14. ABSTRACT
This was an Exploration – Hypothesis Development Award (EHD) in which we modeled, in a mouse model system of xenograft human tumor growth, the natural androgen decline in the aging male (ADAM) as it occurs after the age of 40 years in humans. We explored the possibility that different testosterone levels may influence prostate tumor growth. We have completed the proposed study and found that all mice receiving testosterone at declining concentrations (even as little as 0.5 mg) developed xenograft tumors at about the same time and rate as fully androgenized mice. Only in androgen ablated mice did the tumors developed after months of delay. It therefore seems that tumor growth can be maintained at very low testosterone levels. We analyzed in detail PSA gene expression in tumors from the two extreme groups of animals (no testosterone and normal levels of testosterone) and found that tumors from ablated mice had on average higher steady-state levels of PSA mRNA than those in the testosterone group. However, tumors from ablated mice displayed elevated histone H3-K9/K14 acetylation across the entire body of the PSA gene. The data therefore indicates that loci-specific chromatin alterations contribute to basal gene expression of specific AR target genes in androgen-independent PCa cells and may thus contribute to the androgen-independent phenotype of these cells.

Statement of Work (modified 4-12-07)

Aberrant AR Signaling as a Function of Declining Androgen

Task 1. To standardize IHC methods on CWR22 tumors (Months 1-6):

   a. Grow CWR22 tumors in 5 nude mice fully androgenized (Months 1-2).
   b. Sacrifice mice and perform IHC on tumors using antibodies against AR, p160 coactivators and HER-2 (Month 3).
   c. Determine semi-quantitative cut points by comparison with IHC done on human prostate tumor archival specimens (Months 4-6).

Task 2. To determine CWR22 tumor growth as a function of testosterone levels:

   a. Start the experiment by injecting 1 million CWR22 cell suspension subcutaneously into 5x10 nude mice (Month 7).
   b. Monitor tumor growth until they reach 0.5 cm³, then castrate and implant testosterone pellets with varying testosterone levels (Month 8).
   c. Monitor tumor growth, serum PSA levels every following month (Months 8-14). Sacrifice mice when tumor burden reaches 3 cm³.
   d. Perform IHC and analyze data (Months 14-18).

Modification justification:

The immunohistochemical work, as originally proposed, was not done due to technical reasons. The samples were not optimally prepared in this pilot study to preserve structure and antibody epitopes. In future experiments this can easily be rectified and a positive outcome of the pilot was this realization - future work will rectify this short-coming.

We were however able to secure enough and properly prepared material to enable an analysis of histone H3 acetylation by chromatin immunoprecipitation (ChIP) assays. This allowed us to make the interesting observation that the enhanced PSA expression in the androgen-independent tumors is probably related to locus-wide chromatin modifications conducive to efficient transcription. This novel finding was reported in the MCB paper (pdf attached to back of this).
Body:

A single hypothesis is being evaluated (see above) using a mouse xenograft model growing human prostate cancer cells CWR22 cells in nude mice. We were amazed that all groups of mice grew tumors at similar rates irrespective of the titrated level of testosterone delivered by subcutaneous pellets. Thus, all groups containing testosterone pellets of 0.5, 1.5, 3.0, 6.0 and 12.5 mg behaved as shown for group 1 in Fig 1; i.e. all tumors grew robustly and immediately after implantation. It was only in group 2 (Fig 1), in which the castrated mice did not receive testosterone pellets (thus totally ablated) that tumors took many weeks to start growing. We therefore analyzed tumors from only these the two extreme groups depicted in Fig 1.

We previously determined that histone modification was linked to PCa progression in an LNCaP / C4-2B cell culture model. We next opted to investigate the CWR22 mouse xenografts described above with respect to histone modifications at the PSA locus. The mouse model system approximates clinically relevant PCa progression to androgen independence using a non-tissue culture system. CWR22 tumors express AR, secrete PSA, and whereas they are initially androgen dependent, will progress to androgen independence following castration while retaining a transcriptionally active AR in the recurrent tumors (Fig 1) (3). Therefore, the CWR22 human PCa xenograft model mimics clinical PCa progression and provides an excellent system for studying histone alterations at the PSA locus in the context of failed androgen ablation therapy and subsequent tumor relapse. In the present study ensued after 12-16 weeks following castration (Fig 1A).

In the present experiment we analyzed two groups of mice: Group 1 CWR22 tumors were grown under the influence of testosterone, whereas Group 2 were grown under total ablation conditions, as evidenced by no measurable testosterone levels in this group (Fig 1C). Notably, Group 1 mice had on average lower steady-state levels of PSA mRNA than those in Group 2 (Fig 1B). Histone modifications were analyzed by ChIP assays performed on minced tumor material, which were harvested when the
tumors reached about 3 cm$^3$. Group 2 mice, with androgen-independent tumors, displayed statistically significant elevated histone H3-K9/K14 acetylation at the transcription start site as well as at most of the sites across the body of the PSA gene (Fig 1D). Interestingly, this difference was not observed at the PSA enhancer, although substantial acetylation was observed in both groups at this site. Histone H3-K4 di- and trimethylation were somewhat elevated in Group 2 but due to the variation between animals statistical significance was not reached (data not shown).

