivation of previously methylated genes that have been transcriptionally silent. These analogs have been used clinically for treatment of patients with hemoglobinopathies, myelodysplasia and leukemia (Rivard et al. 1981, Ley et al. 1983). The clinical benefit observed has been associated with reactivation of previously silenced genes as, for example, the observation that 5-aza-treated sickle cell patients have improved hemoglobin and increased fetal hemoglobin (Nienhuis et al. 1985). Such strategies could potentially be applied to epithelial malignancies as well. For example, a gene microarray analysis of the effect of 5-aza-dC on HT29 colon cancer cells identified members of the interferon (IFN) response pathway as re-expressed genes (Karpf et al. 1999). Follow-up studies showed that 5-aza-dC treatment of these cells in vitro sensitized them to growth inhibition by exogenous IFN-a2a. Thus unmasking of new therapeutic targets may be enhanced.

The elevated level of DNMT activity in cancer has also prompted development of more specific agents like antisense oligonucleotides to DNMT1. In vitro studies have shown that antisense treatment of human T24 bladder cancer cells and A549 non-small lung carcinoma cells can cause reduced DNMT1 levels, demethylation of the p16INK4a gene promoter, re-expression of p16INK4a protein, accumulation of the hypophosphorylated form of the Rb protein, increase in p21WAF1, and cell growth arrest (Fournel et al. 1999). Thus, this specific targeting of DNMT1 can activate silent tumor suppressors.

HDAC inhibitors

Several structural classes of HDAC inhibitors have been identified. Phenylbutyrate, a short chain fatty acid that inhibits HDAC at millimolar concentrations and is approved for clinical use by the US Food and Drugs Administration (FDA), is an example of the first class (Carducci et al. 1996). The second class includes the hydroxamic acids, trichostatin A (Yoshida et al. 1990) and suberoylanilide hydroxamic acid (SAHA) (Richon et al. 1998). Nanomolar concentrations of TSA have been used widely in in vitro systems to inhibit HDAC activity and modify gene transcription. SAHA is also active in in vitro models at micromolar concentrations. It induces terminal cell differentiation with milk protein synthesis in MCF-7 cells (Richon et al. 1998). Further, its administration reduced the incidence of N-methyl-
nitrosourea-induced mammary carcinoma in rats without apparent toxicity (Desai et al. 1999). Phase I trials of SAHA are in progress (Marks et al. 2000). The third class of HDAC inhibitor, benzamide derivatives like MS-27-275, also showed marked activity against human tumor xenografts in mice (Saito et al. 1999). The fourth class includes cyclic tetrapeptides containing a 2-amino-5-oxo-9,10-epoxy-decanoyl (AOE) moiety such as trapoxin A (Kijima et al. 1993), while FR 901228 and apicidin are representative of the fifth class of cyclic peptides that lack an AOE moiety (Nakajima et al. 1998).

Combination strategies

Combined therapies may ultimately offer the best antineoplastic approach. If successful, such strategies could utilize agents that alone are ineffective but together result in the desired biological outcome. For example, sequential treatment of colon cancer cells with a demethylating agent followed by an HDAC inhibitor led to reactivation of multiple target genes whose expression was not affected by either agent alone (Cameron et al. 1999). Our own studies show that combined therapy of MDA-MB-231 cells with 5-aza followed by TSA results in re-expression of ER at lower doses than those needed with either single agent (Yang et al. 2001). Thus, it may be possible to use lower doses or shorter exposure durations to achieve the appropriate molecular effects, thereby increasing therapeutic effects, minimizing toxicity and improving ease of administration.

Alternatively, use of an 'epigenetic modifier' may enhance the response to another type of agent. The use of 5-aza and IFN in colon cancer cells was mentioned above. A human proof of principle for this general strategy is seen in the report of a patient with acute promyelocytic leukemia resistant to ATRA who developed a sustained remission after concomitant treatment with phenylbutyrate and ATRA (Warrell et al. 1998).

Conclusions

Taken together, substantial evidence demonstrates the importance of epigenetic mechanisms in the transcriptional regulation of critical tumor suppressor and growth regulatory genes in breast cancer. These genes include those that play crucial roles in DNA repair, cell cycle regulation, cell growth and cell-cell adhesion. These changes, along with the intrinsic ability of 5meC to function as a mutagen and the negative effects of dysregulated DNMT1 activity, can all contribute to breast cancer tumorigenesis and/or progression. A better understanding of epigenetic regulation of gene expression in a gene-specific and tissue-specific fashion will help efforts to modulate gene expression selectively with the ultimate goal of improved breast cancer prevention and therapy.

Role of DNA Methylation and Histone Acetylation in Steroid Receptor Expression in Breast Cancer

Lan Yan, Xiaowei Yang, and Nancy E. Davidson

DNA methylation is an epigenetic modification that is associated with transcriptional silencing of gene expression in mammalian cells. Hypermethylation of the promoter CpG islands contributes to the loss of gene function of several tumor related genes, including estrogen receptor α (ER) and progesterone receptor (PR). Gene expression patterns are also heavily influenced by changes in chromatin structure during transcription. Indeed both the predominant mammalian DNA methyltransferase (DNMT1), and the histone deacetylases (HDACs) play crucial role in maintaining transcriptionally repressive chromatin by forming suppressive complexes at replication foci. These new findings suggest that epigenetic changes might play a crucial role in gene inactivation in breast cancer. Further, inhibition of DNA methylation and histone deacetylation might be a therapeutic strategy in breast cancer, especially for those cancers with ER and PR negative phenotypes.

INTRODUCTION

DNA Methylation and Cancer-Related Gene Expression

Approximately 3–5% of the cytosine residues in the human genome are methylated (1). Seventy to eighty percent of these 5-methylcytosines are located in clusters of CpG dinucleotides, termed CpG islands, typically found in the 5' promoter region and first exon of certain genes (2). This methylation modification is essential not only in mammalian development, but also in epigenetic regulation of gene expression, including genomic imprinting and X chromosome inactivation (3–5). Methylation of a CpG island is frequently associated with loss of expression of the target gene. Recent studies have provoked increasing interest in the role of DNA hypermethylation in tumorigenesis through its ability to alter the expression of tumor suppressor genes (6).

