Abstract

A Positron Annihilation Lifetime Spectroscopy (PALS) system was developed and tested. PALS has the capability to characterize negatively charged defects and voids in materials such as explosives. The timing resolution of the optimized system is 197±14 ps as measured with a known $^{60}$Co source. A single-crystal tungsten sample was used to confirm the system calibration resulting in a lifetime of 101±2 ps (as compared to 105 ±5 ps in the literature (16)). The PALS system was then used to compare the differences between as grown and neutron-irradiated single crystal silicon carbide (SiC), illustrating that neutron bombardment of SiC results in the creation of silicon vacancies in the material. The lifetime of a positron associated with a boron cage anion, dodecahydrododecaborate in aqueous nitrate solution, was 277 ± 10 ps, compared with previous measurements of the cage compound in solid state which yielded 268 ± 8 ps. Competition for positrons between nitrate anion and the boron cage was measured.
Acknowledgements

I wish to express my gratitude to the faculty and staff of The Air Force Institute of Technology for their guidance and assistance without which this thesis would have presented an insurmountable task.

My fellow classmates have made the process of learning, research and analysis tolerable through their humor and fellow suffering.

“It is a miracle that curiosity survives formal education.” - Albert Einstein

“What you've just said is one of the most insanely idiotic things I have ever heard. At no point in your rambling, incoherent response were you even close to anything that could be considered a rational thought. Everyone in this room is now dumber for having listened to it. I award you no points, and may God have mercy on your soul.”

I. Introduction

The purpose of this thesis is to describe the construction of a fast-fast coincidence timing positron annihilation spectroscopy system (PALS) and its use to measure positron lifetimes in an explosives surrogate material. Actual explosives were not used due to restrictions in place on the laboratory facilities. This work supports research being conducted by the Air Force Research Laboratory on nanoscale pore effects in energetic materials. This thesis assumes the reader has a background understanding of basic nuclear physics.

Background

The objects that surround us, those we see, smell and touch everyday, are composed of matter; molecules made up of atoms which are composed of protons and neutrons in a nucleus surrounded by a cloud of electrons. There is another type of matter with which we are not accustomed: antimatter. For each type of matter there is an equivalent type of antimatter, exactly the same in nearly all ways except for electric charge (there are also anti-neutrons with no charge). When matter and antimatter collide they destroy each other, or annihilate, releasing energy.
Positrons, or positive electrons, were first theorized in 1930 by Paul Dirac (1). He described an electron gas that might have holes in it. These holes would appear as positively charged particles with the same mass as an electron. The positron is predicted by the relativistic wave equation for the energy of the electron, which has two real solutions

\[ E = \pm \sqrt{p^2 + mc^2} \]  

(1.1)

where the negative solution gives the energy of the electron and the positive solution gives that of the positron. The positron has the same mass as an electron (0.511 MeV or 9.1x10^{-31} kg) and spin (1/2) but opposite charge (1.602 x 10^{-19} Coulombs). Thus, positrons are the antimatter equivalent to the electron, or the anti-electron. The positron is believed to be a stable particle in a vacuum.

The positron was discovered experimentally by Carl D. Anderson in 1932. His paper, published in 1933, describes his observations of a cloud chamber in which he unexpectedly observed positively charged tracks from cosmic rays (2). By measuring the curvature of the tacks made by charged particles, he determined the particle charge to be equal to that of the proton, but the mass to be on the order of the electron (Figure 1).
Positrons come from a variety of sources. Reactors and accelerators produce many positrons in their operation. Positrons are also formed through pair-production when the energy of a photon having an energy greater than 1.022 MeV (the rest mass energy of the electron-positron pair) is converted into mass. For laboratory experiments, scientists normally use positrons generated through radioactive decay. Many radioisotopes exist which possess an excess of protons and thus can decay by the $\beta^+$ process. $\beta^+$ decay occurs when a proton in the nucleus decays into a neutron, emitting a positron accompanied by a neutrino.

$$p \rightarrow n + e^+ + \nu$$ (1.2)

An isotope is chosen as a positron source for a particular application based on a number of considerations. The characteristic half-life of the radioisotope needs to be of sufficient duration such that the activity of the source remains constant, or nearly so, for the duration of the experiment. The half-life must also be adequate for transportation and storage. The activity of the source must be high enough that it is easily identifiable above background, yet not be so high that multiple positrons will be present in the sample at any
one time. The energy of the $\beta^+$ particle is also of importance; it should stand out from the background radiation to be easily identifiable in an energy spectrum. In PALS, it is important to know when the positron is born. This is usually accomplished with a birth indicator, a gamma emission coincident with the $\beta^+$ decay. In lifetime spectroscopy the difference in time between the birth gamma and the annihilation photon is measured, making the birth gamma extremely important. An important factor in the selection of a radioisotope is cost. It must be available in sufficient quantities and at a reasonable price. For these reasons the most commonly used isotope is sodium-22.

Sodium-22, $^{22}$Na, has many desirable qualities. $^{22}$Na decays by $\beta^+$ to an excited state of 22-Neon, $^{22}$Ne, 90% of the time. The $^{22}$Ne de-excites in 3.7 ps by emitting a 1.274 MeV gamma. The 3.7 ps lifetime is short enough that it can be considered to be emitted simultaneously with the $\beta^+$ particle, making it a suitable birth-indicator. $^{22}$Na has a half-life of 2.6 years, long enough to generate a relatively constant $\beta^+$ flux for the duration of most experiments. Most importantly, $^{22}$Na is readily available and affordable. The decay scheme is shown in Figure 2.

![Figure 2. Sodium-22 Decay Scheme.](image)

Positrons are emitted from nuclei in a $\beta^+$ decay, having a broad spectrum of energies as shown in Figure 3. The $^{22}$Na positron energy spectrum, in particular, has a
peak energy of 546 keV. For most PALS applications, this range of energies is acceptable, but for some instances it is desirable to moderate the positrons to a single energy.

![Figure 3. $^{22}\text{Na}$ positron $\beta^+$ emission spectrum showing also a notional moderated positron peak. (18)](image)

The field of positron spectroscopy consists of three types of techniques. Positron Annihilation Lifetime Spectroscopy (PALS) measures the time difference between a birth gamma and an annihilation photon. PALS is a nondestructive method of measuring defects in materials by relating the lifetime to defect sizes and electron density. Doppler Broadening of Annihilation Radiation (DBAR) measures the Doppler shift in the photon energy resulting from the momentum of the annihilating electron-positron pair. It measures the line width of the annihilation photon energy spectra, detecting changes of a few percent. DBAR is widely used in the study of defects. The final technique is known as Angular Correlation of Annihilation Radiation (ACAR) which measures the slight difference in the angular distribution of the two annihilation photons in the laboratory.
frame of reference. In ACAR one detector is stationary while the other is rotated about
the sample. The count rate at each angular position is used to obtain an angular
correlation curve. For ACAR to obtain good statistics, count times are typically on the
order of 100 hours. ACAR gives information on the interactions and annihilation
mechanisms of e+.

In a vacuum the positron is a stable particle. However, when it encounters an
electron the positron can annihilate. The time it takes from emission, or birth, of a
positron to its annihilation can be measured by detecting the gamma rays emitted at the
time of each event. The lifetime of a positron in a defect-free media is a property
characteristic of the material. However, in a crystalline structure, there are defects such
as vacancies or dislocations. The locally reduced electron densities at defect sites result
in an increased positron lifetime. The lifetimes of positrons in bulk material are
measured and analyzed to determine the relative size and concentration of the defects.

A positron will interact with matter and eventually annihilate with an electron,
resulting in the emission of two photons. The lifetime of a positron is determined by
measuring the time difference between the gamma photons emitted at its ‘birth’ in the β+
decay and those generated at its annihilation. Positron lifetimes are generally on the
order of hundreds of picoseconds and vary with the electron density.

Typically, three lifetimes can be obtained from a lifetime spectrum. The first and
shortest is associated with positrons interacting with the bulk material, the second with
defects in the material and the third with positrons that form a bound state with electrons
(positronium).
The benefit of PALS is that it can find smaller defects in lower concentrations than traditional methods such as x-ray diffraction (18). Because of this, PALS is being used in an ever increasing role to measure material defects. Despite the benefits, PALS is not ideal for all applications. For example, it would not be preferable to check for a broken arm by placing someone under a positron beam for 24 hours.

PALS is a common tool at many universities world-wide, and is used by many industries (3). Basic methods used in PALS have not significantly changed since the 1970’s, with the exception of the introduction of digitization.

At AFIT, previous work has been done in this field by PhD student Capt Paul Adamson (13). In support of his dissertation, he developed a fast-slow PALS (see Figure 4). He helped set up a similar system for AFRL at Eglin Air Force Base for explosives research.

The fast-slow system uses both anode and dynode outputs from the photomultiplier tube. The anode signal is used to determine timing (fast channel) which is gated by the energy discriminated output from the dynode (slow channel). The benefit of using the fast-slow system is the timing resolution improvement made possible by the energy discrimination. However, this improvement is offset by a much longer counting time.

A fast-fast PALS system uses the anode signal to discriminate the energy of the gamma. A fast-fast setup had not yet been used at AFIT.

A less common PALS technique uses a thin scintillator material to detect the positron itself as opposed to the gamma emitted at the birth of the positron. This method,
called the $\beta+\gamma$ coincidence technique, eliminates background and has a high count rate since every positron entering the system is counted (18).

