We have performed proposed studies to test the hypothesis that deregulated EGFR and STAT3 pathways synergistically contribute to the malignant biology of breast cancer and that combined uses of anti-EGFR and anti-STAT3 treatments result in significantly increased breast cancer cell death compared to single agent treatments. Analysis of a panel of human breast cancer cell lines and primary breast carcinoma specimens revealed that EGFR and constitutively activated STAT3 (p-STAT3) are frequent and concurrent. EGFR and STAT3 cooperate to induce epithelial mesenchymal transition by activating expression of TWIST, an E-cadherin repressor. In breast cancer cells with high levels of EGFR and p-STAT3, forced expression of dominant-negative STAT3 significantly suppresses cell proliferation. Importantly, dominant-negative STAT3 sensitizes breast cancer cells with high EGFR/p-STAT3 to anti-EGFR agent, Iressa. In contrast, transfection of constitutively active STAT3 into these cells does not increase cell proliferation nor induces resistance to Iressa, suggesting the endogenous p-STAT3 is sufficient in facilitating cell survival. Consistently, breast cancer cells with no or low EGFR expression do not respond to Iressa treatments. Together, the findings to date point to significant in vivo and in vitro interactions between EGFR and STAT3 oncoproteins in breast cancer as well as a role of STAT3 constitutive activation may play in the resistance of these tumors to anti-EGFR therapy.

INTRODUCTION

The proposal is built on the following observations from our studies and others. (i) Single use of EGFR-targeted therapy, gefitinib/Iressa (an EGFR tyrosine kinase inhibitor) and cetuximab (an EGFR blocking antibody), demonstrated a moderate therapeutic effect in breast cancer patients. (ii) Both EGFR and STAT3 are oncoproteins and frequently over-expressed and/or constitutively activated in breast cancer (2). We observed co-overexpression of both EGFR and p-STAT3 in 60% of EGFR-positive breast carcinomas (3). (iii) STAT3 is constitutively activated in 50% of the breast cancer and can be activated by EGFR and other growth factor- and cytokine pathways (4, 5). (iv) Iressa-treated breast cancer cells and clinical specimens displayed insufficient suppression of STAT3 activity despite with complete EGFR inhibition (3, 6). (v) Although EGFR and STAT3 can mediate different downstream targets, our recent study indicated that they cross-talk at multiple levels (3). (vi) We showed that combined use of anti-EGFR and anti-STAT agent resulted in synergistic cell death in MDA-MB-468 human breast carcinoma cells who express high levels of EGFR and p-STAT3 (3). Based on these rationales, we hypothesize that deregulated EGFR and STAT3 pathways synergistically contribute to the malignant biology of breast cancer and that combined uses of anti-EGFR and anti-STAT3 treatments result in significantly increased breast cancer cell death compared to single agent treatments. The outcome from this proposal is likely to help us achieve the long-term goal of the study, which is to better understand the malignant biology of breast cancer including those with de-regulated EGFR pathway and to provide rationales for more effective therapies for women with breast cancer. AIM 1: To determine whether increased STAT3 activity confers resistance to anti-EGFR therapies in EGFR-expressing breast cancer cells. AIM 2: To investigate whether suppression of STAT3 expression/activity sensitizes EGFR/p-STAT3-expressing breast cancer cells to anti-EGFR therapies. AIM 3: To determine the therapeutic effects of combined use of anti-EGFR and anti-STAT3 treatments in a mammary tumor-bearing animal model.

BODY

Significant co-expression of EGFR and constitutively activated STAT3 in approximately 40% of a cohort of primary breast carcinomas (Task 1a). We observed a positive correlation between EGFR and STAT3 constitutive activation in a cohort of 132 primary breast carcinomas by regression analysis (3A) and Chi-square analysis (3B) (7). Intriguingly, we found 38.6% (51/132) of the primary breast tumors to over-express both EGFR and constitutively activated STAT3. Representative tumors are shown in panel 3B.