The DNA methylation reaction is catalyzed by a family of DNA methyltransferases (DNMTs) by use of the universal methyl donor, S-adenosylmethionine. Three distinct DNMTs have been identified in mammalian cells so far, namely DNMT1, DNMT2 and DNMT3. DNMT1 is constitutively expressed in mammalian cells and its function is to maintain the identical methylation pattern after DNA replication (7). That this function is critical is suggested by the finding that Dnmt1 gene knockout mice demonstrated global DNA demethylation and embryonic lethality (8, 9). On the other hand, somatic knockout of the DNMT1 gene in human colorectal carcinoma cells led to markedly decreased cellular DNMT activity, but only...
a 20% decrease in overall genomic methylation was observed, mainly at juxtacentromeric satellites. Most of the gene-specific CpG islands analyzed remained fully methylated and silenced (10). These results suggest that DNMT1 might not be the only critical enzyme in maintaining human genome methylation status, and its exact role in mammalian development and gene transcription regulation needs to be further elucidated. DNMT2 is expressed at low levels in most adult tissues examined but recombinant mouse DNMT2 has no DNA methyltransferase activity (11-13). Thus the importance of DNMT2 is not clear. DNMT3 does have de novo methyltransferase activity and is highly expressed in embryonic stem cells. It has two isoforms, namely DNMT3A and DNMT3B. Unlike DNMT2, recombinant mouse DNMT3A and 3B can methylate cytosine residues in various native and synthetic DNA templates (14). DNMT3A expression is ubiquitous. It can be readily detected in most adult tissues, whereas DNMT3B expression is highly elevated in several tumor cell lines, including leukemia, melanoma, and colorectal cancer cell lines, to a level comparable to DNMT1 in these cell lines (15). How other DNMT family members, such as DNMT2, DNMT3A, DNMT3B, or other novel methylating proteins contribute to CpG methylation during normal development or tumorigenesis needs to be addressed in future study.

Methylation patterns in tumors are perplexing. In general, the level of 5-methylcytosine in tumor cells is lower than that in normal cells (16, 17). However, this global hypomethylation is observed in conjunction with regional hypermethylation at CpG islands, in turn associated with transcriptional inactivation of an increasing number of cancer-related genes. Thus far, a variety of genes, including tumor suppressor genes, DNA mismatch repair genes, cell cycle related genes, hormone receptors and tissue or cell adhesion molecules have been reported to be regulated by promoter CpG methylation. The inactivation of gene expression by aberrant CpG island hypermethylation is supported by studies using the demethylating agents, 5-azacytidine (5aza) and 5-aza-2'-deoxycytidine (deoxyC). Application of these agents to several cancer cell lines has been shown to demethylate CpG islands and reactivate expression of the previously silenced genes. In addition, recent studies suggest that hypermethylation of a CpG island not only can silence the gene it regulates, but also facilitate genetic alterations in tumor progression. PIGK+4a (18-21), MLH1 (22, 23), and GSTP1 (24, 25) are the best examples to support this “facilitation hypothesis.”

Accumulating evidence suggests that hypermethylation of these three genes occurs in the early stages of tumorigenesis, predisposing cells to later genetic instability, which then contributes to tumor progression. Thus it appears that both epigenetic and genetic changes can contribute to the carcinogenic process.

**Histone Acetylation, Chromatin Stability and Gene Expression**

Chromatin structure and gene transcription are regulated partially by histone acetylation. During the S phase of the cell cycle, histone acetyltransferases (HAT) transfer an acetyl moiety to the ε-amino group of the amino acid, lysine, on histones, leading to neutralization of the positive charge and reduced affinity of histone for DNA. The ultimate consequence of this acetylation modification is the transformation of a tight-coiled inactive chromatin structure into a loose, transcriptionally active one (26). This process is reversed by histone deacetylation mediated by histone deacetylases (HDAC) during the G2 phase of the cell cycle. Deacetylated histones expose their positive charges to negatively charged DNA, leading to a condensed inactive chromatin structure. HDAC seems to play a role in gene silencing as well as in transcriptional activation (27, 28). In addition, HDACs are also involved in cell differentiation, cell-cycle arrest, apoptosis, chemosensitization, radiosensitization, antitumor effects and up-regulation of MHC class I (29). Three families of HDAC have been characterized so far, S. cerevisiae RPD3p (mammalian equivalents HDACs 1, 2 and 3), S. cerevisiae HDAllp (mammalian equivalents HDACs 4, 5 and 6), and Zea mays HD2 (29). The understanding of these deacetylases, especially the roles of HDAC1 and 2 in transcription regulation, is expanding.

Like DNA methylation, histone acetylation has recently been associated with tumorigenesis. For example, HAT CBP (a CREB-binding protein) is fused to the MLL gene in cases of acute leukemia or myelodysplasia secondary to therapy with drugs targeting DNA topoisomerase II (30, 31). This novel fusion protein leads to dysregulated histone acetylation that might contribute to the leukemogenic process (31). Histone acetylation may also play a role in breast cancer. The carboxy-terminal domains of proteins encoded by the breast cancer susceptibility genes, BRCA1 and BRCA2, can interact with Rb and Rb binding proteins as well as HDAC1 and HDAC2 (32). It has been proposed that the recruitment of HDACs
by BRCA proteins could cause gene deregulation in
the progression of hereditary breast cancer (33, 34).
For additional discussion of BRCA1 and BRCA2, see
in this issue the article by Miernicki et al. (35).

Molecular Mechanisms for the Epigenetic
Regulation of Gene Expression

It appears that both DNA methylation and histone
cytokine acetylation are involved in epigenetic regulation
of gene expression in normal mammalian develop-
ment as well as in tumorigenesis through their ability
to modify chromatin structure during transcription. It
also has been demonstrated that methylated inactive
genes are associated with underacylated histones
whereas unmethylated active genes are linked to hy-
peracylated histones (36, 37). These observations
raise the following questions. How do DNA methyla-
tion and histone acetylation inhibit transcription? Do
these processes interact with each other or act sepa-
ately during this process? Are there any other factors
involved?

Recent studies suggested that DNMT1 can form
a repressive transcription complex at replication foci
with HDAC2 and a newly identified protein, DMAP1
(DNMT1-associated protein), at the noncatalytic
amino terminus of DNMT1. DMAP1 has intrinsic
transcription repressive activity and interacts with
DNMT1 throughout S phase, whereas HDAC2 joins
the complex only during late S phase. These findings
indicate that there is a connection between DNMT1
and HDAC, and histone deacetylation mediated by
HDAC occurs after DNA replication (38). In another
study, DNMT1 has been shown to form a transcription
repressive complex with Rb, E2F1 and HDAC1
(39). Therefore, DNMT1, in addition to its function
of maintaining CpG methylation, has direct inhibitory
effects on transcription by formation of a repressive
complex during DNA replication.