These results show that at the PSA locus the histone H3 acetylation in androgen-independent tumors (i.e. Group 2 mice) is increased compared to androgen-dependent tumors (Group 1 mice). The results from this animal model system are therefore in agreement with those obtained in the LNCaP / C4-2B culture system and prove that the histone modifications at the PSA locus are not an artifact of cell culture nor are they specific to a given model system.

A detailed description of this work and related experiments in the LNCaP / C4-2B system can be found in the attached manuscript (MCB in press).

**Key Research Accomplishments:**

Androgen-independent PCa cells have evolved three distinctive alterations in AR-mediated transcription. First, increased RNA polymerase initiation and processivity contribute to increased gene expression. Second, AR-signaling is more sensitive to ligand. Third, locus-wide chromatin remodeling conducive to the increased gene expression in the absence of ligand depends on sustained AR activity. Therefore, increased AR ligand sensitivity as well as loci-wide chromatin alterations contribute to basal gene expression of specific AR target genes in androgen-independent PCa cells. These features contribute to the androgen-independent phenotype of these cells.
Reportable Outcomes:

Locus-Wide Chromatin Remodeling and Enhanced Androgen Receptor-Mediated Transcription in Recurrent Prostate Tumor Cells.

See list of publications below.

Conclusions:

Our comprehensive analyses of histone modifications across the entire PSA locus revealed significant increases in histone H3-K9/K14 acetylation and H3-K4 methylation in androgen-independent cells compared to their androgen-dependent counterparts. These significant alterations of the chromatin structure at the PSA locus suggest an analogy of a ‘soil’ that is more receptive to signaling from the AR ‘seed’. We have generated evidence that these two aspects are closely linked by analyzing both non-chromatin-integrated and chromatin-integrated AR targets. To a large extent the ‘soil’ depends on the ‘seed’ but not vice versa. A positive feedback loop may exist between the AR and its target locus with increased AR activity maintaining the altered chromatin state. We tentatively propose that this link may be related to AR and subsequent polymerase engagements of the target locus leading to a ‘memory’ of transcriptional activity that in turn sustains altered patterns of histone modifications. Removal of AR, as accomplished through experimental reduction of AR protein levels, breaks this link and allows the gene locus to return to its pre-stimulated state. This mechanistic relationship implies that treatment strategies for androgen-independent PCa that currently focus on targeting the AR will be more effective than perhaps previously realized, since targeting the AR will also desensitize AR-regulated gene loci and consequently the entire cancer phenotype. Such treatment strategies are presently being contemplated (4) and our results here support the utility of these approaches to levels not previously appreciated.

Prostate cancers (PCAs) become resistant to hormone withdrawal through increased androgen receptor (AR) signaling. Here we show increased AR-mediated transcription efficiency in PCA cells that have acquired the ability to grow in low concentrations of androgen. Compared to androgen-dependent PCA cells, these cells showed increased activity of transiently transfected reporters and increased mRNA synthesis relative to levels of AR occupancy of the prostate-specific antigen (PSA) gene. The locus also displayed up to 10-fold-higher levels of histone H3-K9/K14 acetylation and H3-K4 methylation across the entire body of the gene. Although similar increased mRNA expression and locus-wide histone acetylation were also observed at another kalirein locus (KLK2), at a third AR target locus (TMPRSS2) increased gene expression and locus-wide histone acetylation were not seen in the absence of ligand. Androgen-independent PCA cells have thus evolved three distinctive alterations in AR-mediated transcription. First, increased RNA polymerase initiation and processivity contributed to increased gene expression. Second, AR signaling was more sensitive to ligand. Third, locus-wide chromatin remodeling conducive to the increased gene expression in the absence of ligand was apparent and depended on sustained AR activity. Therefore, increased AR ligand sensitivity as well as locus-specific chromatin alterations contribute to basal gene expression of a subpopulation of specific AR target genes in androgen-independent PCA cells. These features contribute to the androgen-independent phenotype of these cells.

The molecular processes that mediate transcription orchestrate cell proliferation, differentiation, and disease progression. Central to this regulation is the dynamic organization and modification of nucleosomes, the basic repeating unit of chromatin that is comprised of 146 bp of DNA wrapped around histone octamers. Accessibility to transcription factors and activation of genes largely depend on diverse posttranslational modifications of amino termini (36, 47) and the more recently implicated globular domains of histones (6). These modifications include acetylation, phosphorylation, and methylation, which covalently add acetyl, phospho, and methyl groups, respectively, to specific residues of core histones. The well-characterized acetylation and methylation of lysines in histones H3 and H4 are highly correlated with transcriptional activation. Acetylation, catalyzed by histone acetyltransferases such as p300/CBP, is reversed by the activity of histone deacetylases, which mediate transcriptional repression (21). Methylation at histone H3 (K4) is catalyzed by specific methyltransferases often found in large complexes such as ALL-1 (32). This process is reversed by the action of a recently identified lysine-specific histone demethylase, LSD1 (39, 40). The complex interactions between the different histone tail modifications have led to the “histone code hypothesis,” which suggests that specific histone modifications affect and interact with other histone modifications, thus serving as markers for the recruitment of associated factors for the regulation of chromatin function (41). This system regulates DNA synthesis, genome stability, and the efficiency of gene expression in patterns that are clonally maintained (17). It is therefore expected that clonally derived cancer cells will have distinguishing patterns of locus-specific histone modifications related to the cancer phenotype. In the case of prostate cancer (PCa), gene expression at androgen receptor (AR) target loci is of particular interest as a focal point for examining such patterns of histone modification as they may relate to disease initiation and progression.