Figure 1 Significant co-overexpression of EGFR and p-STAT3 in primary breast carcinomas. Regression (A) and Chi-square (B) analyses were performed in a cohort of human breast carcinomas. In Chi-square analyses, tumors with \( \leq 35\% \) cells staining positive for EGFR were considered with the low levels whereas those with \( > 35\% \), high levels according to previously established classification system (1). As for p-STAT3, tumors with \( \geq 20\% \) cells with positive staining were regarded as constitutively activated, using a well-established system. C: Representative tumors: Left: High EGFR/p-STAT3, Right: Low EGFR/p-STAT3.
Significant co-expression of EGFR and constitutively activated STAT3 in cultured breast cancer cells (Task 1a-c). In light of the in vivo observation showing that EGFR frequently co-expresses with p-STAT3 in primary carcinomas, we further examine whether this correlation exists in culture human breast cancer cells. As shown in Fig. 2A, seven out of eight cell lines that we examined express constitutively activated STAT3. These seven cell lines also express medium to high levels of EGFR, consistent with the role of EGFR as a STAT3-phosphorylating kinase. We also determined their response to Iressa (Fig. 2B) and found that most lines are resistant to Iressa treatments despite EGFR expression and that MCF-7 cells are most resistance likely due to its low dependency of EGFR. Moreover, we transiently transfected constitutively activated STAT3 (STAT3CA) to MDA-MB-468, Hs578T, BT-20 and SK-BR-3 cells and determine Iressa sensitivity, but did not find STAT3CA to increase Iressa resistance. We speculate that this is due to the high endogenous p-STAT3 in these lines which is sufficient to constitute Iressa resistance without additional p-STAT3. But we will commit future effort to confirm this observation using stable transfection and by identifying cell lines with low endogenous p-STAT3 but high EGFR and high Iressa sensitivity.

Dominant-negative STAT3 leads to growth suppression and sensitization to anti-EGFR treatments in two human breast cancer cell lines (Task 2a). In light of the high level of STAT3 constitutive activation observed in human breast cancer, we next examine whether suppressing STAT3 activity using dominant-negative STAT3 (STAT3-DN) inhibits their growth and/or sensitizes them to anti-EGFR treatments. As shown in Fig. 3A, forced expression of STAT3-DN significantly killed Hs5787 and MDA-MB-468 cells who express high levels of p-STAT3. Importantly, STAT3-DN also sensitizes both cell lines to Iressa treatments (Fig. 3B). As indicated in Fig. 3C, STAT3-DN transfection was effective.
Functional interactions between EGFR and STAT3 in promoting breast cancer progression (7). Aberrant EGFR signaling is a major cause of tumor progression and metastasis, the underlying mechanisms, however, are not well understood. In particular, it remains elusive whether deregulated EGFR pathway is involved in epithelial-mesenchymal transition (EMT), an early event that occurs during metastasis of cancers of an epithelial origin. Here, we show that EGF induces EGFR-expressing cancer cells to undergo a transition from the epithelial to the spindle-like mesenchymal morphology. EGF reduced E-cadherin expression and increased that of mesenchymal proteins. In search of a downstream mediator that may account for EGF-induced EMT, we focused on transcription repressors of E-cadherin, TWIST, SLUG and Snail, and found that cancer cells express high levels of TWIST and that EGF enhances its expression. EGF significantly increases TWIST transcripts and protein in EGFR-expressing lines. Forced expression of EGFR re-activates TWIST expression in EGFR-null cells. TWIST expression is suppressed by EGFR and Jak/STAT3 inhibitors, but not significantly by those targeting PI3K and MEK. Furthermore, constitutively active STAT3 significantly activates the TWIST promoter, whereas the JAK/STAT3 inhibitor and dominant-negative STAT3 suppressed TWIST promoter. Deletion/mutation studies further show that a 26 bp promoter region contains putative STAT3 elements required for the EGF-responsiveness of the TWIST promoter. Chromatin immunoprecipitation assays further demonstrate that EGF induces binding of nuclear STAT3 to the TWIST promoter. Immunohistochemical analysis of 130 primary breast carcinomas indicates positive correlations between non-nuclear EGFR and TWIST and between p-STAT3 and TWIST. Together, we report here that EGF/EGFR signaling pathways induces cancer cell EMT via STAT3-mediated TWIST gene expression (manuscript reprint provided).

KEY RESEARCH ACCOMPLISHMENTS
• Significant co-expression of EGFR and constitutively activated STAT3 in primary breast carcinomas and cultured breast cancer cells.
• Functional interactions between EGFR and STAT3 in promoting breast cancer progression.
• Dominant-negative STAT3 leads to growth suppression and sensitization to anti-EGFR treatments in two human breast cancer cell lines.

RNA Aptamers as a Novel Targeted Therapy for Breast Cancer with Aberrant EGFR and STAT3 Pathways

CONCLUSION
Our research effort in the past award year has resulted in several interesting findings and a publication that support the study hypothesis: deregulated EGFR and STAT3 pathways synergistically contribute to the malignant biology of breast cancer and that combined uses of anti-EGFR and anti-STAT3 treatments result in significantly increased breast cancer cell death compared to single agent treatments. First, we found significant co-expression of EGFR and constitutively activated STAT3 in approximately 40% of a cohort of primary breast carcinomas and in the majority of cultured human breast cancer cells. Second, consistent with the co-expression, suppressing STAT3 activity by STAT3-DN leads to growth suppression and sensitization to anti-EGFR treatments in two human breast cancer cell lines. Finally, we found that functional interactions between EGFR and STAT3 promote breast cancer progression via activating TWIST gene expression. Together, these promising results prompt us to further explore the role of STAT3 activation in the resistance of human breast cancer cells to anti-EGFR therapy in the next award year.