DNA METHYLATION AND HISTONE
ACETYLATION IN REGULATION OF ER
AND PR EXPRESSION IN BREAST CANCER

ER and PR Expression in Normal Mammary Gland
and Breast Cancer

Estrogen and progesterone and their receptors
play important roles in the development and function
of the mammary gland as well as other female re-
productive organs. At puberty, the hypothalamus and
pituitary gland stimulate the ovary to secrete estrogen
that is responsible for the proliferation of the mam-
mary epithelial cells and elongation and branching of
mammary ducts. Progesterone is synthesized by the
corpus luteum and placenta to promote the growth of
mammary lobuloalveolar structures, especially dur-
ing pregnancy in preparation for milk secretion after
parturition (40). Although estrogen and progesterone
receptors are expressed at very low basal levels in normal
human mammary epithelial cells after a woman
reaches sexual maturity (41, 42), they seem to play
an important role in the initiation, progression and
prognosis of breast cancer. They are also good predict-
ors for endocrine therapy (43). Approximately two-
thirds of breast cancers express ER transcript and
synthesize ER protein at levels higher than in normal
breast tissues and half of these ER-positive tu-
ors express both ER and PR protein (ER+/PR+) (43).
These tumors tend to be more differentiated and are
more responsive to hormonal therapies. One-
quarter of all breast cancers lack both ER and PR
(ER-/PR-). In general, these tumors are associated
with poorer differentiation, higher growth fraction,
and worse clinical outcome than ER+/PR+ breast
(43). These cancers are estrogen-independent and
rarely respond to hormonal therapies. Of note,
up to one-third of initially ER+ tumors can evolve to
an ER status during tumor progression and become
resistant to hormone therapy (44).

ER Methylation and DNMT Expression
in Breast Cancer

The human ER cDNA and gene were cloned in
1986 (45–47). This 140 kb ER gene has eight exons
and is located on chromosome 6q25.1. Since then,
efforts have been devoted to the possible molecular
mechanisms for the loss of ER expression in breast
cancers. Genetic changes, such as insertions,
deletions, rearrangements, or point mutations of the
ER gene were extensively sought in breast cancer
cells since these in-frame or out-of-frame sequence
alterations would lead to either absence of ER
expression or expression of an unstable mutant that
might be degraded shortly after protein translation
by the ubiquitin protease system. Although several
sequence mutations for the ER gene were identified
and shown to be related to decreased ER expression
and estradiol binding, they are uncommon and can-
not explain the loss of ER expression in a significant
fraction of human breast cancers (40). This finding
suggests that mechanisms other than genetic changes
might also contribute to the loss of ER expression in breast cancer.

One extensively studied epigenetic mechanism that might lead to loss of ER expression is CpG methylation. Interestingly, the ER gene has a CpG island in its promoter and first exon regions marked by a clustering of sites for methylation-sensitive restriction endonucleases (46, 48) (Fig. 1). In addition, absence of ER protein expression in human breast cancer specimens is frequently associated with loss of ER transcript (49). Those findings raise the possibility that absence of ER expression is associated with ER gene hypermethylation.

We have addressed this hypothesis using human breast cancer cell lines as a model system. Ottaviano et al. (50) reported that ER− human breast cancer cells displayed extensive methylation of the CpG island in the 5′ promoter region of the estrogen receptor gene, in association with silencing of ER gene expression. The 6.3 kb ER mRNA transcript was detected easily in three ER+ cell lines (MCF-7, T47D and ZR75-1), but none was detected in three ER− cell lines (Hs578t, MDA-MB-231 and MDA-MB-468). Southern blot analysis using methylation-sensitive restriction enzymes showed that the ER CpG island was methylated at a critical NotI site in multiple ER−negative breast cancer cell lines. As expected for an autosomal gene, the ER gene was unmethylated at the NotI site in the CpG island in all normal tissues studied including breast epithelium. In addition, the ER gene was unmethylated at multiple other restriction sites in its CpG island in all ER+ cell lines studied, but these sites were frequently methylated in ER-negative cell lines. Of note, the major DNA methyltransferase, DNMT1, was highly expressed in ER− cell lines at the mRNA level as well as the protein and enzymatic activity levels. Careful assessment of the relationship between ER expression and DNMT1 showed that DNMT1 protein expression was correlated with S-phase fraction in ER-positive cell lines, but not in ER-negative cell lines. Thus DNMT1 expression was elevated in ER-negative cell lines and was unlinked from cell cycle regulation (51).

A key question is whether these tissue culture findings have any relevance to human breast cancer. Using Southern blot analysis, Lapidus et al. (52) reported that the ER CpG island was methylated at the NotI restriction site in 9 of 39 (25%) of

DNA Methylation and Histone Acetylation in Breast Cancer

primary ER− breast cancers but remained unmethylated in 53 ER+ breast cancers and 9 normal breast specimens (Table I). The possible explanations for the different frequency of ER methylation in cell lines and tissues include the presence of normal cells in primary cancers, heterogeneity of ER expression within breast cancers, methylation of other sites within the CpG island which were not examined, and the relative insensitivity of Southern blot analysis. These possibilities have been partially addressed through the development of a PCR-based assay termed methylation-specific PCR or MSP, a technique designed to analyze methylation of CpG dinucleotides across the entire ER CpG island (Fig. 1). By use of MSP, normal breast tissues and ER+ cell lines showed only an unmethylated product across all 5 primer sets used, whereas ER− cell lines showed methylated products across much of the island (52) (Table II). To confirm that ER CpG methylation could also be detected by MSP in primary human breast cancers, a panel of 33 primary breast cancers of known receptor status was studied. All 33 tumors showed at least some degree of methylation at one or more primer sites. By use of a semiquantitative scoring system for elevated CpG density, the percentage of tumors displaying substantial methylation can be calculated for each tumor set defined by receptor status. As shown in Table III, about one-third of ER+/PR+ tumors showed methylation, whereas the percentage increased to 100% in ER−/PR− tumors (53). Taken together, data derived from both our study and others (54) support a correlation between absence of ER

expression and aberrant CpG island methylation of ER gene. Whether methylation status actually acts solely or partially to silence ER transcription is a key question.