AR signaling serves as a prototypical model of transcriptional regulation and is critical in all phases of PCA development, including the evolution of resistance to androgen ablation therapies. Resistance to androgen ablation is associated with an altered capacity of the AR to remain functional in the androgen-depleted environment (reviewed in references 1, 4, 7, and 12). Growth of androgen-independent PCA cells remains AR dependent, as disruption of the AR by a specific antibody or ribozyme inhibits proliferation (46). Furthermore, aberrant AR activity in androgen-independent PCA includes AR hypersensitivity to androgens and insensitivity to antagonists, possibly due to increased AR expression and/or the impact of other molecular factors in tumors. It was conclusively demonstrated that increased AR expression is necessary and
sufficient to convert androgen-sensitive PCs to an androgen-independent state (5). Moreover, specific expression in mouse prostate epithelial cells of a trans-AR gene containing a gain-of-function mutation (with increased basal activity and response to coregulators) resulted in PCs development in 100% of the animals (16), proving that aberrant AR signaling was sufficient to cause PCs.

An important component of the AR-mediated phenotype observed in androgen-independent prostate cancer is the increased sensitivity to castrate levels of androgen that leads to androgen-independent AR target gene expression and tumor recurrence (5). Because it was recently shown that global histone acetylation and dimethylation patterns predicted the risk of PCa recurrence (38), we hypothesized that part of the increased sensitivity of the AR to low levels or absence of androgen may reside in target gene histone alterations that allow AR-mediated transcription to occur at higher-than-normal efficiency.

In our recent work (18–20, 25, 26) we have made extensive use of the LNCaP/C4-2B cell culture model of PCa progression. LNCaP cells endogenously express the AR and are dependent on the natural AR ligand dihydrotestosterone (DHT) for growth and prostate-specific antigen (PSA) expression (45). C4-2B is an androgen-independent subtype of LNCaP that still expresses a functional AR (9). It was obtained by passage, growth, and isolation of LNCaP from bone metastasis in castrated athymic mice (42). In our most recently published study (19) we have compared AR activity in LNCaP and C4-2B cell lines using PSA expression as a target gene readout. We observed very little PSA expression in LNCaP cells in the absence of androgens, while substantial expression was observed in C4-2B cells under the same condition. The addition of DHT to the culture medium increased the expression of PSA in both cell types. In that study chromatin immunoprecipitation (ChIP) analysis unexpectedly revealed that AR was not significantly detectable at any site within the (ChIP) analysis revealed that AR was not significantly detectable at any site within the culture medium (19). Therefore, in the present study we set out to investigate mechanisms involved in AR-mediated gene expression in androgen-independent PCs and report data consistent with three novel concepts that occur during the progression of PCs to androgen independence. First, increased RNA polymerase initiation and processivity contribute to increased gene expression. Second, AR-mediated transcription is sensitive to lower ligand concentrations. Third, significant androgen-independent chromatin alterations at certain AR target loci depend on sustained AR signaling.

### MATERIALS AND METHODS

#### Cell culture and materials

Human prostate cancer LNCaP and PC-3 cells, obtained from the American Type Culture Collection (ATCC; Manassas, VA), and C4-2B cells, obtained from ViroMed Laboratories (Minneapolis, MN), were maintained in RPMI 1640 supplemented with 5% (vol/vol) fetal bovine serum (FBS). CV-1 cells obtained from the ATCC were grown in Dulbecco modified Eagle medium (DMEM) with 5% FBS. 5α-DHT, dexamethasone (Dex), and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) mRNA expression were analyzed as previously described (20). The primers and probes of real-time PCR for PSA pre-mRNA, PSA mature mRNA, and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) mRNA expression were as previously described (20).

### ChIP assays

LNCaP (3 × 10^6 cells/well) and C4-2B (1.5 × 10^6 cells/well) were plated in 12-well plates and grown in phenol red-free RPMI 1640 containing 5% CSS for 2 days. Cells were then transfected with an AR-responsive firefly luciferase reporter plasmid, PSA-luc, probasin-luc, or MMTV-luc (1 μg) along with pRL-SV40 Renilla luciferase plasmid (Promega) (10 ng) using Lipofectamine 2000 (Invitrogen Corp., Carlsbad, CA) according to the manufacturer’s protocol. The next day cells were exposed to 5 μM MG132 or dimethyl sulfoxide (DMSO) vehicle for 2 h, after which the media were changed to introduce 10 nM DHT or 100 nM Dex or ethanol (EtOH) vehicle for a subsequent 24-hour treatment. Cells were lysed using Passive Lysis Buffer (Promega, Madison, WI), and luciferase activity determinations in cell lysates were conducted as previously described (20). MG132 were purchased from Sigma Chemical Co. (St. Louis, MO). Antibodies were anti-AR (N20), anti-polymerase II (N20), antiactin: 5α-DHT (anti-AR)-K9/K14, anti-dimethyl-H3-K4 (Upstate Biotechnology, Inc., Lake Placid, NY), anti-trimethyl-H3-K4, and anti-histone H3 (Abcam, Cambridge, MA). The probasin-luc (AR3-thymidine kinase-luciferase) and MMTV-luc (mouse mammary tumor virus-luciferase) expression vectors have been used previously in our studies (20). PSA-luciferase (PGL3-PSA585) was a generous gift from Hong-Wu Cheng, University of California at Davis, and was constructed by inserting 5.85 kb of the entire PSA upstream sequence into pGL3 basic vector (29).