Figure 4. Fast-Slow PALS.

The most recent advancement in PALS technology is digitization. A digital PALS setup takes the pulse from the detector directly into a digitizer. Computer software then analyzes the signal. Digital PALS is becoming used more commonly around the world.

Motivation

This work was sponsored by the Munitions Directorate of AFRL. The U.S. Air Force is becoming interested in using Positron Annihilation Lifetime Spectroscopy (PALS) to qualify and characterize material defects in explosives. Studying these
characteristics can improve production methods and aid in the development of new and improved explosives. This method can also be used to non-destructively test older explosives and support decisions to maintain or replace weapon systems. Captain Paul Adamson and Captain Chris Williams, as part of a collaboration in previous work, set up a PALS system for AFRL/RYMER at Eglin Air Force Base.

It is also important for the military to maintain a technical awareness about the current state of knowledge in the subject of antimatter to monitor for any advancement with possible military application. Future hopes are that a storage mechanism will be discovered to keep many positrons from annihilating for a substantial time. Then large amounts of positrons (10^{15} or more) could be annihilated rapidly, resulting in an anti-matter weapon. One gram of antimatter contains as much energy as a 43 kiloton bomb, without the radioactive debris. Major technological hurdles must be overcome before this much antimatter can be stored. The cage structure of the borane molecule is one possible means of extending the lifetime antimatter.

**Scope**

This research focuses on developing a PALS system, verifying its accuracy against known values, and applying it to new materials. The materials of interest include as-grown and neutron-irradiated silicon carbide as well as aqueous nitrate/borate solutions. The spectra for each of the materials were analyzed to determine positron lifetimes in the material. The lifetimes provide an indication of material defects in the case of the silicon carbide, and serve as a probe of positron chemistry for the aqueous solutions.
Silicon carbide is of interest to the Department of Defense as a wide band gap semiconductor for many applications. The most critical need is creation of nearly defect free SiC for advanced power in light-weight directed energy microwave weapons.

The intent was to create a reliable system that can be used by future AFIT researchers. This research is a continuation of research performed by Capt Paul Adamson, in which he constructed a PALS system in support of his work on a computational method to estimate positron lifetimes in materials.

**Problem Statement**

The goal of my research is to construct and optimize a fast-fast PALS system to measure the lifetimes of positrons in crystalline solids and in aqueous nitrate solutions.

To accomplish this I constructed and optimized a fast-fast coincidence timing PALS system. I used this system to collect a timing spectrum on a single crystal tungsten sample for which the annihilation lifetime is well known. This timing spectrum was used to calibrate my results in the PALSfit software by determining the resolution function for the system.

I verified my system by collecting a PALS spectrum on an as-grown SiC wafer and use the calibrated software to determine the positron lifetimes present in the spectrum. The SiC wafer was then neutron-irradiated and a second lifetime spectrum was taken. Pre- and post-irradiation lifetimes were analyzed and compared to determine if any detectable structural changes occurred to the crystal lattice during irradiation.

I also utilized the PALS system to measure the lifetimes of positrons in aqueous solutions to measure the lifetime of positrons associated with the borane cage and with
the nitrate anions. The nitrate anions were observed to inhibit the formation of positronium in the solution by scavenging free electrons. The borane cage competed with the nitrate anions for formation of a longer lived positronium species.

I demonstrated the PALS capability to measure defects in solids and characterize material properties in nitrate matrices relevant to explosives.
II. Theory

This section presents relevant theory of explosives to develop a framework for the importance of this research. It then describes the interactions of positrons with matter. Finally, a discussion on the materials used in the research is presented.

Chemistry of Explosives

Explosives are materials which rapidly produce gas and energy in a chemical reaction. This chemical reaction in most explosives involves molecules consisting of carbon, hydrogen, nitrogen and oxygen. These molecules, when subjected to an activation energy, break down and recombine by oxidation reactions to form more stable molecules at a lower energy, typically CO₂, H₂O and N₂. The energy released by the explosive comes from the energy difference in the molecular bonds between the atoms in the initial and final molecular configurations.

Several properties are used in evaluating explosives, such as density, detonation velocity and detonation pressure. Nanoscale pores in explosive crystalline matrices affect all of these properties. The micro-scale voids create inhomogeneities that allow the formation of hot spots in the explosive. These hot spots form by several methods including: friction between crystals, internal shear within a single crystal and void collapse (4). Hot spots increase the explosive’s sensitivity to shock detonation by increasing local temperature and pressure. They also increase the detonation velocity by offering a lower impedance path for the detonation wave. Voids can be introduced intentionally to control the sensitivity of explosives. For insensitive munitions, voids
should be avoided as much as possible. The study of these nanoscale pores can lead to a greater understanding of explosive’s behavior. PALS provides a method of studying these nanoscale pores. In this work we use borane cage molecules to simulate nanopores in a matrix.

Another property that affects the performance of explosives is the amount of oxygen available to support the chemical reaction. The initial explosive molecule is originally of the general form $C_xH_yN_wO_z$. The lowest energy oxidized form for carbon is $CO_2$, for hydrogen it is $H_2O$, and for nitrogen it is $N_2$, therefore, an ideal oxidation reaction would result in

$$C_xH_yN_wO_z \rightarrow xCO_2 + \frac{y}{2}H_2O + \frac{w}{2}N_2$$

which requires $z \geq 2x + y/2$ for 100% efficiency. However, the explosion is never 100% efficient, resulting in partially oxidized molecules such as $CO$, $H_2$ and $NO$.

Oxygen balance (OB) is a comparison between the total amount of oxygen required to completely oxidize the explosive molecule and the amount of molecular oxygen actually present. This is a relatively simple figure to calculate:

$$OB\% = 100 \frac{AW(O)}{MW(\text{explosive})}(z - 2x - y/2)$$  \hspace{1cm} (1.3)$$

Excess oxygen results in a positive value, while an oxygen deficit results in a negative value. An explosive with an oxygen deficit can produce carbon, resulting in a black cloud after detonation. TNT is an example of an explosive with a low (negative) oxygen balance.

Nitrogen and oxygen are often present in the explosive molecule in the form of nitrates. Nitro groups and nitrates are oxidizing groups; therefore, they are free-electron
scavengers. In an aqueous solution containing nitrates and positron emitting sodium-22, the nitrate serves to inhibit the formation of positronium (Ps), the bound state of a positron and electron, by scavenging electrons. A portion of this research was concerned with observing the Ps inhibition by nitrate.

TNT is a common explosive widely used as a standard for measuring energy output of other explosives. Its structure is shown in Figure 5. TNT has a molar mass of 227.131 g/mol and a density of 1.654 g/cm$^3$. It has a chemical composition of C$_7$H$_5$N$_3$O$_6$. The nitrate ion has a molar mass of 62.0049 g/mol. Since there are two nitrate ions in TNT, the molar fraction of nitrate in TNT is 0.5459. The oxygen balance of TNT is -74%, from equation (1.3):

$$\text{OB\%} = 100 \times \frac{16}{227.131} \times \left[ 6 - (2 \times 7) - \frac{5}{2} \right] = -74\%$$

Figure 5. Trinitrotoluene (TNT). Carbon = black; nitrogen = blue; oxygen = red; hydrogen = white.
Nitroglycerin is another common explosive used in dynamite. The chemical formula for nitroglycerine is $\text{C}_3\text{H}_5(\text{NO}_3)_3$ and it has a molar mass of 227.0872 g/mol, and a density of 1.6 g/cm$^3$ at 15°C. Its oxygen balance is 3.5%. In this molecule it is easier to see the nitrate ions attached to the molecule because nitro groups are bonded to oxygen atoms (Figure 6).

![Nitroglycerin](image)

**Figure 6. Nitroglycerin**

Boranes mixed with nitrate salts are a less common explosive sometimes used for their stability over long periods of time and their insensitivity to shock. Boranes, such as dodecaborane salts mixed with nitrate salts, occasionally are used as propellant in vehicle air bags. The lowest energy form of oxidized boranes is $\text{B}_2\text{O}_3$. In this work the dodecaborane cage is used a stimulant for nanoscale voids of constant size.

In the icosahedral borane molecule, $\text{B}_{12}\text{H}_{12}$, each boron atom at the twelve vertices of an icosahedron is in six-fold coordination, with covalent bonds to an “external” hydrogen atom and five other “internal” boron atoms. This unusual bonding behavior for a group IIA element with a valence of three results in a charge accumulation
about the center of the icosahedron’s 20 triangular faces rather than along the lines that link adjacent boron atoms.

Boron icosahedra readily form dianions and are the main constituents of a large host of insulating refractory solids. For example, in $\text{B}_{12}\text{P}_2$, $\text{B}_{12}\text{As}_2$, and $\text{B}_{12}\text{O}_2$, the $\text{B}_{12}$ dianions are centered at the eight vertices of a rhombohedron’s longest diagonal, the $c$-axis. Strong covalent bonds link six of the boron atoms of each icosahedron to neighboring icosahedra, and the remaining six boron atoms bond to the solid’s cations.