Abstract

Aberrant epidermal growth factor receptor (EGFR) signaling is a major cause of tumor progression and metastasis; the underlying mechanisms, however, are not well understood. In particular, it remains elusive whether deregulated EGFR pathway is involved in epithelial-mesenchymal transition (EMT), an early event that occurs during metastasis of cancers of an epithelial origin. Here, we show that EGFR induces EGFR-expressing cancer cells to undergo a transition from the epithelial to the spindle-like mesenchymal morphology. EGFR reduced E-cadherin expression and increased that of mesenchymal proteins. In search of a downstream mediator that may account for EGFR-induced EMT, we focused on transcription repressors of E-cadherin, TWIST, SLUG, and Snail and found that cancer cells express high levels of TWIST and that EGFR enhances its expression. EGFR significantly increases TWIST transcripts and protein in EGFR-expressing lines. Forced expression of EGFR reactivates TWIST expression in EGFR-null cells. TWIST expression is suppressed by EGFR and Janus-activated kinase (JAK)/signal transducer and activator of transcription 3 (STAT3) inhibitors, but not significantly by those targeting phosphoinositide-3 kinase and MEK/ERK. Furthermore, constitutively active STAT3 significantly activates the TWIST promoter, whereas the JAK/STAT3 inhibitor and dominant-negative STAT3 suppressed TWIST promoter. Deletion/mutation studies further show that a 26-bp promoter region contains putative STAT3 elements required for the EGFR-responsive activation of the TWIST promoter. Chromatin immunoprecipitation assays further show that EGFR induces binding of nuclear STAT3 to the TWIST promoter. Immunohistochemical analysis of 130 primary breast carcinomas indicates positive correlations between non-nuclear EGFR and TWIST and between phosphorylated STAT3 and TWIST. Together, we report here that EGFR/EGFR signaling pathways induce cancer cell EMT via STAT3-mediated TWIST gene expression. [Cancer Res 2007;67(19):9066–76]

Introduction

Accumulating evidences suggest a role of epidermal growth factor receptor (EGFR) in tumor metastasis (1–5). It has been reported that EGFR activates its downstream modules protein kinase C-δ, extracellular signal-regulated kinase (ERK), and phospholipase C-γ and facilitates migration of EGFR-overexpressing cancer cells (6, 7). It has also been shown that EGFR increases production of matrix metalloproteinase-9, possibly via phosphoinositide-3 kinase (PI3K), leading to cell migration (8, 9). However, the involvement of EGFR in epithelial-mesenchymal transition (EMT; an early step during tumor metastasis) remains elusive. Nevertheless, chronic EGFR treatment has been shown to lead to down-regulation of E-cadherin expression and loss of cell-cell adherence junction (10). Down-regulation of E-cadherin is considered as a critical step and an indicator for EMT, and the down-regulation of which can be achieved by transcriptional suppression mediated by transcription factors TWIST, SLUG, and Snail (11–14).

TWIST is a basic helix-loop-helix (bHLH) transcription factor that has been known to be essential for proper gastrulation mesoderm formation, and neural crest migration (15). Intriguingly, increased TWIST expression is detected in metastatic breast cancer cells and is required for EMT and breast cancer metastasis (11). Role of TWIST in EMT has also been reported in other cancer types, including those of prostate (16) and uterus (17). High TWIST expression further correlates with tumor invasion and metastasis in breast carcinomas (11), esophageal squamous cell carcinomas (18), and gliomas (19). A recent study reported that STAT3 knockdown of mouse 4T1 mammary tumor cells led to altered expression of several genes, including those of activated src, phosphorylated Akt, c-Myc, and Twist, but not p53 nor total src (20). How mouse STAT3 knockdown led to reduced phosphorylation of src and Akt remains unknown. Whereas c-Myc is a known STAT3 target gene, mouse Twist has yet been shown to be a direct transcriptional target of STAT3. STAT-binding sites are not found in the mouse twist gene promoter, suggesting its expression reduction by STAT3 small interfering RNA was likely due to indirect effects. As for the human TWIST gene, its transcriptional regulation is yet investigated.