### Transient-transfection and luciferase assays

CV-1 cells were seeded in 96-well plates at 7 × 10^3 cells/well in phenol-red free DMEM containing 5% charcoal/dextran-stripped FBS (CSS). One day later cells were transfected with MMTV-luc reporter (100 ng/well) along with AR (10 ng/well) or glucocorticoid receptor (GR) (10 ng/well) using Lipofectamine 2000 (Invitrogen Corp., Carlsbad, CA) according to the manufacturer’s protocol. The next day cells were exposed to 5 μM MG132 or dimethyl sulfoxide (DMSO) vehicle for 2 h, after which the media were changed to introduce 10 nM DHT or 100 nM Dex or ethanol (EtOH) vehicle for a subsequent 24-hour treatment. Cells were lysed using Passive Lysis Buffer (Promega, Madison, WI), and luciferase activity determinations in cell lysates were conducted as previously described (20).

### Histone isolation and immunoblotting

Total histone isolation and immunoblotting were performed as previously described using the indicated antibodies (18, 26). Real-time RT-PCR.

#### After the indicated treatments, total RNA from cells or tissues was extracted using the SV Total RNA Isolation System (Promega). A two-step reverse transcription-PCR (RT-PCR) method was employed using the TaqMan Gold RT-PCR kit (Applied Biosystems, Branchburg, NJ) and Opticon (MJ Research, Inc., Waltham, MA). The primers and probes of real-time PCR for PSA pre-mRNA, PSA mature mRNA, and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) mRNA expression were as previously described (20).

### Results are given as percentages of input.

#### siRNA transfection.

Cells were transfected with small interfering RNA (siRNA)-mediated AR knockdown was nevertheless affected indirectly via an unknown AR-dependent mechanism(s).

Therefore, in the present study we set out to investigate mechanisms involved in AR-mediated gene expression in androgen-independent PCs and report data consistent with three novel concepts that occur during the progression of PCs to androgen independence. First, increased RNA polymerase initiation and processivity contribute to increased gene expression. Second, AR-mediated transcription is sensitive to lower ligand concentrations. Third, significant androgen-independent chromatin alterations at certain AR target loci depend on sustained AR signaling.
using Oligofectamine reagent (Invitrogen Corp.) according to the manufacturer’s instructions. After transfection, cells were grown in phenol red-free RPMI 1640 containing 5% CSS for 3 days and then pretreated with 5 μM MG132 or DMSO vehicle for 2 h, followed by 10 nM DHT or EtOH vehicle for 2 h. AR and RNA polymerase II (Pol II) occupancies at the indicated sites of the PSA gene were examined by ChIP analyses. The results are representative of two independent experiments, and values are presented as percentage input and represent mean values ± standard deviations. IgG, immunoglobulin G. C. LNCaP and C4-2B cells were treated as described for panel B. Immunoblot analyses of AR and actin protein levels from whole-cell extracts were conducted. The number above each lane of AR expression indicates the relative intensity of each band normalized to actin expression. The data are representative of two independent experiments. D. LNCaP and C4-2B cells were treated as described for panel B. PSA pre-mRNA levels were examined by real-time RT-PCR. The results are shown as PSA pre-mRNA/GAPDH ratios. Values are presented as the means ± standard deviations of triplicate determinations. E. CV-1 cells were incubated in phenol-red free DMEM containing 5% CSS for 1 day prior to transfection with MMTV-luc reporter (100 ng/well) along with AR (10 ng/well) or GR (10 ng/well) in 96-well plates. Cells were exposed to 5 μM MG132 or DMSO vehicle for 2 h, followed by 10 nM DHT or 100 nM Dex treatment for 24 h. Data are measured in relative light units (RLU) and are representative of results obtained from three independent experiments. Values are means ± standard deviations of triplicate wells.