Icosahedral boron-rich solids are generally very hard and have high melting
temperatures. These solids also survive extremely well in high radiation environments, and could find a variety of uses in aerospace applications. This resiliency has been attributed to a “self-healing” process in which a boron atom that is displaced from the icosahedron leaves behind an electron, resulting in a Coulomb attraction that facilitates recombination. The small size of the boron cation also aids in the recombination. Also, the relative stability of the icosahedron relative to the distorted anion caused by knock-on displacement also contributes to the “self-healing”. The bond length between boron atoms is 1.8 Å giving an internal radius of 1.36 Å (13).

**Positron Interactions with Matter**

When a high energy positron enters a material it will interact with the molecular structure largely through scattering interactions with electrons. A high energy positron will lose energy by ionization and electronic excitations of molecules. At high energies, the behavior of the positron is very much like that of an electron due to the equal mass. The positron quickly reaches thermal energies, on the order of a few picoseconds. This thermalization time is short with respect to positron lifetimes in matter and is neglected in the lifetime calculation. The thermalized positron will then travel through the material by diffusion.

The positron can either annihilate with a free electron directly, by electron pick-off or it can form a quasi-stable bound state with an electron (positronium):

\[ M + e^+ \rightarrow M^+ + \text{Ps} \]  

(1.4)
The positron will annihilate with an electron in a time inversely proportional to the local electron density in the material. Annihilation can occur by several methods resulting in zero, one, two, three or more gamma rays (See Figure 8).

![Feynman diagrams of the lowest order contributions to a) radiationless, b) one-gamma, c) two-gamma, d) three-gamma ray annihilation. A^{2+} and A^{-} denote the charge states of the remnant atomic ion. (18)](image)

For free positrons, the two-gamma annihilation process is the most probable. The ratio of three to two gamma annihilations is approximately 1/370. Higher numbers of gamma-emitting annihilation have even lower probability. The zero- and one-gamma annihilations require a nearby nucleus to conserve energy and momentum, making them much less probable. For these reasons, positron spectroscopy is generally concerned with the two-gamma process. The two annihilation gamma rays are emitted collinearly with respect to the momentum frame of reference. From the laboratory frame, the gammas differ from linearity slightly, by a few milliradians, due to the angular momentum of the bound electron-positron pair.
Positronium (Ps) is a bound state of an electron and a positron. Ps is a neutral particle with a binding energy of 6.8 eV. Positronium can exist in one of two spin states. Ortho-positronium is the state in which the spins of the electron and positron are parallel. Para-positronium has anti-parallel spins. The spin configuration greatly affects the lifetime of the positronium atom. Para-positronium annihilates much faster than ortho-positronium (0.125 ns versus 142 ns in vacuum).

The two gamma annihilation rate is much greater than that for the three gamma process (18). Ps forms o-Ps and p-Ps in a 3:1 ratio simply due to spin statistics, but Ps can undergo a spin conversion as it interacts with the surrounding media. The o-Ps can be converted to p-Ps by spin conversion.

Ortho-positronium normally annihilates by a three gamma process in a vacuum. However, in ordinary molecular media the o-Ps can pick-off an electron from the surrounding media that has an anti-parallel spin and then annihilate as para-positronium by the two-gamma process. This pick-off annihilation greatly shortens the lifetime of o-Ps to a few nanoseconds, and causes it to annihilate by two photons rather than three. Even for the longer-lived o-Ps the two gamma annihilation is much more probable than the three gamma annihilation, with the $2\gamma/3\gamma$ ratio being 1115, because ortho-positronium is likely to undergo a spin conversion which causes it to transform into para-positronium (5).

There are two processes for positronium formation. The first, Ore gap theory, proposes that a hot positron picks off an electron as it passes through a medium. The second, recombination theory, says the positron loses its energy through ionization of the medium and then binds to one of the secondary electrons released in the ionization. The
Ore gap model is more suited to describing processes in gases while the recombination process better describes positronium formation in condensed matter. There are two models that describe the recombination process, the spur model and the blob model.

**Positrons in Solids**

The spur model for positronium formation describes a recombination in which a thermalized positron interacts with an electron from an ionized molecule near the end of the positron’s track. In this model, several different reactions are possible, including: ionization, Ps formation, recombination, localization, Ps formation of localized e+, Ps oxidation, and e+ solvation. Solutes that are electron scavengers (such as NO3⁻) inhibit Ps formation, decreasing the intensity of the o-Ps component in the lifetime spectrum by reducing the number of electrons available to interact with the e+.

The blob model is a modification to the spur model, differing in describing the final thermalization and positronium formation in the terminal blob of ionized particles and electrons. The blob model termination consists of about 30 ion-electron pairs, while the spur contains only 2 or 3 (18). The difference is the density of free electrons near the positron.

While there are formulas to determine the size of a void in solids using only the positron lifetime, assumptions have to be made about the geometry of the void and type of interaction. Positrons and Ps can form bound states with anions in the material. These bound states require the use of DBAR or ACAR for size characterization. The bound state lifetimes are too close to those of the free positron lifetime for PALS to resolve the separate lifetime components when more than one species is present.
**Positrons in Liquids**

The bubble model describes the trapping of Ps in liquids. The Ps atom creates a potential well or bubble in which it gets trapped. In water the radius of this bubble is calculated as 0.291 nm (as compared to .272 nm for borane) resulting in a lifetime of 1.81 ns o-Ps in water (18). Therefore, the lifetime in borane should be slightly shorter than in water. In solids the Ps is trapped in pre-existing defect sites.

Solutes that serve as effective electron scavengers inhibit the formation of positronium by reducing the number of electrons with which positrons can bind. This inhibition reduces the intensity of the Ps lifetime relative to those of the free positrons. It is possible to derive the relationship between lifetime intensity and concentration. The o-Ps intensity ($I_3$) for different concentrations follows the Stern-Volmer equation

$$I_3(C) = \frac{I_3(0)}{1 + kC}$$

where $C$ is the concentration of the solute and $k$ is the total inhibition constant. There are two other classes of inhibitors, one that deviates from the Stern-Volmer equation and a second that exhibits a plateau (6).

The PALS system was demonstrated by lifetime measurements on a solid SiC sample and on aqueous solution samples.

**Silicon Carbide**

Silicon carbide (SiC) is a crystalline solid that exhibits great physical, electrical and chemical properties. The tetrahedral crystalline covalent bonds are relatively strong. SiC is also well suited for use in radiation environments. Normal silicon in transistors or
semi-conductor devices has a mean time to failure of 10 years at 100°C, but SiC can
survive for a similar time at 500°C (7). SiC promises to provide electronics that require
less maintenance and are more durable in adverse environments. Its properties are being
studied extensively for a wide variety of applications, including in such exotic uses as
future fusion reactors (8).

SiC was not widely available until the late 20th century due to the difficulty of
producing mass quantities of low defect material. As such, most research has been
conducted on this material within the last decade.

There are many types of SiC. They can be categorized as cubic, hexagonal and
rhombic. The letter C, H or R designates the type. A number precedes the type
designator describing the stacking of layers within the crystal structure. This number-
letter combination is known as Ramsdell notation. The two most common types are 4H
and 6H SiC. The different types of SiC have similar, though not the same, positron
lifetimes in bulk material and in defects (9).

Since SiC lends itself to use in high radiation environments, effects of fast neutron
bombardment on the material are important. Neutrons lose energy in SiC through
collisions. Since the neutron is not a charged particle, the influence of the electron cloud
surrounding an atom is minimal, allowing the neutron to collide directly with the nucleus.
These collisions may move an atom from its original location in the crystal lattice to a
new point resulting in a vacancy and an interstitial atom. Another possibility is a
distortion of the lattice resulting in a defect due to charge distribution. Defect clusters
can form if the displaced atom has enough energy to displace other atoms from their
location in the crystal structure. Defects can be removed by annealing at high
temperatures. Many studies have been done that examine the effect of annealing on irradiated SiC (7). Several studies have been done that examine the effects of neutron irradiation of SiC (10).

![Crystalline structure of SiC](image)

**Figure 9. Crystalline structure of SiC.**

**Nitrates**

The nitrate ion is composed of three oxygen atoms attached to a nitrogen atom, $\text{NO}_3^-$. Nitrates are a naturally occurring chemical essential to natural processes. Nitrates are commonly used in fertilizers.

Nitrates are also commonly used in explosives. The oxygen atoms provide essential material for the oxidation process which results in explosive energy release. Molecules having nitro groups as part of their molecular structure can be more efficient and faster burning explosives than hydrocarbons mixed with nitrates as in gunpowder.
Figure 10. Resonance hybrid showing the bonds in the nitrate ion and an electrostatic potential map. Red areas show lower potential than the green.
III. Experimental Procedure

This section describes the electronic modules necessary for a timing application. It discusses the construction and optimization of the PALS system. Then it describes the sources used in the experiment.

Overview

I acquired a timing spectrum that is of better resolution and quality than what was collected on the fast-slow setup created by Capt Paul Adamson and described in his PhD dissertation (13). This was facilitated by high quality, lower noise photomultiplier tubes than were available for the fast-slow setup. A typical PALS setup is shown in Figure 11.

Figure 11. Fast-fast PALS.(11)

PALS Electronics

The detectors consist of a scintillator crystal made of barium fluoride, BaF₂ and a photomultiplier tube. BaF₂ has a very fast component in its scintillation decay (.7 ns) and a high atomic number which make it attractive for applications requiring both high
efficiency and fast response. The incoming gamma ray excites a molecular electron which emits a UV photon upon deexcitation (12). The BaF$_2$ scintillator is optically coupled to a Hamamatsu photomultiplier tube that changes the optical signal from the detector into an electronic current pulse via a photocathode coupled to an electron multiplier structure.