Demethylation of the ER Gene Results in Re-Expression of ER

If silencing of ER expression is a function of CpG island methylation of ER gene, it is possible that demethylation should result in the re-expression of ER in ER− breast cancer cells. In accord with this prediction, treatment of the ER− human breast cancer cell line, MDA-MB-231, with the demethylating agents, 5-aza and deoxyC, led to re-expression of ER (55). After treatment with either drug, the DNA from these cells became partially demethylated at several methylation-sensitive restriction enzyme sites, including HhaI, NotI, and SacII, within the ER promoter CpG island. Demethylation correlated with re-expression of the ER gene as detected by reverse transcriptase-PCR (RT-PCR) as demonstrated in Fig. 2 and Western Blot analysis. Functional activity of this ER protein was examined in two ways. First, its ability to activate expression of an endogenous estrogen-inducible gene, PR, was assessed. PR mRNA and protein were induced by estrogen treatment of deoxyC treated MDA-MB-231 or HS578T cells. Second, the ability of the deoxyC-induced ER to transduce expression of a luciferase reporter gene linked to an estrogen response element (ERE) was assessed. MDA-MB-231 cells were stably transfected with an ERE-tk-luciferase construct with the expectation that deoxyC-induced ER expression would increase luciferase expression. As expected, increased luciferase activity (1.5–5.6 fold in 10 independent clones) over the background level of the untreated cells was observed (54). These results provide powerful evidence that DNA methylation of the ER CpG island plays a functional role in suppression of ER expression in ER− breast cancer cells.
DNA Methylation and PR Gene Expression

As discussed in the Introduction, one quarter to one-third of breast cancers lack both ER and PR, whereas another one-third are ER+ but PR−. It also has been demonstrated that the expression of PR requires ER as a transcriptional activator (56). Therefore, the presence of PR in ER+ tumors may be a better predictor of hormone responsiveness than ER alone (43). Interestingly, the PR gene also has a typical CpG island in its first exon. The PR CpG island is 1 kb in size, has 70% GC content, and contains a wide array of methylation-sensitive restriction sites. Southern analyses targeted at three methylation-sensitive restriction sites in the PR CpG island showed that these sites are not methylated in normal breast tissue specimens but are hypermethylated in 40% of primary tumors that lack PR protein expression (52). Thus the question of why the PR hypermethylation could be responsible for a lack of PR expression was studied in MDA-MB-231 cells which lack both ER and PR (57). Treatment of these cells with the demethylating agent, deoxyC, led to partial demethylation of the ER and PR CpG islands and was associated with induction of PR protein expression as demonstrated by Western blot analysis. However, Ferguson et al. (57), using MDA-MB-231 cells stably transfected with an inducible expression vector for ER, found that the induction of PR gene expression by ligand-bound ER did not require demethylation of the PR CpG island. In addition, induction of PR transcription was inhibited by blocking the interaction of ER with SRC-1A, a coactivator of ER function. These results suggested that a transcriptional factor with the potential to remodel heterochromatin (ER) could activate PR gene expression without altering the methylation status of the CpG island in the PR gene. These results raise the possibility that demethylation and histone acetylation are distinct but complementary mechanisms for destabilizing heterochromatin and activating gene transcription (58).

Histone Acetylation and ER Expression

As discussed earlier, histone acetylation and deacetylation are intimately involved in chromatin structure changes during transcription. In addition, new models of transcriptional suppressive complexes suggest that HDACs and DNMT1 are in direct contact. Recent studies indicate that silencing of a gene by methylation involves the generation of an inactive chromatin structure in which methyl CpG-binding protein (MeCP2) and the adapter protein, mSin3A, recruit histone deacetylase (59, 60). The deacetylation of lysine groups of histones H3 and H4 allows ionic interactions between positively charged lysines and negatively charged DNA, resulting in a more compact nucleosome structure that limits gene activation. The question emerges of whether epigenetic modification of histone acetylation alone could result in re-expression of genes that are inhibited by the transcriptional suppressive complex, or whether both histone acetylation and CpG demethylation are required for this event.

The answers to this question have been variable. For example, HDAC inhibitors like trichostatin (TSA) or phenylbutyrate alone restored retinoic acid receptor α (RARα) expression in retinoic acid (RA) resistant acute promyelocytic leukemia (APL) cell lines as demonstrated by the differentiation of APL cells in the presence of RA (61–63). However, hypermethylated genes, such as MLH1, TIMP3, INK4B (p15) and INK4a (p16), could not be transcriptionally reactivated by TSA alone, but could be re-expressed in colon cancer cells with a combination of TSA and the demethylating agent, 5-aza (58).

To study the role of histone acetylation in ER expression, ER− MDA-MB-231 cells were treated with HDAC inhibitor, TSA. A time- and dose-dependent reactivation of ER mRNA expression was observed (64). As shown in Fig. 2, TSA alone at 100 ng/ml for 2 days could reactivate ER expression as well as deoxyC in ER− MDA-MB-231 breast cancer cell line. By use of quantitative competitive PCR assay, an increase of 5.0 fold of ER transcript expression was reported (64). MSP analysis of the ER CpG island showed no
change in its methylation after TSA treatment, suggesting that TSA's effects on ER re-expression were not associated with a change in methylation status. This finding was confirmed via a more rigorous assay, bisulphite genomic sequencing of the ER promoter region, a technique which permits the direct examination of the methylation status of each CpG dinucleotide within the promoter region. Multiple clones of control and TSA-treated cells were examined and did not show any change in the methylation status of the ER gene with TSA. A logical extension of these studies will be to examine the effect of combinations of demethylating agents and HDAC inhibitors on expression of ER as well as other methylated genes in breast cancer cells.

DNA Methylation and HDAC Inhibitors as Therapeutic Strategies in Breast Cancer

Abundant evidence indicates that epigenetic mechanisms play pivotal roles in the pathogenesis of cancer. Both DNA methylation and histone acetylation have been shown to be involved in the regulation of expression of cancer-related genes. The studies in breast cancer summarized earlier demonstrated that both demethylating agents and HDAC inhibitors could re-activate expression of a number of important growth regulatory genes in several breast cancer cell lines, thus raising the possibility of using these types of agents as therapeutic strategies for breast cancer.

Two demethylating agents, 5aza and decyox, have been studied clinically, particularly in patients with hemoglobinopathies. For example, 5aza has been successfully used to treat patients with β-thalassemia. It has been reported that loss of expression of the γ-globin gene is associated with methylation of its promoter (65). Infusion of 5aza into β-thalassemia patients led to an increase of γ-globin expression and amelioration of anemia (66). Similarly, 5aza can increase HbF production and reduce anemia in sickle cell disease (67). In addition, in an ongoing trial, the efficacy of treatment of nasopharyngeal tumors with 5aza is being evaluated. The promoter of one of the Epstein Barr Virus-related proteins is heavily methylated in nasopharyngeal carcinoma. It has been proposed that demethylation of this promoter could lead to reactivation of an EBV latency protein that could then become the target for a secondary immune therapy (R. Ambinder, Johns Hopkins Oncology Center, personal communication). Another possible approach is to use antisense oligonucleotides against DNA methyltransferase to inhibit DNA methylation. It has been shown that antisense oligonucleotides have in vitro and in vivo antitumor activity and a clinical trial of this approach is in progress (68, 69).