VOL. 26, 2006 AR-MEDIATED ENHANCED TRANSCRIPTION EFFICIENCY 7333

RESULTS

Unliganded AR occupancy at the PSA enhancer is associated with high PSA expression in androgen-independent PCa cells. In the present study we have addressed the novel concept
that an AR target locus may become more sensitive to the transcription factor by extending our analyses across the entire PSA gene (Fig. 1A). Although AR did not significantly localize to any site at this locus in C4-2B cells in the absence of DHT, it could be detected at the PSA enhancer if the cells were pretreated with the potent 26S proteasome inhibitor MG132 (Fig. 1B) (27). MG132 disrupts proteasome involvement in the cyclical recruitment of transcription factors to steroid receptor-mediated transcription sites (10, 22). The proteasome-mediated turnover of the estrogen receptor (ER) on responsive promoters was previously shown to be an integral feature of ER signaling (33). Therefore, we surmised that inhibition of the proteasome may cause accumulation of AR at the PSA enhancer even if AR occupies the site transiently and that this could result in enhanced detection sensitivity. Significant AR levels accumulated at the PSA enhancer after MG132 treatment in the absence of DHT, more so in C4-2B than in LNCaP cells. However, this did not lead to substantial RNA polymerase II recruitment to any site at the locus (Fig. 1B), consistent with proposals that proteasome-mediated effects on RNA polymerase II resolve stalled polymerase complexes during transcription (14).

Another insight was revealed by the polymerase occupancy data obtained from C4-2B cells not treated with MG132 (Fig. 1B). Although the polymerase occupancy levels were similar between cells treated and cells not treated with DHT at the promoter (site F), the levels were significantly higher through the body of the genes in cells treated with DHT. Polymerase II occupancy at the transcription start site in the absence of DHT (vehicle) in C4-2B cells is in line with significant PSA expression under these conditions, whereas its increased presence through the body of the gene after DHT treatment is consistent with an increase in polymerase processivity (30). However, the fact that the polymerase occupancy levels were higher at the enhancer, promoter, and gene body in C4-2B cells than in LNCaP cells may be due to increases in both processivity and transcription initiation events in C4-2B cells. Exactly how this is achieved is unclear, but it seems to be unrelated to AR occupancy at the enhancer, which was similar in LNCaP and C4-2B cells.

The increased AR accumulation at the PSA enhancer in C4-2B compared to LNCaP cells after MG132 treatment indicates that AR turnover, mediated by proteasomal action, may occur at higher rates in the absence of ligand in C4-2B than in LNCaP cells. The MG132 treatment marginally stabilized the AR protein by 20 to 30% (Fig. 1C). As expected, AR occupancy levels increased to similar levels as a result of 2-h DHT treatment in both cell types. Therefore, AR does in fact localize to the PSA enhancer in C4-2B cells in the absence of ligand, if only transiently and at a relatively low level, and can thus mediate PSA expression in the absence of DHT. These data also suggest that very low steady-state levels of AR occupancy can mediate substantial PSA expression in the absence of DHT specifically in C4-2B cells (Fig. 1D). PSA pre-mRNA expression was 4- to 11-fold higher in C4-2B cells under all conditions (Fig. 1D). Therefore, in androgen-independent C4-2B cells, AR-mediated transcription of PSA was markedly more efficient than in LNCaP cells as defined by mRNA synthetic rates relative to AR occupancy levels at the PSA enhancer. As expected, MG132 treatment inhibited PSA expression in both

**FIG. 2.** DHT-sensitive AR phenotype in androgen-independent PCa cells. A. LNCaP and C4-2B cells were transiently transfected with PSA-luc reporter plasmid along with *Renilla* luciferase plasmid as described for panel B. Immunoblot analyses of AR and actin protein levels from whole-cell extracts were conducted. B. LNCaP and C4-2B cells were transiently transfected with one of three AR-responsive firefly luciferase reporter plasmids, PSA-luc, probasin-luc, or MMTV-luc (1 μg/well), along with the pRL-SV40 *Renilla* luciferase plasmid (10 ng/well) in 12-well plates and incubated with different concentrations of DHT as indicated for 24 h. Dual luciferase assays were conducted. The results were normalized for the internal *Renilla* control of each well and expressed as the mean relative light units (RLU) ± standard deviation from quadruplicate samples.
FIG. 3. Histone modification analyses at the PSA locus. A. Schematic representation of the PSA gene. Vertical arrows show real-time PCR-targeted regions. UTR, untranslated region. B. LNCaP, C4-2B, and PC-3 cells were incubated in phenol red-free RPMI 1640 containing 5% CSS for 3 days and then treated with 10 nM DHT or EtOH vehicle for 4 h. AcH3, dimethylated H3-K4, trimethylated H3-K4, and unmodified histone H3 were examined by ChIP analyses at each of the PSA target regions. Duplicate IPs for each antibody and duplicate real-time PCR for each IP sample were done. Values are presented as percentages of input and represent mean values ± standard deviations.
cell types in the presence or absence of DHT. Also, AR-mediated regulation of an ectopically expressed luciferase reporter in CV-1 cells was inhibited by MG132 treatment (Fig. 1E). It is understood that these inhibitory effects result from sequestration of the AR at AR binding sites in response to proteasome inhibition. It is known that MG132 does not inhibit GR activity (11), a phenomenon that we have used in this experiment to demonstrate that the inhibition of AR-mediated transcription by MG132 was not due to cytotoxic effects of the drug.