The crystal size on the start detector is 2x3 cm and the stop detector crystal size is 2x2 cm. The larger crystal size on the start detector is more efficient at capturing the higher energy gamma photons of the start pulse. Bias voltage was set to -2300 V on each detector.

The photomultiplier electronic signal is sent to a Constant Fraction Discriminator (CFD). The CFD multiplies and inverts the signal to generate a trigger at a predetermined fraction of the incoming pulse. This eliminates the walk error of a leading-edge type trigger, which adds uncertainty to the timing. The lower-level discriminator of the CFD receiving the signal from the start detector is set to accept pulses in the 1.274 MeV peak and ignore the pulses of lower energies. The stop detector pulses are discriminated in the same way, eliminating signals with energies lower than the 0.511 MeV peak.

A Fast Coincidence Unit (FCU) selects those pulses that occur within the selected time frame (initially set at 200 ps, then adjusted as necessary to obtain the best time resolution) indicating that they are a birth/annihilation photon pair. A Time-to-Amplitude Converter converts the signal into a timing spectrum which is sent to the laptop computer for analysis via a Multi-Channel Analyzer. The TAC window was set to 50 ns, the lowest available setting.
Finally, the PALSfit program deconvolves the timing spectrum into its component lifetimes. Typically about $10^6$ annihilations need to be recorded to resolve the spectrum. PALSfit uses a least squares method to fit the measured spectrum to a sum of decaying exponentials.

The expected system resolution is less than 250 ps. Possible alterations to the setup may provide a better resolution. The use of Timing Single Channel Analyzers instead of the CFDs may provide better energy discrimination resulting in better timing resolution (12). Also, a logic module might be used in lieu of the FCU for better timing properties. There may also be another method of using the CFDs to better discriminate the energies so that the stop detector does not record a birth pulse. I attempted to optimize the system to provide the best possible timing resolution. A typical timing spectrum is shown in Figure 12.

![Image: A typical PALS timing spectrum](image)

**Figure 12. A typical PALS timing spectrum.** (13)
System Setup and Optimization

To visualize the scales involved in PALS, consider that in a resolving time of 150 ps, light travels 0.5 cm, and a 5 μCi source produces 185,000 positrons per second. Gathering so many data points in such a short time requires the use of special electronics. The equipment, software and radioisotopes used in this research are listed in Appendix B.

Improving timing resolution allows a more accurate analysis of time spectra. There are many variables in the system that affect the timing resolution. The type of scintillator used, the photomultiplier tube (PMT) characteristics and the electronic modules all have an intrinsic electronic noise which degrades the resolution of the system. Setting up a PALS system requires iteratively improving settings to improve the timing resolution.

A $^{60}$Co source was used to determine the timing resolution. $^{60}$Co emits two gamma rays in its decay process at energies of 1332 and 1173 keV. These gammas are emitted nearly simultaneously and should produce a delta function on the timing spectrum. The inefficiencies and noise in the system result in a Gaussian distribution, the FWHM of which is the system timing resolution.

The time-per-channel was determined by running the output from a single CFD to the TAC start and stop inputs. The stop channel was sent through a delay box. The delay was increased by known amount. The time per channel at 8192 channels was determined to be 6.2 ps per channel, the same as the calculated value. Therefore, at this number of channels the FWHM needs to be under 33.3 channels for a resolution of 200 ps.
Figure 13. Calibration of Time per Channel. The fit is linear giving 6.2 ps per channel.

Relocation of the source from the side of the detector axis to a position between the two detectors greatly increased the count rate of the system due to improvement in the solid angle and did not appear to have an appreciable negative effect on the timing resolution. There was an anomalous peak in the timing spectrum, attributed to a reflected photon, which was eliminated by moving the detectors further apart.

Positioning the detector faces at 90° relative to each other appeared to improve the FWHM by about 10 percent. However, the count rate dropped by several orders of magnitude, negating the benefit to the timing resolution.
An attempt was made at utilizing a third channel in the quad CFD to eliminate counts above the 0.511 MeV peak value. The input pulse from the stop detector was split into two CFD channels: one set below the 0.511 MeV peak and the other above. The two channels were then sent to the quad logic card which counted an event when the signal was on the first channel and not the second.

Another iteration of the three detector setup utilized two stop detectors in coincidence to provide the stop signal to the TAC. The third detector added substantial noise through the additional electronics which negated any benefit. The three detector setup also had a count rate several orders of magnitude below that of the two detector setup due to the decreased solid angle.

Methods to improve timing resolution included selection of window widths, walk voltages on the CFD, delay settings enroute to the TAC, detector geometry and possibly...
interchanging the start and stop detectors. This latter method would probably not work
for my setup since the two detectors are different sizes, to better capture different energy
level gamma rays. According to Knoll (12), the FWHM should be between 5-10
channels to minimize electronic distortions in low count rates. This would dictate a
width of 1024 channels which would result in a FWHM of 4.09 to give a resolution of
200 ps. However, I chose to use 8192 channels to maximize the resolution in the timing
peak.

The CFD walk was adjusted in accordance with the operator’s manual. Making
this adjustment significantly improved the resolution, cutting the timing resolution from
about 450 ps to 246 ps.

The cables connecting the modules needed to be 50 ohm cables for most of the
connections. There was an odd reflection in the cable from the delay box to the TAC
which was not resolved by changing cables or by adding in termination. The probable
cause of the reflection is a tee connector which goes to the oscilloscope and the TAC. I
removed the tee but then was unable to observe the pulse to verify if the reflection was
eliminated.

A 10 ns delay is required between the gate pulse threshold and the start pulse
threshold of the TAC input. Therefore, there is a minimum delay requirement for the
start channel. Adjusting the delay on the stop channel to optimize the system led to the
conclusion that the minimum delay possible should be used.

The delay cable length on the CFD is important. This cable sets the constant
fraction to 20 percent of the pulse height. The formula provided in the user’s manual
indicates the delay-cable length should be 0.3 m. The actual length of cable that gave optimum results was 0.48 m.

Figure 15. Fast-fast PALS system initial setup.

Values for timing resolution found in the literature vary greatly, from 300 ps to 150 ps. One fast PALS setup achieved a resolution of 140 ps by surrounding their system with magnets to isolate from outside influences (14). They also constructed their own PMTs and customized their CFDs. A digital system was reported to have a timing resolution of 119 ps in 2001 (15).

A calculation showed the activity level of the source only allowed for one positron in the sample at a time. This negated the need for the quad logic module.
Removing the quad logic module further reduced the electronic noise in the system and resulted in the final timing resolution of 197 ps.

![Diagram of PALS system final geometry](image)

**Figure 16.** PALS system final geometry.

After timing resolution optimization, the system was setup for positron counting by setting the CFD windows back to the gamma ray energies emitted from $^{22}\text{Na}$. Final settings on the components are listed in Appendix A.

**Sample-Source Configuration**

The thin-film positron source used for experiments with solids (AFIT source T112A) was previously made by Capt Paul Adamson by evaporating a $^{22}\text{Na}$ solution onto a Mylar film (13). This Mylar source is placed between two pieces of the sample material. This sample-source sandwich configuration gives the greatest chance of
positron interaction with the sample material while minimizing annihilations outside of
the sample. The sample-source sandwich is placed between the start and stop BaF$_2$
detectors.

The source created by Capt Adamson did not exhibit any signs of leakage and so
was judged to be viable for use with the solid samples, W and SiC. The activity was
6.02 $\mu$Ci as measured using a HPGe detector on 17 October 2007.

The aqueous solutions for the nitrate and borane solutions were mixed in the
chemistry lab following the procedure shown in Appendix D. They were made from a
borane solution mixed with differing concentrations of potassium nitrate. The activity in
each sample was intended to be about 5 $\mu$Ci.

It is desirable to minimize the contribution to the timing spectrum of annihilations
within the positron source itself. To do this the geometry of the container can be
optimized. The surface-to-volume ratio should be minimized to reduce the chance the
positrons will annihilate in the walls of the container. The optimum shape would be a
sphere which has the smallest surface-to-volume ratio of any three dimensional shape.
Since practical containers do not come in spherical shapes, we must choose the best
available geometry. Several containers were considered with the best being a glass vial
with 15 mL nominal capacity. The lid is a rubber septum secured by a crimp-on top,
which has the advantage of preventing absorption of gases.

Due to the uncertainty in the measured volume of $^{22}$Na added to each solution,
and the differences in volume added to each solution, the activity needed to be
determined in some way other than estimating volume added and multiplying by the
activity per unit volume of source. To determine activity, a $^{22}$Na calibration source
(T106) of known activity (0.293 μCi) was measured in the PALS system to determine the count rate (3.94 cps). The sample activity was then calculated using the simple ratio

\[ \frac{A_1}{\dot{c}_1} = \frac{A_2}{\dot{c}_2} \]  

(1.6)

where \( A \) is the activity and \( \dot{c} \) is the count rate. As a check of the accuracy, and to guard against non-linearity in the counting system, the calculation was repeated for a higher activity source, T112A, whose activity was verified in an HPGe detector system. The results of both calculations were similar, as shown in Table 1.