Given the association between EGFR overexpression and high metastatic potential, we speculate that the EGFR/EGFR pathway promotes EMT via activation of EMT mediators, such as TWIST, SLUG, and Snail. Our initial examination of a breast cancer cell line, MDA-MB-468, indicated that TWIST is expressed at a higher level...
compared with SLUG and Snail, which prompted us to further investigate the regulatory role of the EGF/EGFR pathway in TWIST expression and in TWIST-mediated EMT. Here, we report that EGF treatment and EGFR expression are important for TWIST expression. However, unexpectedly, we also found that the underlying mechanisms involve transcriptional regulation of TWIST by STAT3, an oncoprotein constitutively activated in many human cancers and implicated in tumor progression (21–23). The information derived from these studies provides critical insights into the regulation of TWIST gene expression and into the biology of tumors with deregulated EGFR and STAT3 pathways and is important in the management of metastatic tumors.

**Experimental Procedures**

**Cell lines and cell culture.** A431 human epidermoid carcinoma cells, MDA-MB-468 human breast carcinoma cells, and EGFR-null Chinese hamster ovary (CHO) cells and Madin-Darby canine kidney (MDCK) epithelial cells were obtained from American Type Culture Collection. CHO-NEO, CHO-EGFR, and CHO-EGFR-NLS stable cells were derived from the parental CHO cells as previously described (24). HEK293 cells are stable EGFR transfectants of Swiss 3T3 cells, and NR-6 cell line is an EGFR-null Swiss 3T3 variant. All cells were maintained in DMEM supplemented with 10% FCS, except that CHO-NEO, CHO-EGFR, and CHO-EGFR-NLS stable lines were supplemented with 1 mg/mL G418 additionally. Panc28 human pancreatic cancer cell line was a kind gift from Dr. Paul Chiao at the University of Texas M. D. Anderson Cancer Center.

**Chemicals, plasmids, and mammalian transfection.** PD158780, AG490, AG1478, and the PI3K inhibitor LY294002 were obtained from Calbiochem Corp. The specific MEK/ERK inhibitor PD158780, AG490, AG1478, and the PI3K inhibitor LY294002 were obtained from Calbiochem Corp. The specific MEK/ERK inhibitor PD158780, AG490, AG1478, and the PI3K inhibitor LY294002 were obtained from Calbiochem Corp. The specific MEK/ERK inhibitor PD158780, AG490, AG1478, and the PI3K inhibitor LY294002 were obtained from Calbiochem Corp.

**Reverse transcription-PCR.** In these studies, cancer cells of exponential growth were starved for serum for 24 h and stimulated with EGF (100 ng/mL) for 0, 1, and 2 h. Cells were harvested, and total RNA was extracted using the SV total RNA isolation system (Promega) according to manufacturer’s instructions (27, 28). Extracted total RNA was then subjected to reverse transcription using reverse transcriptase (Invitrogen) to generate first-strand cDNA using the oligo dT primer. PCR was then carried out for 30 cycles, and each cycle was with 95°C for 1 min, 55°C for 1 min, and 72°C for 1 min. Primers with sequences 5'-TTAGCCACCCCTGGCAAGG-3' and 5'-CCTTACTCCCTGGAGGC-CATG-3' were used for glyceraldehyde-3-phosphate dehydrogenase (GAPDH). For TWIST, primers 5'-GGGATCCGACGACTTACAG-3' and 5'-CTGTGAGAGCCTTCTTAGG-3' were used in PCR. For SLUG, primers 5'-TTGATGAGAGGAAAGACATC-3' and 5'-GCTCATATGCTTCTCATACC-3' were used in the PCR reactions. Primers 5'-GGAAAGG CACTTACCTGCAAAT-3' and 5'-ACTGG-TACCTTCTGACATCTG-3' were used to generate Snail PCR products. For real-time PCR, SYBR-Green Master PCR mix was used in the iCycler system (Bio-Rad) in triplicates as previously described (24). All quantification was normalized to an endogenous control GAPDH. The PCR program was 95°C for 4 min, followed by 40 cycles of 95°C for 15 s and 60°C for 45 s.

**Western blot analyses.** Western blot analyses were done as previously described (24, 26). The antibodies used for these studies included rabbit polyclonal EGFR, TWIST, and STAT3 antibodies and goat polyclonal Snail antibody, which were purchased from Santa Cruz Biotech. Rabbit polyclonal phosphorylated STAT3 (p-STAT3; Y-705), phosphorylated EGFR (Y-1045), and Akt/phosphorylated Akt antibodies were from Cell Signaling. Additional antibodies used for Western blot were mouse monoclonal β-actin and α-tubulin (Sigma), E-cadherin (BD Pharmigen), ERK/phosphorylated ERK (Upstate), fibronectin (NeoMarkers), and vimentin (NeoMarkers) antibodies.