DHT-stimulated, non-chromatin-integrated, ARE-luciferase reporters are expressed at higher levels and are more sensitive to DHT concentrations in androgen-independent cells. In order to determine AR activity on non-chromatin-integrated promoters, we transiently transfected and measured expression of androgen response element (ARE)-driven luciferase reporters in C4-2B and LNCaP cells (Fig. 2). With the use of any one of three reporter constructs (PSA-, probasin-, or MMTV-luciferase), the C4-2B cells were able to respond to DHT at concentrations lower by several orders of magnitude and with severalfold-higher expression levels. The results could not be explained by differences in transfection efficiency or AR steady-state levels (Fig. 2A). The data indicate that an AR ligand-sensitive phenotype exists in C4-2B cells, unrelated to integrated chromatin architecture of the target locus. This is probably due to altered AR activation mechanisms (4, 8, 12). Similar hypersensitivity to DHT was observed when endogenous PSA expression was measured (19). However, a significant difference between basal expression levels (no added DHT) of the transient reporter and the endogenous PSA was apparent; whereas luciferase expression levels under these conditions were very low and similar in C4-2B and LNCaP cells (Fig. 2), endogenous PSA expression values in the absence of DHT were more than 10-fold higher in C4-2B than in LNCaP cells (Fig. 1D). We conclude that although a chromatin-independent, hypersensitive AR phenotype exists in C4-2B cells, efficient transcription in the absence of DHT depends on chromatin-integrated genes.

The PSA locus is hyperacetylated and hypermethylated in androgen-independent cells. To test the hypothesis that the chromatin structure at the PSA locus may be conducive to AR-mediated transcription at very low levels of AR occupancy and in the absence of added ligand, we examined histone modifications across the entire PSA locus (Fig. 3A). Histone H3 acetylation levels at residues K9 and K14 were markedly higher in C4-2B cells than in either LNCaP or AR-negative PCa cells (PC-3), even in the absence of DHT treatment (Fig. 3B). Very high levels of histone H3 acetylation were apparent at the transcription start site and also most dramatically throughout the body of the gene in C4-2B cells, returning to basal levels only downstream of the 3′ end of the gene. Although the highest levels of acetylation were observed in introns 1 (site G) and 2 (site H), the high levels of acetylation across the entire body of the gene are in contrast to acetylation islands at the transcription start sites of many actively transcribed genes as revealed in genome-wide screens (28, 34, 35). Furthermore, both dimethylated and trimethylated H3-K4 levels in C4-2B cells were significantly increased across the body of the gene (Fig. 3B). The current data suggest that the situation in specifically activated genes, such as PSA in PCa cells, represents a special condition of sustained “open” chromatin structures across entire loci that facilitate hypersensitivity to the AR-mediated transcription. In this regard the PSA locus is similar to the locus control region of the active ε-globin gene where histone H3 and H4 acetylation and H3-K4 methylation were found to be continuous over a 17-kb region during active gene expression (23). Similarly, a nearly continuous H3-K4 methylated 60-kb region stretches from HOXAI to HOXA7 in human lung fibroblasts (2). Loci such as these have apparently evolved to allow sustained expression of their component genes.

FIG. 4. p16 gene expression and histone modifications. A. LNCaP and C4-2B cells were incubated in phenol red-free RPMI 1640 containing 5% CSS for 3 days and treated with 10 nM DHT and EtOH vehicle for 18 h. p16 and GAPDH mRNA levels were measured by real-time RT-PCR. The p16 expression levels are shown as p16/GAPDH mRNA ratios. Values are presented as the means ± standard deviations of triplicate determinations. B. Schematic representation of the p16 gene. Vertical arrows show real-time PCR-targeted regions. C. ChIP DNA samples, obtained from the experiment depicted in Fig. 3B, were analyzed for AcH3, dimethylated H3-K4, and trimethylated H3-K4 histones at the p16 locus.
DHT treatment increased the levels of histone H3 acetylation in C4-2B and LNCaP cells but not in AR-negative PC-3 cells (Fig. 3B). Di- and trimethyl-H3 levels at residue K4 decreased after DHT treatment at most sites, as we have reported previously, which is possibly due to epitope masking (26). Total histone H3 density was similar at most sites in all cells, indicating that the observed hyperacetylation and hypermethylation were not because of discrepancies in histone densities. However, at both the enhancer and promoter (sites B and F, respectively), H3 density decreased somewhat after DHT treatment, possibly due to nucleosome displacement at these sites by the docking of transcription initiation factors. Similar dips in levels of histones H3.3 and H3 were seen at active promoters of Drosophila melanogaster and interpreted as areas depleted of nucleosomes (31).

At the non-AR-target p16 locus the levels of above-mentioned histone modifications were similar in LNCaP and C4-2B cells, as was p16 mRNA expression (Fig. 4). Furthermore, the total genome-wide levels of acetylated and methylated histone H3 were similar in the three cell types regardless of DHT exposure (see Fig. S1 in the supplemental material). These results indicate that the dramatic alterations of histones in C4-2B cells are PSA locus specific, which strongly implicates AR activity in the process.

In vitro electromobility shift assays using an androgen response element containing double-stranded DNA oligonucleotide as a probe revealed no differences in activity from whole-cell extracts of LNCaP and C4-2B cells (see Fig. S2 in the supplemental material), indicating that the cellular milieu was not different between the two cell types in allowing AR to interact with its cognate DNA response element.