**Table 1. Solution Source Activity. Activity calculated with calibrated reference source T106 (0.293 μCi), and with T112A (6.02 μCi).**

One important consideration in developing a source is to ensure that there is no overlap of annihilations in the material which could lead to false stop signals in the PALS system. For a 6 μCi source, the average time between decays is \( 4.6 \times 10^{-6} \) sec. The lifetime of the positrons in the material is three orders of magnitude lower. Therefore, it is concluded that there is only one positron in the material at a time, as desired.

Initially, the molar fraction of nitrates to water was intended to closely mimic the fraction of nitrates in trinitrotoluene (TNT) in order to maximize the applicability of the results of this study to use in explosives. This intention was later relaxed to allow for a
study of positron chemistry in aqueous solution as related to inhibition of positronium formation. The initial list of samples was modified during the injection of the $^{22}$Na into the vials (See Appendix C) due to a lower volume of $^{22}$Na than expected. The as-made solution samples are listed in Table 2.

IV. Results and Analysis

This section presents the data obtained during the PALS construction and measurements. It presents a steady-state kinetics model of positron annihilation to describe the chemical processes in the solutions.

Time Resolution

The timing resolution of the system was determined to be 197 ps by directly measuring the FWHM of a $^{60}\text{Co}$ timing spectrum (See Figure 17) calculated by multiplying the FWHM of the spectrum, 31.84 channels, by the time per channel, 6.2 ps. $^{60}\text{Co}$ is used because it emits two gammas during its decay (1332 and 1173 keV) nearly simultaneously. This should result in a timing peak of a single channel. Any spread is caused by the timing resolution of the system.

Figure 17. $^{60}\text{Co}$ timing spectrum.
All adjustable parameters involved have been optimized to reduce contributions to resolution uncertainties. Thus, it is hypothesized that the major remaining contributor to resolution inaccuracy is the detector/PMT combination.

**PALSfit Software**

Perhaps the most important aspect to PALS is the deconvolution of the spectra to determine the lifetimes present in the spectra. PALSfit is a program developed by the Riso National Laboratory in Denmark and is based on well-tested software. The program contains two modules: ResolutionFit and PositronFit. ResolutionFit determines the time resolution function of the PALS system while PositronFit extracts the lifetimes and intensities from the spectra using that resolution function. The model function consists of a sum of decaying exponentials convoluted with a resolution function, plus a constant background. The resolution function is a sum of Gaussians.

In ResolutionFit, an iterative process is used to determine the number of Gaussians and their intensities. This is the most time-consuming part of the process. The resulting resolution function is imported into PositronFit.

One important aspect of PositronFit is the ability to remove a source contribution. Source contributions from applicable materials are listed in Table 3.

PositronFit then outputs the calculated lifetimes and their standard deviations. Outputs also include a graph of the fitted spectrum and a residual plot.

(References 5, 15, 16, 17)

Tungsten Sample

Measurement of the positron lifetime in tungsten (W) was used to determine the resolution function and verify the operation of the system. Tungsten is commonly used as a verification material since it has been well studied and has a well-defined bulk lifetime of $105 \pm 5$ ps (16). It also served as a way to learn the use of the PALSfit software.

The $^{22}$Na source is sandwiched between the 5mm diameter tungsten crystals (100 plane). A timing spectrum was collected for 43200 seconds resulting in $1.69 \times 10^6$ counts.

PALSfit analysis of the spectrum gave a three Gaussian resolution function. The Gaussians were $0.2324$, $0.5408$ and $0.2113$ ns FWHM with intensities of $77$, $17$ and $6\%$. The Gaussians were shifted from time zero by $0.0$, $0.0690$, and $0.1882$ ns. The three intensities and the shift of the first Gaussian were fixed parameters. The tungsten spectrum is shown in Figure 18. PALSfit input parameters are listed in Appendix E.
The ResolutionFit software looked for three lifetimes with $\tau_1$, the bulk lifetime in tungsten, initially fixed at 105 ps. After an iterative process determined the proper resolution function, PositronFit was used to find the lifetimes in the crystal. The program removed the source contribution, 471 ps at 24.6\% and 2.35 ns at 7.55\%. The resulting two lifetimes were $101 \pm 2$ ps and $220 \pm 11$ ps with a variance of fit of 1.030. Corresponding intensities were 82.3\% and 17.7\%. The second lifetime is believed to be caused by vacancies within the crystal lattice. The value for the bulk lifetime is within the $105 \pm 5$ ps of published data, but the vacancy lifetime is slightly higher than the $195 \pm 10$ ps in the literature (16).

**Silicon Carbide**

Single crystal samples of 4H SiC were measured using the PALS system as a demonstration of the technique in analyzing a defected solid. Virgin samples were measured, then irradiated with a neutron fluence of $1\times10^{13}$ n/cm$^2$ with $>0.5$ MeV neutrons at the Ohio State University Nuclear Research Reactor. After irradiation, the samples were measured again, in the same configuration.
The SiC samples were measured pre-irradiation for 18000 seconds resulting in a PALS spectrum with $1.07 \times 10^6$ counts. The post-irradiation counting resulted in $1.36 \times 10^6$ counts in 18000 sec. The spectra were then analyzed using the PALSfit software. Pre- and post-irradiation spectra are shown in Figure 19. Residual plots are shown in Figure 20.

![Figure 19. PALSfit spectra of pre- (top) and post-irradiated (bottom) SiC](image-url)
Figure 20. PALSfit residual plots of pre- (top) and post-irradiated (bottom) SiC.

Positron lifetime values for bulk SiC are given in the literature ranging from 134 – 150 ps. Vacancies are common in as-grown, or un-irradiated, SiC. Lifetime values for these vacancies are given in the range between 250 – 350 ps. A lifetime of 250 ps in SiC has been calculated to correspond to a vacancy of similar size to two missing silicon-carbon pairs, four atoms in all (17). Figure 21 shows the calculated positron lifetimes in vacancy clusters of a given size.

Using the PALSfit software, lifetimes were determined. In the un-irradiated sample, the bulk lifetime, $\tau_1$, was determined to be $142 \pm 3$ ps and the defect lifetime, $\tau_2$, was determined to be $298 \pm 22$ ps. Variance of the fit after source correction was 1.016. Both lifetimes are within the tolerance of published results.
Figure 21. Calculated positron lifetimes in vacancy clusters in 4H SiC. (17)

After irradiation, the bulk lifetime increased to 148 ± 2 ps with the intensity increasing by 11% to 76%. This seems to indicate the presence of another, unresolved lifetime that is influencing the $\tau_1$ result.

The silicon atom vacancies are more likely to attract positrons since carbon vacancies can be positively charged, and the resulting silicon vacancy has a positron lifetime on the order 195 ps. Carbon vacancies exhibit a lifetime of 160 ps (17). A calculation assuming one additional lifetime using

$$ (\tau_1)(I_1)+(\tau_{\text{unk}})(I_{\text{unk}})=(\tau_{\text{tot}})(I_{\text{tot}}) $$

(1.7)
where the subscript 1 represents the values in the virgin sample, gives the additional lifetime, \( \tau_{\text{unk}} \), of 201 ps with an intensity of 10.1 percent \( (I_{\text{tot}} - I_1) \). Therefore, it is concluded that the concentration of silicon vacancies has been increased by the neutron irradiation and that this is the primary contributor to the increase in bulk lifetime and its intensity.

The defect lifetime, \( \tau_2 \), increased to 397 ± 35 ps. This value is expected for a vacancy cluster of the size of 10 missing silicon or carbon atoms (17). However, the decrease in intensity lends itself to the conclusion that the greatest effect of the neutron bombardment was to increase the number of silicon vacancies. Lifetimes of pre- and post-irradiated SiC are shown in Table 4.

The third lifetime calculated in PALSfit is a convolution of source contributions from the Mylar \( (\tau = 1.91 \text{ ns}) \) and plexiglass \( (\tau = 2.0 \text{ ns}) \) surrounding the source. Its value, 2.01 ± 0.01 ns versus 2.06 ± 0.02 ns, was relatively constant with a small decrease in intensity, 2.7%, attributed to the increase in \( I_1 \). Variance of the fit post-irradiation was 1.061.

**Nitrate Solution Samples**

All the solution samples were measured for a length of time that allowed for capturing a spectrum with greater than 1x10^6 counts. Count times varied from 14400 sec to 111600 sec based on the activity of the samples. Spectra were analyzed using the
PALSfit software. The resolution function was determined by iteratively finding the best fit to the data. It consisted of three Gaussians of the same intensity as the silicon carbide, despite different sample geometry. This is not surprising as the detector setup was exactly the same. The initial results are displayed in Table 5.

It can be noted that the samples containing 5M NO₃⁻ do not exhibit an easily identifiable o-Ps lifetime as indicated by the τ₃ lifetime component varying greatly from the τ₃ for o-Ps in water (1.81 ns). This is supported by the fact that NO₃⁻ is an electron scavenger that at high concentration inhibits the formation of o-Ps by reducing the availability of free electrons (18).