**Construction of the human TWIST promoter-driven luciferase reporter constructs.** The human genomic TWIST plasmid was a kind gift from Dr. Vincent J. Cristofalo (Allegeny University of the Health Science, Philadelphia, PA). The full-length human TWIST promoter was amplified from the genomic TWIST plasmid to contain the promoter region up to nt −824 using forward primer 5'-CGTCTACATTTGGAGCTGTCCTTTCC-3' and reverse primer 5'-AGTAAGCTTGGAGGTGGAGCAGG-3'. The PCR product was digested with NheI and HindIII and subsequently cloned to the pGL-3 basic luciferase reporter vector (Promega), and positive clone was designated pTWIST-824. The reverse primer was used to generate other TWIST promoter segments. For pTWIST-604, pTWIST-120, and pTWIST-94 constructs, forward primers 5'-CGTCTACATTTGGAGCTGTCCTTTCC-3' and reverse primer 5'-AGTAAGCTTGGAGGTGGAGCAGG-3'. The PCR product was digested with NheI and HindIII and subsequently cloned to the pGL-3 basic luciferase reporter vector (Promega), and positive clone was designated pTWIST-120/MA mutant, forward primer 5'-AAACTTCTTATAAACTTCGCGCCTCCTCCTCCTCGT-3' and reverse primer 5'-GGAGACCCGCGAACGAGCGAGGCAAGGCATAGAAAGGT-3'. The PCR product was digested with NheI and HindIII and subsequently cloned to the pGL-3 basic luciferase reporter vector (Promega), and positive clone was designated pTWIST-120/MA mutant, forward primer 5'-AACTTCTTATAAACTTCGCGCCTCCTCCTCCTCCTCGT-3' and reverse primer 5'-GGAGACCCGCGAACGAGCGAGGCAAGGCATAGAAAGGT-3'. The PCR product was digested with NheI and HindIII and subsequently cloned to the pGL-3 basic luciferase reporter vector (Promega), and positive clone was designated pTWIST-120/MA mutant, forward primer 5'-AACTTCTTATAAACTTCGCGCCTCCTCCTCCTCCTCGT-3' and reverse primer 5'-GGAGACCCGCGAACGAGCGAGGCAAGGCATAGAAAGGT-3'. The PCR product was digested with NheI and HindIII and subsequently cloned to the pGL-3 basic luciferase reporter vector (Promega), and positive clone was designated pTWIST-120/MA mutant, forward primer 5'-AACTTCTTATAAACTTCGCGCCTCCTCCTCCTCCTCGT-3' and reverse primer 5'-GGAGACCCGCGAACGAGCGAGGCAAGGCATAGAAAGGT-3'. The PCR product was digested with NheI and HindIII and subsequently cloned to the pGL-3 basic luciferase reporter vector (Promega), and positive clone was designated pTWIST-120/MA mutant, forward primer 5'-AACTTCTTATAAACTTCGCGCCTCCTCCTCCTCCTCGT-3' and reverse primer 5'-GGAGACCCGCGAACGAGCGAGGCAAGGCATAGAAAGGT-3'. The PCR product was digested with NheI and HindIII and subsequently cloned to the pGL-3 basic luciferase reporter vector (Promega), and positive clone was designated pTWIST-120/MA mutant, forward primer 5'-AACTTCTTATAAACTTCGCGCCTCCTCCTCCTCCTCCTCGT-3' and reverse primer 5'-GGAGACCCGCGAACGAGCGAGGCAAGGCATAGAAAGGT-3'. The PCR product was digested with NheI and HindIII and subsequently cloned to the pGL-3 basic luciferase reporter vector (Promega), and positive clone was designated pTWIST-120/MA mutant, forward primer 5'-AACTTCTTATAAACTTCGCGCCTCCTCCTCCTCCTCCTCGT-3' and reverse primer 5'-GGAGACCCGCGAACGAGCGAGGCAAGGCATAGAAAGGT-3'. The PCR product was digested with NheI and HindIII and subsequently cloned to the pGL-3 basic luciferase reporter vector (Promega), and positive clone was designated pTWIST-120/MA mutant, forward primer 5'-AACTTCTTATAAACTTCGCGCCTCCTCCTCCTCCTCCTCGT-3' and reverse primer 5'-GGAGACCCGCGAACGAGCGAGGCAAGGCATAGAAAGGT-3'. Site-directed mutagenesis was done as previously described (24). All constructs were subjected to DNA sequencing to confirm no PCR-generated artifacts.

**Mammalian transfection and luciferase assay.** Cells were transfected using the cationic liposome method using SN as described previously (25) or Fugene HD (Roche), pRL-TK (Promega) was cotransfected as a control for transfection efficiency. After transfection and experiment treatments, cells were lysed and luciferase activity was measured using Dual Luciferase kit (Promega) according to manufacturer’s instructions (27, 28).