Overall the results indicate that the hypersensitization of the PSA locus by significant histone H3 acetylation and methylation that encourage an “open” chromatin structure is a likely mechanism behind the elevated androgen-independent PSA expression observed in C4-2B cells.

Gene expression and histone H3 acetylation at two other AR target loci. In order to determine the generality of AR-mediated gene overexpression and locus-wide histone hyperacetylation found at the PSA locus, we analyzed two additional AR target loci, tissue kallikrein 2 (KLK2) and TMPRSS2. KLK2 is 18.5 kb downstream from the PSA locus (also known as KLK3) and similarly belongs to a family of 15 tissue kallikrein genes on chromosome 19 (3). KLK2 is a distinct locus from PSA4, and histone H3 acetylation increases observed at the PSA locus do not continuously extend to the KLK2 locus (data not shown). TMPRSS2 is an AR target gene on chromosome 21, and its promoter (and androgen dependence) is often translocated to ETS transcription factor genes in PCa (43, 44). This translocation has not happened in LNCaP cells (44) and presumably also not in C4-2B cells, since in both cell lines TMPRSS2 expression was significantly stimulated by DHT (Fig. 5A). In the absence of DHT, KLK2 was significantly more expressed in C4-2B than in LNCaP, whereas expression levels of TMPRSS2 were similar in the two cell lines under the same nonligand conditions. The expression of both genes in both cell lines was significantly induced by the addition of DHT to the medium. In the absence of DHT, the KLK2 locus had an enhanced histone H3 acetylation pattern across the entire gene body in C4-2B compared to LNCaP cells (Fig. 5B). At the TMPRSS2 locus only the promoter and 5' end were acetylated and the levels were similar in the two cell lines in the absence of DHT (Fig. 5C). At both loci, and in both cell lines, the levels of acetylation increased after DHT treatment. Thus, KLK2 behaved with greater similarity to PSA than does TMPRSS2.

Increased histone acetylation is associated with the development of androgen independence in vivo. To determine whether the data linking histone modification with PCa progression reported thus far are confined to the LNCaP/C4-2B cell culture model, we opted to investigate CWR22 mouse xenografts, a powerful model system to study clinically relevant PCa progression to androgen independence in a nontissue culture system. CWR22 tumors express AR and secrete PSA and whereas they are initially androgen dependent, will progress to androgen independence following castration while retaining a transcriptionally active AR in the recurrent tumors (24). Therefore, the CWR22 human PCa xenograft model mimics clinical PCa progression and provides an excellent system for studying histone alterations at the PSA locus in the context of failed androgen ablation therapy and subsequent tumor relapse. In the present study this process lasted 12 to 16 weeks following castration (Fig. 6A).

In the present experiment we established two groups of mice: group 1 CWR22 tumors were grown under the influence of testosterone, whereas group 2 tumors were grown under total ablation conditions, as evidenced by the absence of measurable testosterone levels in this group (Fig. 6C). Notably, group 1 mice had on average lower steady-state levels of PSA mRNA than did group 2 mice (Fig. 6B). Histone modifications were analyzed by ChIP assays performed on minced tumor material, which was harvested when the tumors reached about 3 cm³. Group 2 mice, with androgen-independent tumors, displayed statistically significant elevated histone H3-K9/K14 acetylation at the transcription start site as well as at most of the sites across the body of the PSA gene (Fig. 6D). Interestingly, this difference was not observed at the PSA enhancer, although substantial acetylation was observed in both groups at this site. Histone H3-K4 di- and trimethylation were somewhat elevated in group 2, but due to the variation between animals statistical significance was not reached (data not shown).

These results show that at the PSA locus the histone H3 acetylation in androgen-independent tumors (i.e., group 2 mice) is increased compared to that in androgen-dependent tumors (group 1 mice). The results from this animal model system are therefore in agreement with those obtained in the LNCaP/C4-2B culture system and prove that the histone modifications at the PSA locus are not an artifact of cell culture, nor are they specific to a given model system.

Histone alterations at the PSA locus in androgen-independent PCa cells are AR dependent. In our previous study we observed that siRNA knockdown of AR using two independent siRNA constructs inhibited PSA expression in C4-2B cells grown in the absence and presence of androgens (19). Recently it was also shown that cell proliferation was attenuated by siRNA-mediated knockdown of the AR (13). In the present experiments we knocked down AR and analyzed histone modifications at the PSA locus. As our work has previously demonstrated, after 4 days of AR knockdown nearly all AR protein was depleted from the cells as shown by immunoblot analysis.
Histone H3-K9/K14 acetylation and histone H3-K4 methylation (both di- and trimethylation) were reduced at many sites after the AR knockdown (Fig. 7B). With regard to acetylated histones, this was most apparent at sites F to H, but less so at the other sites, whereas both di- and trimethylated levels were quite dramatically reduced by the treatment at most sites. We interpret the difference between the reduction levels in acetylation versus methylation as reflecting a lower...
It is interesting that the levels of dimethylated sites were more dramatically reduced than the levels of the trimethylated ones, again suggesting a difference in turnover rates. Nevertheless, the fact that the histone alterations were reduced after AR

turnover rate of acetylation than of methylation marks. It is
knockdown indicates that the altered modified histone levels seen in C4-2B cells are maintained by sustained AR activity, possibly due to sustained transcription at this locus. Therefore, the AR represents the link between gene expression and histone alterations at the PSA locus.