The most striking visualization of the o-Ps inhibition can be seen by comparing the spectra of the sample that contained no NO₃⁻ to the sample with 5M NO₃⁻. The differences can be viewed in Figure 22. The o-Ps lifetime is manifested in the spectrum as a long tail which is not present in the high concentration nitrate spectrum.
Figure 22. Ortho-positronium, shown by the long tail of the top figure (no NO$_3^-$), is absent in bottom figure (5M NO$_3^-$).

A second analysis using PALSfit, this time fixing the $\tau_3$ component at 1.81 ns shows the decreasing intensity of the o-Ps component with the concentration of NO$_3^-$.

The results are similar to published data (18).

To determine the lifetime of positrons in the borane, it is noted that the 5M NO$_3^-$ in borane solution result should be directly comparable to the 5M NO$_3^-$ in water result, with any difference being attributable to the borane. By subtracting the $\tau_2$ lifetime component seen in 5M NO$_3^-$ in borane solution, 0.413 ns at 64.7% intensity, from the 5M NO$_3^-$ in water spectrum we see a residual lifetime in the spectrum of 0.277 ± 0.010 ns at 73.8% intensity. This lifetime is that associated with the borane. The resultant lifetime, 0.277 ± 0.010 ns, is similar to previous data taken on a solid sample (13). Capt Paul Adamson, in his research, obtained a positron lifetime of 0.2645±0.0077 ns for K$_2$B$_{12}$H$_{12}$ with an intensity of 25.9±0.3 %. Two additional lifetimes were obtained: 12.6651±0.1872 ns and 1.9450±0.0154 ns, with intensities of 20.2±0.1 % and 53.9±0.3 %, respectively, which were attributed to source contributions.

Applying this result to the data from T112B (no nitrate) gives lifetimes of: $\tau_1 = 0.152 \pm 0.011$ ns (8.97%), $\tau_2$ fixed at 0.277 ns (69.0%), $\tau_3 = 1.71 \pm 0.008$ ns (21.9%).
These values differ markedly from the original values because the PALSfit software was unable to resolve the $\tau_1$ and $\tau_2$ lifetimes without more parameters. The data suggests that the borane acts as a quenching mechanism for the o-Ps, reducing its lifetime (as opposed to inhibition which reduces intensity). For the other solutions, similarly fixing $\tau_2$ at 0.277 ns in an effort to force the PALSfit software to find this lifetime only led to greatly degraded fits to the data as indicated by an increase in the variance of the fit. Therefore, I was unable to determine the intensity of the $\tau_2$ lifetime component that was due to the decreasing nitrate concentration.

However, removing the source contribution, 0.413 ns, from the 0.5 M sample spectrum results in only two lifetimes of $\tau_1 = 0.138 \pm 0.002$ ns and $\tau_3 = 1.84 \pm 0.01$ ns. The other two spectra, 0.1 M and 0.01 M solutions, have a $\tau_2$ too close to the source term to be deconvolved. These lifetimes indicate the presence of an unresolved fourth lifetime for a positron-nitrate bound state.

Figure 24. Variation of 1/I₃ versus Concentration of NO₃⁻ and Linear Fit.

From the solution without nitrate τ₃ = 1.71 ± 0.01 ns. It appears that the borane serves to quench positronium formation, reducing its lifetime from 1.81 ns expected for water. This quenching effect is not seen in any subsequent solutions indicating that the quenching mechanism is eliminated by the presence of the nitrate. Another possibility is that the borane may have a somewhat shorter o-Ps lifetime than that for pure water and that the two are so close together that they remain unresolved.
Compared to previous experiments in which the o-Ps intensity, $I_0^o$, for pure water was determined to be 27.9% (18), the $I_3$ for the borane solution has a much reduced intensity, 19.8%. Therefore, there is an inhibiting effect as well as a quenching effect.

This indicates that some other process is at work. Several other processes can occur such as enhancement and partial inhibition (6). However, to fully characterize this relationship would require different concentrations of borane solution and the use of DBAR to determine the momentum of the positron.

**A Steady State Model for Positron Annihilation**

A steady state model (19) for the annihilation of positrons in nitrate/borane solution consists of the following interactions:

\[
K \cdot R_{pf} = R_{ef} \\
e^+ + e^- \xrightarrow{k_{sp}} Ps \xrightarrow{k_{ap}} 2\gamma \\
e^+ + NO_3^- \xrightarrow{k_{pa}} NO_3^- \cdots e^+ \xrightarrow{k_{ap}} 2\gamma \\
e^+ + B_{12}H_{12}^{2-} \xrightarrow{k_{pb}} B_{12}H_{12}^{2-} \cdots e^+ \xrightarrow{k_{ap}} 2\gamma \\
e^+ + H_2O \xrightarrow{k_{pa}} e^+ \cdots H_2O \xrightarrow{k_{ap}} 2\gamma \\
Ps + NO_3^- \xrightarrow{k_{pa}} e^+ + NO_2^- + O^- \\
e^+ + NO_3^- \xrightarrow{k_{pa}} NO_2^- + O^- \\
e^+ + H_2O \xrightarrow{k_{pa}} e^- \cdots H_2O
\]

This model assumes homogeneity of the positron distribution. It also assumes that solvated electrons are removed from the population available to interact with positrons.

Activity, rather than concentration, is used in chemical calculations because solutions containing ionic solutes do not behave ideally in salt solutions and activity takes
into account the interaction of a molecule with its surroundings. The activity is proportional to the concentration (for constant ionic strength) but takes into account the interaction of ions in the solution. At very low concentrations the activity can be approximated by the concentration. However, at higher concentrations ( > 0.1 M) the activity can be significantly different than the concentration. Therefore, the derivation of reaction rates is made more accurate by using activity in this case.

The Debye-Huckel equation is normally used to determine the unitless activity coefficient for low ionic strengths. However, the Davies approximation, a modification of the Debye-Huckel equation, is more valid for our purposes since we have a higher concentration (20). The Davies approximation is valid up to 0.5 M. The Davies approximation for the activity coefficient, \( \gamma \), is

\[
\log \gamma = -Az^2 \left( \frac{\sqrt{I}}{1 + \sqrt{I}} - 0.2I \right) 
\]

where A is a constant depending on the solvent (for water A = 0.5), z is the charge of the ion and I is the ionic strength given by

\[
I = \frac{1}{2} \sum C_i z_i^2 
\]

The activity is then calculated by

\[
A = \gamma C 
\]

Using this formula, and data from (21) we get the unitless activity for the various nitrate concentrations as shown in Table 8.

* Calculated using Davies Equation
* Data from (21).

Describing the positron steady state kinetics yields:

\[
\frac{d[e^+]}{dt} = R_{pf} - k_{ep}[e^-][e^+] - k_{pA}[e^+][A^-] - k_{ApW}[e^+] = 0
\]  (1.11)

Where [ ] denotes activity and A represents the anion. Rearranging to solve for positron activity gives:

\[
[e^+] = \frac{R_{pf}}{k_{ep}[e^-] + k_{pN}[N] + k_{pB}[B] + k_{ApW}}
\]  (1.12)

Conducting a similar calculation for positronium activity results in:

\[
[Ps] = \frac{k_{ep}[e^+][e^-]}{k_{ApS} + k_{PsN}[N]}
\]  (1.13)

Electron activity is likewise found to be:

\[
[e^-] = \frac{K R_{pf}}{k_{ep}[e^+] + k_{eN}[N] + k_{eW}}
\]  (1.14)

Where K is a constant depending on the theory used (either 3 or 30). Note that the electron activity depends on the nitrate activity and the positron source activity. The
electron activity only depends on the borane activity indirectly through \([e^+]\), which is small. Anion steady state kinetics are defined by:

\[
[A \cdots e^+] = \frac{k_{pA}[e^+][A]}{k_{AP}}
\]  \hspace{1cm} (1.15)

In analyzing the long lifetime component, we begin with:

\[
k_{APs}[Ps] = k_{ep}[e_+][e_+] - k_{pN}[Ps][N]
\]  \hspace{1cm} (1.16)

in which the second half is the correction for high nitrate activity. If we begin by neglecting the nitrate correction and take the intensity of the long lifetime component as the Ps annihilation rate over the rate of positron formation we get:

\[
I_3 = \frac{k_{APs}[Ps]}{R_{pf}} = \frac{k_{ep}[e^+]}{k_{ep}[e^+] + k_{eN}[N] + k_{eW}}
\]  \hspace{1cm} (1.17)

by substituting from (1.16) and (1.14).

The zero nitrate intensity is simply:

\[
I_3^0 = \frac{k_{ep}[e^+]}{k_{ep}[e^+] + k_{eW}}
\]  \hspace{1cm} (1.18)

We can now apply a Stern-Volmer type analysis by taking the ratio of (1.17) and (1.18) resulting in:

\[
\frac{I_3^0}{I_3} = 1 + \frac{k_{eN}[N]}{k_{ep}[e^+] + k_{eW}}
\]  \hspace{1cm} (1.19)

where \(I_3\) is the intensity of the long lifetime component, \(I_3^0\) is the intensity of the long lifetime with no nitrate, \(k_{eN}\) is the rate constant for the oxidative scavenging of electrons by the nitrate, \([N]\) is the activity of the nitrate, \(k_{ep}\) is electron-positron binding (or positronium formation) rate, \([e^+]\) is the activity of the positrons, \(k_{eW}\) is the electron in
water solvation rate. Plotting this intensity ratio versus [N] should give a line with intercept 1 and slope of \( \frac{k_{eN}}{k_{ep}[e^+] + k_{eW}} \).