**Biotinylated oligonucleotide precipitation assays/oligo pull-down assay.** These studies were done as described previously (24, 29). The nucleotide sequences of biotinylated oligonucleotide corresponds to TWIST-120, TWIST-120/MA, and TWIST-120/MB are 5'-AAACTTCTTATAAACTTCGCGCCTCCTCCTCCTCCTCGT-3', 5'-AACTTCTTATAAACTTCGCGCCTCCTCCTCCTCCTCGT-3', and 5'-AACTTCTTATAAACTTCGCGCCTCCTCCTCCTCCTCGT-3', respectively. A functional STAT3-binding site [acute-phase response element (APRE)], known to bind to STAT3/APR factor (30, 31), was used as the positive control for STAT3 binding and was designated as STAT3-BS. The sequence for STAT3-BS is 5'-GATCCCTTCTGGAGAATCTTACATATG-3'. After annealing complementary strands (1 μg), binding reactions were carried out at 4°C for 16 h to include 6.5 μg nuclear extracts isolated from the control.
and EGF-stimulated MDA-MB-468 cells. Protein-bound probe was precipitated using ImmunoPure streptavidin-agarose beads (Pierce), washed, and subjected to detection of p-STAT3 and EGFR via Western blot analyses as described earlier.

**Chromatin immunoprecipitation assay.** This procedure was done as described previously (24, 32). In brief, MDA-MB-468 cells were serum-starved overnight and treated without and with EGF (100 ng/mL) for 30 min. The cells were cross-linked with 1% formaldehyde at room temperature for 10 min, and the reaction was stopped by the addition of glycine to a final concentration of 0.125 mol/L. After washing twice with ice-cold PBS, the cells were scraped off the plate, centrifuged, and resuspended in 400 μL of cell lysis buffer [5 mmol/L Tris-HCl (pH 8.0), 85 mmol/L KCl, 0.5% NP40, 1 μg/mL aprotinin, and 1 mmol/L phenylmethylsulfonyl fluoride (PMSF)]. After incubation on ice for 10 min, the cells were dounced to isolate nuclei, and the nuclei were collected, resuspended in 200 μL nuclei lysis buffer 50 mmol/L Tris-HCl (pH 8.1), 10 mmol/L EDTA, 1% SDS, 1 μg/mL aprotinin, and 1 mmol/L (PMSF), and sonicated 4 pulses for 10 s each. After centrifugation, the supernatant was diluted 1:10 with immunoprecipitation dilution buffer [0.01% SDS, 1.1% Triton X-100, 1.2 mmol/L EDTA, 16.7 mmol/L Tris-HCl (pH 8.0), 167 mmol/L NaCl, 1 μg/mL aprotinin, and 1 mmol/L PMSF]. The cell lysates were precleared with normal IgG and protein A-agarose beads and subjected to immunoprecipitation with mouse monoclonal anti-EGFR antibody (Ab-13; NeoMarkers), polyclonal anti-STAT3 antibody (C-20; Santa Cruz Biotechnology), or normal IgG at 4°C overnight. Immunoprecipitated complexes were collected by adding salmon sperm DNA/protein A-agarose (Upstate) for 15 min at 4°C. Precipitated complexes were collected by adding salmon sperm DNA/protein A-agarose (Upstate) for 15 min at 4°C. Immunoprecipitated complexes were washed twice with diethylpyrocarbonate buffer [2 mmol/L EDTA, 50 mmol/L Tris-HCl (pH 8.0)] and four times with immunoprecipitation wash buffer [0.5 mol/L LiCl, 1% NP40, 1% sodium deoxycholate, 100 mmol/L Tris-HCl (pH 8.0)]; the DNA/protein complex was eluted twice using elution buffer (50 mmol/L NaHCO3, 1% SDS) and treated with RNase A for 30 min at 37°C. The protein/DNA cross-links were reversed by heating at 65°C for 16 h, and then the DNA were extracted using QIAquick PCR purification kit (Qiagen). For PCR, 3 μL from a 40-μL DNA preparation was used for amplifications. Specific sequences of the human TWIST promoter in the immunoprecipitates were detected by PCR with primers forward 5′-AGTCTCTCCGACCGCTTCTCG-3′ and reverse 5′-CTCCGTGACGGCAGGATTGTG-3′. The resulting PCR product spans the –364 to –33 region that includes the putative STAT3-binding sites. The c-fos promoter has been previously shown to bind to nuclear EGFR and STAT3 and thus also was amplified as positive controls (24).

**Immunohistochemical analyses, histologic scoring, and statistical analyses.** The cohort of primary breast carcinoma specimens, previously stained for EGFR and iNOS, was consisted of 130 cases (24, 26). Immunohistochemical staining was done as previously described (24, 26). In this study, rabbit polyclonal TWIST and p-STAT3 (Y705) antibodies from Santa Cruz Biotech and Cell Signaling, respectively, were used. The immunoreactivity for TWIST was semiquantitatively scored using a well-established system in which H score was generated by incorporating both the percentage of positive tumor cells and the intensity of staining (33). All slides were independently viewed and scored by two pathologists (W.X. and Y.W.). Slides in which there was a scoring discrepancy of >10% were reevaluated and reconciled on a two-headed microscope. Statistica 6.0 (Statsoft) and regression analysis were used to analyze the correlation.