Several HDAC inhibitors have the potential to be used as anti-cancer agents (29). The most plausible and extensively studied are butyrate, TSA, and trapoxin (TPX) and their relatives. The IC50 of butyrate for HDAC is in the millimolar range, whereas TSA and TPX act at low nanomolar concentrations. One triglyceride analogue of the short-chain fatty acid butyrate, tributyricin, has been reported to induce transcription of p21, arrest of cells in G2/M and apoptosis in MCF-7 human breast cancer cell lines. (70). Two butyrate derivatives, phenylbutyrate (PB) and phenylacetate (PA), have powerful growth inhibitory effects on several cell types including ovarian and prostate cancers (71). A clinical trial with sodium phenylacetate in patients with thalassemia showed an increase of fetal hemoglobin in some patients (72). Other HDAC inhibitors under study include FR901228, oxamflatin, depudecin, suberoylanilide hydroxamic acid (SAHA), m-carboxycinnamic acid bishydroxamide (CBHA) and apicidin.

A potential strategy is to combine demethylating agents and HDAC inhibitors. From a clinical point-of-view, the potential benefits of this combination could include lowering of drug concentration requirements, shorter periods of drug exposure, and lower toxicity, as well as the possibility of synergy. For example, synergistic effects were observed in a combination study with both a demethylating agent and a HDAC inhibitor in colon cancer cells. If cancer cells were treated with 100 nM 5aza (a dose that had little effect on gene expression if used alone) for 24 hours followed by 300 nM TSA for 24 hours, (again a treatment that was ineffective alone), re-expression of several genes was obvious (58). A key question in development of this strategy will be the specificity and selectivity of gene re-expression patterns and how they might be exploited clinically.

Finally, it should be noted that demethylation and histone acetylation are only two mechanisms for epigenetic regulation of target genes like ER. Other transcriptional modulators might also contribute to the epigenetic regulation of gene expression. For example, it was reported that AP2 transcription factor can trans-activate the cloned human ERα promoter in MDA-MB-231 cells (73).
CONCLUSIONS

The evidence for epigenetic regulation of gene expression in tumorigenesis is accumulating. Two components, demethylation of C5-methylcytosines at the CpG island within the promoter region of target genes and histone acetylation of chromatin, have been studied extensively by use of demethylating agents and HDAC inhibitors. ER and PR, two critical genes in breast cancer development and treatment, have been reported to be densely methylated in ER— but not ER+ human breast cancer cell lines. Treatment of ER— human breast cancer cells with a demethylating agent or a HDAC inhibitor can lead to reactivation of ER expression in these cells. However, demethylation of PR CpG island is not required for PR expression. These data in combination with similar results observed with other critical genes in breast cancer and other types of cancer support the potential for compounds that can modulate epigenetic regulation in the treatment of human cancers.

The Johns Hopkins Oncology Center, Johns Hopkins University, Baltimore, Maryland 21231

Abstract

Formation of transcriptional repression complexes such as DNA methyltransferase (DNMT) histone deacetylase (HDAC) or methyl-CpG binding protein (HDAC) is emerging as an important mechanism in silencing a variety of methylated tissue-specific and imprinted genes. Our previous studies showed that treatment of estrogen receptor (ER)-α-negative human breast cancer cells with the DNMT inhibitor 5-aza-2'-deoxycytidine (5-aza-dC) led to ER mRNA and protein re-expression. Also, the HDAC inhibitor trichostatin A (TSA) could induce ER transcript about 5-fold. Here we show that 5-aza-dC alone induced ER transcript about 30-40-fold, and the addition of TSA elevated ER mRNA expression about 10-fold more in the human ER-negative breast cancer cell lines MDA-MB-231 and MDA-MB-453. Overall, the combination of 5-aza-dC and TSA induced a 300-400-fold increase in ER transcript. Restoration of estrogen responsiveness was demonstrated by the ability of the induced ER protein to elicit estrogen response element-regulated reporter activity from an exogenous plasmid as well as induce expression of the ER target gene, progesterone receptor. The synergistic activation of ER occurs cooperatively with markedly reduced soluble DNMT1 expression and activity, partial demethylation of the ER CpG island, and increased acetylation of histones H3 and H4. These data suggest that the activities of both DNMT1 and HDAC are key regulators of methylation-mediated ER gene silencing.

Introduction

ERα is a ligand-activated nuclear receptor that regulates transcription of estrogen-responsive genes in diverse target cells (1). ER and its ligand, 17β-estradiol, not only play a critical role in normal breast development but also have long been linked to mammary carcinogenesis, breast tumor progression, and outcome of breast cancer patients (2). Given the fact that 17β-estradiol stimulates the growth of ER-positive breast tumors via functional ER, endocrine therapy such as antiestrogen or ovarian ablation has been established as an important portion of breast cancer management (3). However, up to one-third of breast carcinomas lack ER at the time of diagnosis, and a fraction of cancers that are initially ER positive lose ER during tumor progression (4). Genetic alterations, such as homozygous deletion, loss of heterozygosity, or ER gene mutation, have not been reported to play a major role in loss of ER expression. There is increasing evidence that epigenetic alterations play a role in inactivation of ER gene expression (5, 6). As demonstrated by Southern and MSP analyses, the ER CpG island is unmethylated in normal breast tissue and most ER-positive tumor cell lines, whereas it is methylated in ~50% of unselected primary breast cancers and most ER-negative breast cancer cell lines (7). The methylation of these CpG cluster sites is associated with either reduced or absent ER expression.

The DNMT inhibitor 5-aza-dC is widely used to study the reexpression of genes silenced by promoter methylation (8). 5-aza-dC exerts its demethylating function through sequestration of DNMT1 to 5-aza-dC-substituted DNA by the irreversible binding of the cytosine in the catalytic domain of the DNMT1 enzyme to the 6 position of the cytidine ring (9, 10). In our previous study, treatment of ER-negative human breast cancer cells with the methyltransferase inhibitors 5-aza-cytidine or 5-aza-dC led to partial demethylation of the ER CpG island, reexpression of ER mRNA, and synthesis of functional ER protein. Restoration of ER function was documented by eliciting ERE-driven promoter activity from an exogenous plasmid as well as the expression of the ER-responsive gene, PR (11).

Inactive chromatin built on methylated CpG clusters is emerging as an important molecular mechanism to silence a variety of methylated tissue-specific and imprinted genes (12, 13). This process involves methyl CpG-binding proteins to recruit HDAC family members. These HDACs remove acetyl groups from lysine residues of core histones, particularly H3 and H4, to increase ionic interactions between positively charged lysines of histones and negatively charged DNA, thereby generating a more compact nucleosome structure that limits gene activity. In our previous study, TSA, a potent and reversible HDAC inhibitor, could induce ER mRNA by 5-fold. This transcriptional activation is associated with increased sensitivity to DNase I at the ER locus without alteration of the methylated CpG sites, suggesting that an accessible chromatin structure is important in ER expression (6).