![Figure 25. Intensity Ratio Versus Nitrate Activity.](image)

This plot does deviate somewhat from linearity due to data uncertainty and the breakdown of the Davies approximation above 0.5 M. Omitting the 5M data point, which likely has the greatest uncertainty due to the inapplicability of the model at that high of concentration, the trendline formula is \( y = 4.5587x + 1.003 \) with a fit of \( R^2 = 0.9969 \). The error of the model is determined by the error in the intercept value, .003.
Figure 26. Linear Fit to Intensity vs Activity with 5 M data point removed.

Using the value of 0.24 ps for electron solvation (18) results in $k_{eW} = 4167$ ns$^{-1}$ (or $0.4167 \times 10^{13}$ s$^{-1}$) and $k_{ep} [e^+]$ as 0.41 ns$^{-1}$ we can estimate the value of $k_{eN} = 19000$ M$^{-1}$ns$^{-1}$ ($1.9 \times 10^{13}$ M$^{-1}$s$^{-1}$, as compared to $2 \times 10^{13}$ M$^{-1}$s$^{-1}$ found in the literature (18)). This reaction rate indicates that electron scavenging takes place very rapidly, on the order of $5 \times 10^{-14}$ s.

The above analysis neglects the oxidation of Ps by the nitrate ion (the high nitrate concentration correction). If the oxidation is included, the intensity ratio becomes a quadratic:

$$\frac{I_3^0}{I_3} = 1 + (a + b)[N] + ab[N]^2$$  \hspace{1cm} (1.20)

Where $a$ is the slope from the previous analysis:

$$a = \frac{k_{eN}}{k_{ep}[e^+] + k_{eW}}$$
and

\[ b = \frac{k_{PsN}}{k_{APs}} \]

Attempts to solve (1.20) result in nonreal solutions. This indicates that Ps oxidation plays a very minor role, if any, in the inhibition of Ps. Rather, the Ps is prevented from forming in the first place by electron scavenging.

The analysis of the intermediate lifetime requires a slightly different approach. In this analysis we are assuming the intermediate lifetime is primarily due to positron interaction with the water. The $^{22}\text{NaCl}$ is also a contributor to this lifetime. The rate of annihilation, from (1.11) is:

\[
k_{ApW}[e^+] = R_{p} - k_{eq}[e^+][e^+] - k_{PN}[e^+][N^-] - k_{PN}[e^+][B^-] - k_{ApW}[e^+] - k_{APWS}[e^+] \tag{1.21}
\]
where $k_{ApW1}$ and $k_{ApWs}$ represent the reaction rates for the longer and shorter components of annihilation of positrons in water, which account for the complex structure of water.

The intermediate lifetime intensity is then:

$$I_2 = \frac{R_{pf}}{k_{pf} e^+[e^-]} - k_{pN}[e^+][N^-] - k_{pB}[e^+][B^-] - k_{ApW1}[e^+] - k_{ApW2}[e^+]$$

And the no nitrate intensity is similarly:

$$I_2^0 = \frac{R_{pf}}{k_{pf} e^+[e^-]} - k_{pB}[e^+][B^-] - k_{ApW1}[e^+] - k_{ApW2}[e^+]$$

In the Stern-Volmer type analysis, we would take the ratio of the intensities, however, this approach does not result in the intensity ratio versus slope equation as it did for the long lifetime component. Instead we take the difference between the intensities.

$$I_2 - I_2^0 = \frac{k_{pN}[e^+][N]}{R_{pf}} = \Delta I_2$$

A plot of $\Delta I_2$ versus $[N]$ gives a linear relation with increasing nitrate activity.
Figure 27. Change in Lifetime Intensity due to Activity.

This plot (Figure 27) shows the relation between the values, however, it should be noted that 0 M and 5 M solution values for \( I_2 \) were calculated using \( I_2 = 0.277 \) ns as opposed to a value closer to 0.413 ns that was calculated for the other three samples. A linear fit through the middle three data points gives a line \( \Delta I_2 = 28.398[N] + 0.6353 \). The intercept provides, which should cross at zero a means of evaluating the error of the method.

Evaluating the fitted slope with known values for \( k_{pN} \) and \( R_{pf} \) yields a value for the activity of the positrons as \([e^+] = 0.00105\).

The short lifetime has contributions from nitrate and borane interactions with the positrons, as well as water species, such as OH\(^-\), whose total short contribution is \( W_{e^+} \). Assuming that all species are in steady state,
The positron annihilation rate becomes

\[ R_1 = k_{ApN}[Ne^+] + k_{ApB}[Be^+] + k_{ApW}[We^+] \]

\[ = k_{pN}[e^+][N] + k_{pB}[e^+][B] + k_{WS}[e^+][W] \]

The intensity is the short annihilation rate, \( R_1 \), divided by the total formation/annihilation rate \( R_{pf} \).

\[ I_1 = \frac{k_{pN}[e^+][N] + k_{pB}[e^+][B] + k_{WS}[e^+][W]}{R_{pf}} \]  \hspace{1cm} (1.25)

and

\[ I_1^0 = \frac{k_{pB}[e^+][B] + k_{WS}[e^+][W]}{R_{pf}} \]  \hspace{1cm} (1.26)

Assuming that \([e^+]\) does not vary with experiment:

\[ I_1 - I_1^0 = \frac{[e^+] k_{pN}[N]}{R_{pf}} = \Delta I_1 \]  \hspace{1cm} (1.27)

which indicates a linear increase with increasing \([N]\). The data does not support this conclusion which suggests that association of free \(e^+\) with \(NO_3^-\) anions is weak.

Calculation of the reaction rate of positrons with the nitrate solution using

\[ k_{ApN} = \frac{\ln(2)}{\tau_1} \]  \hspace{1cm} (1.28)

gives \( k_{ApN} = 3.59 \text{ ns}^{-1} \). A similar calculation for the borane gives \( k_{ApB} = 2.50 \text{ ns}^{-1} \).

V. Conclusions and Recommendations

Conclusions

The fast-fast PALS system worked as expected with a timing resolution of 197 ps as measured directly with a $^{60}$Co source. Minimizing the number of electronic components in the system provided the best timing resolution by reducing the contribution of noise. The system succeeded in acting as a probe into the physical and chemical properties of solids and solutions.

The positron lifetime in single crystal tungsten was measured to be $101 \pm 2$ ps (as opposed to the published data of $105 \pm 5$ ps) with a monovacancy lifetime of $220 \pm 11$ ps. This data served to verify the operation and accuracy of the PALS system.

The PALS lifetime observed for silicon carbide exhibited evidence of forming silicon vacancies in the crystal lattice following neutron irradiation.

The aqueous nitrate anions inhibited the formation of ortho-positronium. Examination of the o-Ps intensities indicates that NO$_3^-$ completely inhibits o-Ps formation with increasing concentration. The primary mechanism for Ps inhibition is electron scavenging, rather than oxidation of Ps. The borane is seen to reduce the effect of inhibition.

Recommendations for Future Work

Digitization of the PALS system should be the next step in improving AFIT’s positron research. This step involves simply hooking the detectors directly up to a digitizer. The signal from the digitizer is directly analyzed by a computer. The hurdles
are hardware interface and programming the computer to perform all the tasks of the
PALS. Digitized PALS is the current state-of-the art.

Positron storage is an interesting field with practical importance for the future. A
positron trap would allow for positron pulse analysis which will open up new avenues for
the study of positron chemistry. This technology would enhance AFIT’s ability to
conduct detailed studies of materials. It is also a step on the pathway toward
weaponizing antimatter.

Appendix C: Procedure for Mixing Aqueous $^{22}\text{Na}$ Sources

Procedures for Preparing Aqueous $^{22}\text{Na}$ Solution Positron Sources

The following is a procedure for preparation of liquid $^{22}\text{Na}$ (as $^{22}\text{NaCl}$) solutions by dilution of a stock $^{22}\text{NaCl}$ solution for use in positron spectroscopy, e.g. Positron Annihilation Lifetime Spectroscopy (PALS).

The sample preparation procedure will be conducted at the radiation hood in the radiochemistry lab in B470. Proper radiation safety and chemical safety procedures will be followed at all times.

1. Safety:
   a. Personal Protective Equipment (PPE) will be worn at all times during this operation: disposable gloves (top two inches rolled down to allow removal without contaminating undergarments), lab coat, safety glasses.
   b. At least two people will conduct the procedures, a primary operator and an assistant. The procedure will be conducted by the primary worker. The assistant will assist as necessary, e.g. if necessary the assistant can bring materials needed into the radiation hood after radioisotope transfer has begun so that there is little potential to bring contamination outside the hood.
   c. Additionally, at least one radiation safety monitor will be present to verify the operation and to collect verification swipes.
c. All workers involved will wear TLDs, including a finger TLD.

d. Lead bricks will be used to minimize exposure to primary worker and assistant.

e. Radionuclide solution will be transferred from the radionuclide source container to the sample containers using disposable syringe.