**Results**

**EGF exposure induces transition of the epithelial to the mesenchymal-like phenotype in cultured breast cancer cells.** Cancer cells of epithelial origin undergo EMT as an early event that leads to local invasion and metastasis to distant sites. Despite accumulating studies showing a positive link between high EGFR expression and cancer invasion/metastasis, the specific involvement of EGFR in EMT remains elusive. We, therefore, aimed to examine whether EGF stimulation induces EMT in cancers of the breast and pancreas, two epithelial cancers that can invade and metastasize. This is also important as the survival rate for metastatic breast cancer was reported to be only 9.1% to 14.7% between 1991 and 1995 (34). As indicated in Fig. 1A, the human breast carcinoma MDA-MB-468 cells maintained in a minimal amount (0.5%) of FCS (a) retained the epithelial morphology, whereas those supplemented with EGF (b) and TGF-α (c) displayed mesenchymal-like morphology after 5-day treatments. Approximately, 500 cells were examined for each treatment, and three independent experiments were carried out. Similar observations were found in human pancreatic cancer cells PANC28 and A431 human epidermoid carcinoma cells (data not shown). Both cell lines express EGF (Fig. 2). We next examined whether E-cadherin repressors, TWIST, SLUG, and Snail may play a role in EGF-induced EMT in MDA-MB-468 cells. Using reverse transcription-PCR (RT-PCR), we found that MDA-MB-468 cells express detectable levels of TWIST and Snail transcripts, but not that of SLUG (Fig. 1B). Western blot analyses further showed that these cells contained high levels of TWIST protein, but not Snail, and that EGF enhanced TWIST protein expression (Fig. 1C). In fact, Snail expression was very low, and the signals became visible only after prolonged autoradiography. Together, these results suggest that EGF ligands EGF and TGF-α induce EMT-like morphologic changes in human cancer cells, and among the three transcriptional repressors for E-cadherin, TWIST is the only one that expresses at a detectable level and also responds to EGF stimulation.

**EGF induces expression of TWIST and mesenchymal markers, as well as reduction of an epithelial marker.** TWIST, a bHLH transcription factor and repressor of E-cadherin expression, is frequently detected in metastatic cancer cells and is required for EMT and breast cancer metastasis (11, 16, 18). To date, human TWIST gene regulation remains largely unknown. To determine whether EGF/EGFR promotes EMT via TWIST, we first examined the effect of EGF treatment on the human TWIST gene transcription in EGFR-expressing MDA-MB-468 (Fig. 2A) and human epidermoid carcinoma A431 cells (Fig. 2B). After serum starvation for 24 h, EGF significantly increased TWIST gene transcripts at 2 h, as indicated by RT-PCR (left) and quantitative real-time PCR (right). Expression of GADPH served as a loading control. Consistently, EGF stimulation increased the levels of TWIST protein in a panel of EGFR-expressing cancer cells, including MDA-MB-468, A431, and PANC28 (Fig. 2C, left). EGF in the PANC28 cells seem to undergo down-regulation after EGF treatment as expected. In contrast, EGFR-overexpressing MDA-MB-468 and A431 cells contain sustained levels of EGFR. This observation is consistent with the notion that overexpression of EGFR undergoes faster recycling and impairs its down-regulation due to limiting levels of regulatory molecules that mediate rapid endocytosis and lysosomal targeting EGFR (35, 36). Interestingly, EGF-null CHO-NEO and NR-6 cells do not contain detectable levels of TWIST, and forced EGFR expression in these cells induced TWIST expression (Fig. 2C, middle and right).
CHO-EGFR and Her5 are stable lines derived from parental CHO and NR-6 cells, respectively, to express high levels of EGFR, as reported previously (37).

In addition to EGF, other EGFR ligands, HB-EGF and TGF-α, similarly activated the human TWIST gene expression in MDA-MB-468 cells (Fig. 2D, left), which is consistent with their implication in tumor invasion (38). Consistent with the phenotypic observation in Fig. 1, chronic EGF exposure reduced expression of E-cadherin, an epithelial marker, and increased levels of vimentin and fibronectin, mesenchymal markers (Fig. 2D, right). At day 5 post-EGF stimulation, both EGFR-expressing MDA-MB-468 and A431 cells expressed significantly more TWIST compared with the untreated controls. Taken together, these data indicate that EGF/TGF-α stimulation and EGFR expression are important for the human TWIST gene expression and that EGF induced gene expression changes typically found in cancer cells undergoing EMT.