Recently, in vitro studies have shown that DNMT1 interacts physically with either HDAC1 or HDAC2 (14, 15), in addition to its ability to methylate hemimethylated CpG sites in DNA. These findings suggested that the ability of DNMT1 to repress transcription after replication through its regulatory NH2 terminus is partially dependent on HDAC activity. Furthermore, a study using 5-aza-dC followed by TSA treatment of human colon cancer and leukemia cells robustly reactivated multiple methylated genes such as MLH1, TIMP3, CDK2B, and CDK2A. This finding supports the essential roles of both DNMT and HDAC in silencing expression of endogenous methylated genes (16).

Here we show that cotreatment with DNMT and HDAC inhibitors can synergistically induce ER gene expression in ER-negative breast cancer cells. Induced expression of ER mRNA and protein is associated with expected ER function on estrogen-responsive targets. First, ERE-driven reporter activity from an exogenous plasmid is induced by the treatments and blocked by the ER antagonist ICI 182,780. Secondly, the treatments stimulate expression of the ER-responsive
gene, PR, which is again suppressed by ICI 182,780. Our data show that synergistic induction of ER occurs in conjunction with reduced soluble DNMT1 expression and DNMT activity, partial demethylation of the ER CpG island, and increased acetylation of histones H3 and H4. These data suggest that pharmacological intervention against both DNMT and HDAC can synergistically reactivate the methylated ER gene expression and restore ER function.

Materials and Methods

Cell Lines, Reagents, Antibodies, and Treatment Protocols. The human breast cancer cell lines (MDA-MB-231, MDA-MB-435, MCF-7/ct, and T-47D) and their culture conditions were as reported previously (17). Rabbit antihuman DNMT1 antisera were described previously (18). Specific anti-acetylated H3 and H4 rabbit polyclonal antibodies and PCNA monoclonal antibody were purchased from Upstate Biotechnology (Lake Placid, NY) and Oncogene Research Products (Cambridge, MA), respectively. The anti-ER-α antibody, ID5, was obtained from Coulter Immunotech (Marseille, France). The pure antiestradiogen ICI 182,780 was a generous gift from AstraZeneca Pharmaceuticals (Macclesfield, United Kingdom). For treatment, cells were seeded at a density of 5 x 10^5 cells/100-mm tissue culture dish. After 24 h of incubation, the culture media were changed to media containing 5-aza-dC for up to 96 h or TSA for 12 h. For the combination study, 5-aza-dC was present in culture for 96 h, and TSA was added for the last 12 h.

RNA Isolation, RT-PCR Analysis of ER and PR, and Quantitative Competitive PCR Analysis of ER. Total cellular RNA was extracted by Trizol reagent (Life Technologies, Inc., Rockville, MD). RT-PCR was carried out according to our previously described method (6). RNAs under comparison were simultaneously reversibly transcribed to achieve equal efficiency for reverse transcription. ER mRNA expression was initially screened by RT-PCR. If ER mRNA was present, a previously reported quantitative competitive PCR assay was performed to determine the level of ER transcript in treated MDA-MB-231 cells and MCF-7/ct cells as compared with the expression level in untreated cells or the control ER-positive MCF-7 cells (6). PR RT-PCR primers were described previously (11), and the PCR reaction was performed with an Advantage GC2 PCR kit (Clontech, Palo Alto, CA) according to the protocol recommended by the supplier.

Genomic DNA Isolation and MSP Analysis of ER CpG Island. DNA was isolated by standard phenol-chloroform extraction. Isolated DNA was subjected to modification by sodium bisulfite to convert unmethylated cytosines but not methylated cytosines to uracils as described previously (19). Methylation status of the bisulfite-modified DNA at the ER locus was characterized by MSP using our previously reported method (7).

Western Blot Analysis of ER, PCNA, or DNMT1 Expression. Proteins from detergent-lysed cells were quantified by using the BCA protein assay kit (Pierce, Rockford, IL). The Western blotting procedure was reported previously (20). Briefly, after protein separation by electrophoresis and transfer to nitrocellulose, blots were probed for 1 h with 2 μg/ml either mouse monoclonal antibody 1D5 (ER specific) or Ab-1 (PCNA specific) or affinity-purified rabbit polyclonal IgG (DNMT1 specific) at a 1:1000 dilution in PBS containing 5% dry milk. After incubation with peroxidase-labeled secondary rabbit antiserum or goat antirabbit antibodies, the immunoreactive proteins were detected by the enhanced chemiluminescence method as recommended by the manufacturer (Amersham Pharmacia Biotech, Piscataway, NJ). Protein band intensities were quantified by densitometry (ImageSight Software of Eagle Eye II Imaging System; Stratagene, La Jolla, CA).

DNMT Activity Assay. Lysates from cells growing in the presence or absence of 5-aza-dC, TSA, or 5-aza-dC and TSA were prepared and assayed for enzyme activity by the incorporation of [3H]methyl-5-adenosylmethionine into poly(dC-dC) as described previously (21).

Analysis of Acetylated Histones. Cellular histone extraction was performed using 2 x 10^5 cells according to the procedure of Yoshida et al. (22), with the following modifications. The acid (H2SO4)-soluble supernatant was precipitated with 10 volumes of cold acetone. After overnight precipitation, histones were collected by centrifugation. The pellet containing histones was dissolved in 50 μl of H2O, and proteins were quantified by using the BCA protein assay kit.

The extracted histones were separated by electrophoresis on a 15% SDS-PAGE gel and transferred to nitrocellulose membrane. After sequential incubations with rabbit anti-acetylated H3 and H4 polyclonal sera and goat antirabbit horseradish peroxidase-conjugated secondary antibody, the immunoreactive proteins were detected by the enhanced chemiluminescence method.

Transfections and Luciferase Assays. The ERα-tk-luciferase/SV-neo plasmid has been described previously (11). MDA-MB-231 cells were transfected with the plasmid using LipofectAMINE reagent and selected with G418 (1 mg/ml; Life Technologies, Inc.) for 2 weeks. Isolated colonies of G418-resistant cells were pooled and used for analysis. The pooled, transfected cells were maintained in culture media with 1 mg/ml G418. Luciferase activities were determined by Bright-Glo Luciferase Assay System (Promega, Madison, WI), and the activities were normalized for protein concentrations.