2. Procedure:

a. Setup

The setup is designed to minimize the amount of contaminated waste and to minimize the risk of contamination outside the radiation hood. This will be accomplished by the day prior to the sample transfer operation.

   i. The radiation hood lab bench tops where radioactive material will be handled will be covered with plastic sheeting taped down at corners. The plastic will be covered by absorbent material. In the event of a radionuclide spill the plastic can be wrapped around the paper and added to radiation waste container to prevent any spreading of radiation.

   ii. Prior to opening the radioactive source all materials will be laid out in accordance with the planned setup shown in the diagram below. All solutions except the radionuclide source will be transferred into sample containers prior to opening the radionuclide source solution. The current $^{22}$NaCl radionuclide solution is AFIT number T-112 (4 g in 5 mL vial of 40 $\mu$Ci $^{22}$Na, 10 $\mu$Ci/mL as of 1Dec07)

   iii. A sign will be prepared for posting outside the door of the radiation chemistry laboratory indicating that radioactivity is present and TLD is required for entry during the preparation procedure; the sign will remain in place until the transfer and
cleanup is completed. A check will be made to ensure that radiation hazard signs outside the radiation chemistry laboratory and on the radiation hood are in place.

iv. A proof of concept container will be filled with tap water and sealed by crimping using the procedure planned to seal sample containers. The sample bottle will be injected with water. This will also give the primary operator practice using a syringe prior to using the radioisotope source.

v. Sample solutions of non-radionuclide chemicals will be prepared ahead of time with the appropriate concentration. Samples will be sealed by crimping.

vi. Prior to beginning the transfer procedure the volume of $^{22}$NaCl solution required to achieve the desired activity for each sample will be determined. For example,
using a stock solution of activity 10 μCi of $^{22}$NaCl per mL at the time of procedure, to add 5 μCi of $^{22}$NaCl to each sample container, 0.5 mL of stock solution would be added to each sample container.

vii. Labels for each sample container will be filled out ahead of time and applied to containers. All containers will be clearly identified and labeled with name of compound, radionuclide, date, $^{22}$Na activity, and radiation type.

viii. Samples will be placed in a disposable sample holder.

b. Sample Preparation Operation

i. Personnel from 88 ABW/EMB Radiation Safety will be present to observe and advise during this procedure prior to opening the container of $^{22}$NaCl stock solution and adding $^{22}$NaCl to the sample containers.

ii. The volume of $^{22}$Na radionuclide solution necessary to achieve the desired sample activity (usually 5-10 microcuries per sample) will be transferred from the source container to a sample container in a single syringe transfer. (All other non-radioactive solutions will have been previously added to this sample container.) This $^{22}$Na transfer operation will be completed for each sample container. After all $^{22}$Na transfers, the contaminated syringe will be immediately placed into the radiation waste container. The operator will seal the top of each container using silicon. The filled and sealed sample container will be set to the side in the sample container holder and shielded. The assistant will make measurements using a survey meter to preliminarily determine whether gross contamination exists. Then swipes will be taken. The results
will determine what cleaning and disposal procedures are necessary. The preliminary sample preparation checklist is given in section 4 below. The checklist will be modified by the operator during practice, prior to transfer operations, to reflect the best procedure that will minimize radioactive waste and minimize risk of radioactive spill.

4. Procedure Checklist:

a. Setup

☐ Tape down plastic liner and locate absorbent

☐ Lay out sample container holder, sample containers, syringes, wipe test filter papers, rad waste container.

☐ Label rad waste container with name of compound, radionuclide, date and radiation type leaving a blank for $^{22}$Na activity.

☐ Confirm non-radiation solutions have been added to sample containers

☐ Confirm labels on sample containers.

☐ Arrange all equipment except sources in the hood.

☐ Practice syringe use and sample sealing procedure.

☐ Ensure survey meters are operational

☐ Coordinate with machine shop personnel the time of planned transfer operation.

b. Transfer Operation

☐ Check, post signs

☐ Put on PPE
☐ Notify machine shop personnel of operation to bring $^{22}$Na source into the radiation chemistry laboratory.

☐ Bring source solution from vault to radiation chemistry lab with assistant leading and monitor personnel following.

☐ Place $^{22}$Na source in the radiation hood.

☐ Assistant hands sample containers to operator for $^{22}$Na transfer.

☐ Operator remove lid from $^{22}$Na source solution and place on filter paper.

☐ Measure total volume of $^{22}$Na and divide by number of samples to determine exact amount to transfer to each sample.

☐ Carefully transfer aliquot of $^{22}$Na solution into each sample container, ensure pressure in the sample is equalized or slightly negative prior to removing needle

☐ Place syringe into rad waste container

☐ Replace lid on $^{22}$Na source solution.

☐ Use caulk gun to put silicon sealant on each sample

☐ Have assistant check operator’s gloves and caulk gun for contamination using survey meter

☐ Swipe test all containers.

☐ Swipe tests will be conducted by 88 ABW/EMB Radiation Safety for all containers to ensure there is no radioactivity present on the outside of the sample containers or original source container.

☐ Repeat check of operator’s gloves for contamination.

☐ Dispose of gloves and known contamination in rad waste.
☐ Conduct final cleanup after swipe analysis.

☐ Write the $^{22}$Na activity on label for rad waste container.

☐ Place sample containers in individual container bags

☐ Check surface for contamination. Check the working surface with a gamma and beta counter for signs of radiation.

☐ All items will be swipe tested for contamination before disposal/removal from the table. If no contamination found, surface coverings will be left in place for possible future use.

☐ Check operator and assistant for contamination using survey meter.

☐ Move source and samples in container to room 107 lab via machine shop, with escort leading to open doors

☐ After removal of the source all items in the hood will be inspected by a hand held radiation detector to locate any significant contamination.

☐ Remove and discard PPE

☐ Check self for contamination again

☐ Wash hands

☐ Rad waste will be transferred to 88 ABW/EMB Radiation Safety for proper disposal immediately following completion of procedure and monitoring for contamination.

5. Accident procedures.

   a. Prevent spreading of spill with paper towels.
b. Potentially contaminated PPE will be removed and measured for radiation prior to discarding.

b. Inform laboratory manager, Mr. Taylor and AFIT Radiation Safety Officer, Dr. Petrosky.

c. Clean spill area until contamination is below action level using instructions provided by AFIT Radiation Safety Officer.

6. Disposition.

a. Samples will be retained for use for up to 2 half lives (5 yrs) for possible follow on experiments.

b. Sources will be stored with multiple containment systems, impervious to the liquids contained inside (e.g., stainless steel or glass containers lined with absorbent paper).

b. When no longer needed, dispose of via sewer IAW 10 CFR 20 App B.

Monthly avg concentration allowed: $6 \times 10^{-5}$ μCi/mL = $6 \times 10^{-2}$ μCi/L = 6 μCi/100 L.
Appendix D: Procedure for Preparing Aqueous Solutions

The aqueous nitrate solutions were created in the AFIT chemistry laboratory under the direction of Dr. Feltcher. The first step, after determining requirements and initial lab familiarization, was to wash all the glassware to reduce the risk of outside contaminants affecting the PALS results.

The potassium dodecahydrodoedecaborate salt suffers a dearth of physical information. The manufacturer’s website list the salt as being only ‘slightly soluble’ in water. Using this information as a guide, the salt was added to water slowly, at a rate of 0.5 g per 15 minutes of stirring. Eventually, the entire bottle of salt was added, totaling 97.4 g. The solution was allowed to stir and cool over night.

The next step was to mix the stock solutions by adding the nitrate in varying concentrations. The stock solutions were made by adding the masses shown below. The stock solutions were then diluted to make the sample solutions of the desired concentration.

</tbody>
</table>

Once the solutions were mixed, they were bubbled with nitrogen for 15 minutes and transferred into the nitrogen purged glove box to prevent absorption of oxygen. Approximately 12 mL of each solution was then transferred into the sample vial. The
vial was sealed by crimping, labeled and placed in a storage container. $^{22}\text{Na}$ was added to each vial as described in Appendix C.

DEVELOPMENT AND OPTIMIZATION OF A POSITRON ANNIHILATION LIFETIME SPECTROMETER TO MEASURE NANOSCALE DEFECTS IN SOLIDS AND BORANE CAGE MOLECULES IN AQUEOUS NITRATE SOLUTIONS

Matthew A. Ross
MAJ, USA

Air Force Institute of Technology
Graduate School of Engineering and Management (AFIT/EN)
2950 Hobson Way WPAFB, OH 45433-7765

A Positron Annihilation Lifetime Spectroscopy (PALS) system was developed and tested. PALS has the capability to characterize negatively charged defects and voids in materials such as explosives. The timing resolution of the optimized system is 197±14 ps as measured with a known 60Co source. A single-crystal tungsten sample was used to confirm the system calibration resulting in a lifetime of 101±2 ps (as compared to 105 ±5 ps in the literature (16)). The PALS system was then used to compare the differences between as grown and neutron-irradiated single crystal silicon carbide (SiC), illustrating that neutron bombardment of SiC results in the creation of silicon vacancies in the material. The lifetime of a positron associated with a boron cage anion, dodecahydrododecaborate in aqueous nitrate solution, was 277 ± 10 ps, compared with previous measurements of the cage compound in solid state which yielded 268 ± 8 ps. Competition for positrons between nitrate anion and the boron cage was measured.

Positron, Positron Annihilation Lifetime Spectroscopy, PALS, voids in materials, positrons in tungsten, positrons in silicon carbide, positrons in neutron irradiated silicon carbide, positrons in aqueous solution, positrons in boron cage, electron scavenging