**DISCUSSION**

Progression of PCa is typified by conversion of cells from androgen dependence to independence as a result of ablation therapy failure. The consensus view is that this is due to the conversion of AR signaling from ligand dependence to independence (most recently reviewed in reference 8). Our present studies revealed that androgen-independent PCa cells became more amenable to AR-mediated gene expression because of increased polymerase engagement at target genes, an AR hypersensitive to ligand, and chromatin alterations of target genes conducive to increased transcription efficiency. This combined phenotype resulted in elevated AR signaling at very low or no androgen levels. We propose that cells containing this phenotype are selected during the transition from androgen-dependent to independent PCa. This can be appreciated by considering the AR as the “seed” and AR target loci as the “soil” that combine to yield more efficient transcription as a consequence of more effective polymerase engagement. Locus-wide chromatin alterations were observed at some, but not all, AR target loci. Thus, the two kallikrein genes (PSA and KLK2), behaved similarly in that locus-wide histone acetylation in C4-2B cells not exposed to ligand was associated with substantial gene expression at the loci. Such genes belong to a subset of AR target genes, since TMPRSS2 did not behave in this manner and acetylation was confined to the 5' end of the gene with similar levels of acetylation in the two cell lines in the absence of ligand. We do not know how many genes belong to each of the two groups of AR targets; neither do we know the functional significance of the two groups with respect to PCa progression to androgen independence. It is even possible that simply the size of a particular locus determines the extent of locus-wide acetylation. On the other hand, functional selection of efficient expression of kallikreins may aid tumor growth in a diminished-androgen environment; it is proposed elsewhere that kallikreins are major players in cancer progression.

Many more AR target genes need to be analyzed before general rules can be established that determine efficiency of expression and associated locus-wide histone modifications in androgen-independent PCa cells. However, the chromatin structure and gene expression behavior at the two kallikrein loci provide a novel insight in AR-mediated gene expression during PCa progression to androgen independence.

It is known that AR expression/activity and its associated signaling partners may be altered during the androgen-independent development of PCa clones (1, 4, 5, 12). However, these proposed mechanisms that focus solely on alterations of the AR itself cannot explain the data presented here or those of our previous work (18–20). Although KLK2 behaved similarly to PSA, here we have concentrated on PSA gene expression and the best-studied kallikrein gene and was the target of our previous investigations. It is remarkable that the rate of PSA mRNA expression did not correlate with AR occupancy at the PSA enhancer or promoter when LNCaP and C4-2B cells were compared. In the androgen-independent C4-2B cell line PSA mRNA expression in the absence of DHT was nearly an order of magnitude higher than that in LNCaP even though the AR occupancy was barely detectable. When DHT was added to the culture medium, PSA mRNA expression rates increased in both cell lines but the expression in LNCaP reached only a level comparable to that in C4-2B cells not treated with DHT. These results indicate that perhaps the PSA locus itself was more conducive to transcriptional stimulation in C4-2B cells, either by histone modifications or by loss of repressors.

Our comprehensive analyses of histone modifications across the entire PSA locus revealed significant increases in histone H3-K9/K14 acetylation and H3-K4 methylation in androgen-independent cells compared to their androgen-dependent counterparts. These significant alterations of the chromatin structure at the PSA locus suggest an analogy of a “soil” that is more receptive to signaling from the AR “seed.” We have generated evidence that these two aspects are closely linked by analyzing both non-chromatin-integrated and chromatin-integrated AR targets. Our experiments using transiently transfected reporters indicate that the ligand-sensitive AR phenotype in C4-2B cells was chromatin independent. On the other hand, the siRNA knockdown of the AR showed that the chromatin-modified phenotype depended on sustained AR signaling. Furthermore, the significant target gene expression in the absence of added DHT was dependent on both the AR and its target locus with increased AR activity maintaining the altered chromatin state. We tentatively propose that this link may be related to AR and subsequent polymerase engagements of the target locus leading to a “memory” of transcriptional activity that in turn sustains altered patterns of histone modifications. Removal of AR, as accomplished through experimental reduction of AR protein levels, breaks this link and allows the gene locus to return to its prestimulated state. This mechanistic relationship implies that treatment strategies for androgen-independent PCa that currently focus on targeting the AR will be more effective than perhaps previously realized, since targeting the AR will also desensitize AR-regulated gene loci and consequently the entire cancer phenotype. Such treatment strategies are presently being contemplated (37), and our results here support the utility of these approaches to levels not previously appreciated.

**ACKNOWLEDGMENTS**

We thank Christopher W. Gregory (University of North Carolina) for supplying us with CWR22 tumors and advice on how to maintain them and Debbie Johnson (USC) for helpful discussions. This work was supported by grants from the NIH/NCI (R01 CA109147) (to G.A.C.), the United States Department of Defense (W81XWH-04-1-0049 and W81XWH-04-1-0823) (to G.A.C.), and the Prostate Cancer Foundation (to G.A.C.).