Results and Discussion

Induced ER Expression by DNMT and HDAC Inhibitors. The ER- and PR-negative cell line MDA-MB-231, which has densely methylated ER and PR CpG islands, was used as a cell model to test whether both DNMT and HDAC inhibition could synergistically reactivate ER expression. To test the hypothesis that pharmacological modulation of DNMT and HDAC by 5-aza-dC and TSA could synergistically activate ER gene expression, we first performed dose-response and time-course studies to characterize the effects of each individual drug. Maximal ER gene re-expression was achieved with 100 ng/ml TSA (0.33 μM) for 48 h or with 2.5 μM 5-aza-dC for 96 h (data not shown) when cells were treated with TSA or 5-aza-dC alone. Therefore, to test the hypothesis that combination treatment might have additive or synergistic effects, a treatment strategy of an optimal dose of 5-aza-dC (2.5 μM) for 96 h with the addition of TSA at 100 ng/ml for the last 12 h was used. We postulated that the reactivating effects of the demethylation agent may be potentiated by a short treatment with the HDAC inhibitor. Thus, for the combination studies, MDA-MB-231 cells were treated with 5-aza-dC for 96 h, and TSA was added for the last 12 h. As shown in Fig. 1A, ER mRNA expression was induced 31-fold by treatment with 5-aza-dC for 96 h as compared with vehicle-treated cells, whereas treatment with TSA alone for 12 h had little effect. The combined treatment led to a 400-fold induction in ER transcript. Thus, the brief addition of TSA to optimal 5-aza-dC treatment increased ER mRNA by about 13-fold, suggesting a synergistic effect.

To ascertain whether both DNMT and HDAC activities could play a role in repression of ER expression more generally, the dual treatment strategy was evaluated in another ER-negative human breast cancer cell line, MDA-MB-435. Optimal ER gene re-expression was observed after treatment of these cells with either 50 ng/ml (0.165 μM) TSA for 48 h or 0.6 μM 5-aza-dC for 96 h when these drugs were used as single agents (data not shown). The same combination treatment used for MDA-MB-231 cells was used for MDA-MB-435 cells. As shown in Fig. 1B, treatment with 5-aza-dC alone induced ER mRNA by 36-fold, whereas treatment with TSA alone for 12 h had little effect. The combined treatment led to a 318-fold induction of ER transcript compared with that of vehicle-treated MDA-MB-435 cells (Fig. 1B). Thus, two different ER-negative cell lines showed evidence of synergistic reactivation of ER by the combined approach of DNMT and HDAC inhibitors.

We next studied how the levels of ER reactivation compared with endogenous ER expression in the human breast cancer cell line MCF-7. As shown in Fig. 1C, 5-aza-dC induced ER transcripts in MDA-MB-231 and MDA-MB-435 cells to 4% and 2%, respectively, of the expression level found in MCF-7 cells. The addition of TSA to the 5-aza-dC-treated cultures induced ER mRNA to 50% and 20% of the MCF-7 expression levels, respectively. Thus, the combination treatment consistently and synergistically induced ER transcript in ER-negative breast cancer cell lines, supporting our hypothesis that
the activities of both DNMT and HDAC are key regulators in ER gene silencing. The synergistic effect with an optimal exposure to DNMT inhibitor and a suboptimal exposure to HDAC inhibitor suggested a layered action on ER activation.

However, the combination of DNMT and HDAC inhibitors apparently did not reactivate ER mRNA expression to the levels seen in MCF-7 cells. This finding could reflect experimental variation or differences in genotypes between cell lines. Alternatively, it is possible that other mechanisms might also play a role in the silencing process. For example, other transcriptionally repressive complexes such as methyl-CpG binding protein/HDAC could also be involved in the silencing process. Also, some corepressor proteins in various repressive complexes are partially HDAC independent. For instance, a component of the repression mediated by the MeCP2 transcriptional repression domain is partially HDAC independent, and mSin3A could retain some ability to repress transcription, even in the absence of associated HDACs (12). Also, DMAP-1, a co-repressor in the DNMT1/HDAC gene transcriptional repression complex, is HDAC independent (14). Therefore, simultaneous inhibition of several components in the methylation-associated repressive complexes might be necessary to achieve maximal reactivation of repressed genes.

This effect appeared to be relatively specific for the methylated ER gene because the treatments (alone or in combination) had no apparent effect on the level of expression of the unmethylated housekeeping gene, β-actin, using a competitive quantitative PCR assay (data not shown). However, the combined treatment of the ER-negative breast cancer cells did reactivate expression of other genes silenced by methylation such as RARβ2 or cyclin D2 (data not shown) in addition to ER.

Next, we investigated whether the activated ER transcript was translated into ER protein by Western analysis. The ER protein signal in 5-aza-dC-treated MDA-MB-231 cells was compared with that in the combination-treated cells after normalizing with β-actin protein. As shown in Fig. 1D, 5-aza-dC treatment of MDA-MB-231 cells reactivated the M67,000 ER protein, whereas TSA had little effect. The amount of ER protein in combination-treated cells was about twice that in cells treated with 5-aza-dC alone. These data provide further evidence that ER gene expression was enhanced by the combined treatment with 5-aza-dC and TSA as compared with that seen with either drug alone.

Analyses of Activated ER Function in MDA-MB-231 Cells. The ability of the re-expressed ER protein to mediate an estrogen response was tested next. For this study, a plasmid that contains a firefly luciferase gene under the transcriptional regulation of two EREs driving a thymidine kinase promoter was stably transfected into MDA-MB-231 cells. These cells were treated with 5-aza-dC or TSA alone and with the combination of both (see “Materials and Methods”) in estrogen-containing culture media. As shown in Fig. 2A, treatment

Fig. 2. Effects of DNMT or HDAC inhibition on ERE-driven promoter activity and endogenous estrogen-responsive PR gene transcription in MDA-MB-231 cells. A, effects of treatments on ERE-regulated reporter activity in MDA-MB-231 cells stably transfected with ERE-luc/neo plasmid. Fold activity is calculated from the relative luciferase values in drug-treated versus vehicle-treated cells in triplicate samples after the luciferase units were adjusted for the protein concentration in each setting (mean fold activity ± SD). A result from one of three independent experiments that give similar results is shown. B, effects of treatment on PR gene expression. Top panel, the predicted 400-bp PR transcript expression in MDA-MB-231 cells. A representative example of four experiments with similar results is shown. Y-740 was used as a PR-PCR-positive control, and H2O was used as a PCR-negative control. AZA, 5-aza-dC; IC1, IC182, 780. Bottom panel, β-actin RT-PCR product provides a control for the amount of intact RNA used in the reaction.
with 5-aza-dC alone led to a 1.4-fold increase in promoter activity. TSA alone induced the reporter activity by 5-fold, an unexpected finding because 12 h of TSA induced little ER mRNA or protein. Possibly, this is due to the chromatin remodeling effect of TSA instead of ER involvement. Nevertheless, cotreatment with 5-aza-dC and TSA elicited a more than additive induction of reporter activity (about 8-fold, Fig. 2A). Thus, the combination treatment enhanced ERE-driven reporter transcription in MDA-MB-231 cells when compared with single agents.

To confirm that drug-activated reporter activity was a specific estrogen effect mediated through the action of the activated ER, the ER antagonist ICI 182,780 (5 μM) was used to block estrogen effects in the culture (23). As shown in Fig. 2A, ICI 182,780 suppressed 5-aza-dC-stimulated ERE-mediated reporter activity but had no effect on TSA-mediated transcription. These results indicate that 5-aza-dC-activated reporter transcription (5-aza-dC alone or the combination) is a specific hormone effect and suggest that the effect of treatment by TSA alone on this reporter activity is not completely related to estrogen response. Indeed, the exact nature of the effect of TSA on this reporter needs to be further explored.

We further investigated the ability of the drug-induced ER to activate expression of the endogenous ER-responsive gene, PR. As shown in Fig. 2B, treatment of MDA-MB-231 cells with 5-aza-dC or the combination induced PR mRNA expression, whereas ICI 182,780 or TSA alone had little or no effect. Cotreatment of MDA-MB-231 cells with 5-aza-dC/ICI 182,780 suppressed PR expression. Similarly ICI 182,780 treatment of cells growing in 5-aza-dC and TSA led to a marked decrease in PR expression. Together, these data suggest that drug-induced ER is functionally active.

Changes in DNMT1 Expression, ER CpG Island Methylation, and Increased H4 and H2 Acetylation Induced by DNMT and HDAC Inhibitors. To study the underlying mechanisms associated with the synergistic activation of the methylated ER gene, we examined the expression and activity of the methylation maintenance enzyme, DNMT1. The results in Fig. 3A showed that addition of 2.5 μM 5-aza-dC to the culture of MDA-MB-231 cells for 96 h markedly depleted soluble DNMT1 protein expression and total DNMT activity from the whole cell protein lysates (Fig. 3B).

Interestingly, TSA also down-regulated soluble DNMT1 protein expression with some reduction in DNMT activity. Down-regulation of DNMT1 expression by TSA was consistently obtained in several independent experiments. The combination treatment further reduced the amount of DNMT1 protein and total DNMT activity. Although the effect of 5-aza-dC on soluble DNMT1 protein and total DNMT activity was expected because it sequesters DNMTs after its incorporation into genomic DNA and inhibits its enzyme activity (10), the effect of TSA was not. One possible explanation is that the effect of TSA on DNMT1 expression and DNMT activity reflects its ultimate antiproliferative effects. A second explanation is that a possible functional or physical interaction exists between DNMT1 and HDAC. Because the cell proliferation marker PCNA interacts physically with DNMT1 (24), we examined its expression by immunoblot. As shown in Fig. 3A, PCNA expression was not obviously modulated by any treatment. Thus, our data suggest a possible functional connection between DNMT1 and HDAC or physical dependency for protein stabilities because no obvious down-regulation of DNMT transcript was observed by the various treatments (data not shown). However, the discrepancy between the level of DNMT1 depletion and reduction in total DNMT activity induced by TSA could also reflect a role of other DNMT family members that are not affected by TSA.

Next, the MSP assay was used to examine the methylation status of the ER CpG island in MDA-MB-231 cells after the treatments (Fig. 3C). The ER CpG island remained methylated in MDA-MB-231 cells treated with vehicle or TSA (100 ng/ml for 12 h). However, treatment with 5-aza-dC alone or in combination with TSA led to partial demethylation of the CpG island, in conjunction with ER gene expression. These data are consistent with our previous findings and reaffirm that DNA methylation is a participant in the regulation of ER gene expression (11).

We then studied whether HDAC inhibition directly acetylates histones and whether the increased histone acetylation is associated with ER gene activation. As shown in Fig. 3D, the HDAC inhibitor TSA up-regulated H3 and H4 acetylation as expected, although the magnitude of ER gene activation was not clearly proportional to the degree of histone H3 and H4 acetylation.
In summary, a demethylated ER promoter sequence with increased histone H3 and H4 acetylation by sequential inhibition of both DNMT and HDAC is correlated with the synergistic activation of the ER gene. These data indicate that pharmacological intervention against DNMT and HDAC can lead to alteration of ER gene methylation and chromatin conformation change characterized by hyperacetylated histones. Future studies using coimmunoprecipitation or chromatin-immunoprecipitation assay to elucidate the individual components that form the transcriptionally repressive complex at the ER gene locus will be pursued, and the effects of pharmacological manipulation will be further explored.

Because ER is a critical growth-regulatory gene in breast cancer, it is important to better understand its transcriptional regulation. Our data suggest that a combination drug regimen of both DNMT and HDAC inhibitors can synergistically activate functional ER protein. Additional studies will be necessary to evaluate the clinical implications of this finding with regard to sensitivity to selective ER modulators such as tamoxifen or ICI 182,780.

Acknowledgments

We thank Dr. Sandra M. Swain for helpful discussions and critical review of the manuscript and Jay E. Manning for technical assistance with the DNMT activity assay.

Polyamine analogues have demonstrated considerable promise against many important solid tumor models including breast cancer. However, the precise mechanism of anti-tumor activities of polyamine analogues is not well understood. We have evaluated and characterized seven representatives of a new generation of conformationally constrained polyamine analogues and oligoamines that exhibited significant growth inhibitory effects against human breast cancer cell lines including MCF7 and MDA-MB-231 cells. The polyamine analogue concentrations required for 50% growth inhibition (IC50) were generally less than 1 microM for 96 h. Modest induction of polyamine catabolic enzyme spermidine/spermine N1-acetyltransferase (SSAT) and polyamine pool depletion was observed by 24h. For a majority of compounds tested, internucleosomal DNA fragmentation was determined to be time and concentration dependent. Further analyses indicate that the intrinsic mitochondrial apoptotic pathway is activated by polyamine analogues in MDA-MB-231 cells, but not in MCF7 cells, suggesting that different mechanisms and pathways are involved in polyamine analogue-induced apoptosis. In addition, polyamine analogues significantly inhibited the growth of transplanted MDA-MB-231 cells in nude mice. These results suggest that the newly synthesized polyamine analogues show effective antitumor action against human breast cancer cells.