**EGFR-induced TWIST expression involves STAT3.** Because EGFR/EGFR can activate many signaling modules to regulate gene expression, we then asked via which downstream pathways the human TWIST gene becomes activated. To address this, we pretreated MDA-MB-468 cells with inhibitors to EGFR (Iressa and AG1478), Janus-activated kinases (JAKs)/STATs (AG490), PI3K/Akt (LY294002), and MEK/ERK (U0126) and examined TWIST’s activity after normalization against the activity of the transfection control Recilla luciferase. As indicated in Fig. 4A, all three EGFR ligands (EGF, TGF-α, and HB-EGF) significantly activated the human TWIST promoter. Interestingly, the phTWIST-120 construct showed similar extents of EGF responsiveness to the phTWIST-604 plasmid, indicating that the critical DNA elements are within the −120 bp region of the promoter. Relative luciferase activity was derived from firefly luciferase activity after normalization against the activity of the transfection efficiency control Recilla luciferase.

**EGFR with STAT3 Induces EMT in Cancer Cells**

**EGF exposure induced the epithelial to the mesenchymal-like phenotype in cultured breast cancer cells.** Human breast carcinoma MDA-MB-468 cells were used in these studies. Three independent experiments were done. Cancer cells were serum-starved for 24 h before treatments. A, EGF-treated MDA-MB-468 cells displayed mesenchymal morphology. Cells were treated with 0.5% FCS only (a), 0.5% FCS with 50 ng/mL EGF (b), and 0.5% FCS with 50 ng/mL TGF-α (c). Cell morphology was examined and photographed daily using a phase-contrast microscope. At day 5, unstimulated MDA-MB-468 cells retained their epithelial phenotype (a). In contrast, cells treated for 5 d with EGF (b) and TGF-α (c) displayed detached mesenchymal-like morphology.

**B, transcripts of EMT mediators, TWIST and Snail, were detected.** Total RNA was isolated and subjected to RT-PCR to detect TWIST, SLUG, Snail gene transcripts. Expression of GAPDH serves as a loading control. C, TWIST, but not Snail, protein was expressed at high levels. Cancer cells were starved for 24 h and treated without and with EGF for 6 h; total cell lysates were extracted and subjected to Western blot analyses for expression of TWIST and Snail. Note the exposure time to detect the expression of Snail was 5 times longer than that of TWIST.

**Figure 1.** EGF exposure induced transition of the epithelial to the mesenchymal-like phenotype in cultured breast cancer cells. Human breast carcinoma MDA-MB-468 cells were used in these studies. Three independent experiments were done. Cancer cells were serum-starved for 24 h before treatments. A, EGF-treated MDA-MB-468 cells displayed mesenchymal morphology. Cells were treated with 0.5% FCS only (a), 0.5% FCS with 50 ng/mL EGF (b), and 0.5% FCS with 50 ng/mL TGF-α (c). Cell morphology was examined and photographed daily using a phase-contrast microscope. At day 5, unstimulated MDA-MB-468 cells retained their epithelial phenotype (a). In contrast, cells treated for 5 d with EGF (b) and TGF-α (c) displayed detached mesenchymal-like morphology. B, transcripts of EMT mediators, TWIST and Snail, were detected. Total RNA was isolated and subjected to RT-PCR to detect TWIST, SLUG, Snail gene transcripts. Expression of GAPDH serves as a loading control. C, TWIST, but not Snail, protein was expressed at high levels. Cancer cells were starved for 24 h and treated without and with EGF for 6 h; total cell lysates were extracted and subjected to Western blot analyses for expression of TWIST and Snail. Note the exposure time to detect the expression of Snail was 5 times longer than that of TWIST.
activity (Fig. 4B). Consistently, EGFR kinase inhibitors (Iressa and PD158780) and JAKs inhibitor (AG490) reduced the activity of the TWIST gene promoter. Furthermore, STAT3 expression knockdown by STAT3 small interfering RNA, but not by the control small interfering RNA, reduced TWIST expression (Fig. 4C, left). Together, these data indicate an important role of STAT3 in EGFR-mediated TWIST gene expression.

As we recently found that nuclear EGFR contains transcriptional activity and activates expression of cyclin D1, iNOS, and B-Myb (24, 28, 32), we then examine the involvement of nuclear EGFR in EGF-induced TWIST gene activation. Using isogenic lines CHO-NEO, CHO-EGFR, CHO-EGFR-NLS (CHO with the nuclear entry-defective EGFR), we found that EGFR-NLS mutant displayed a constitutive TWIST promoter activity but failed to respond to EGF (Fig. 4D). Although the EGF responsiveness of EGF-NLS/CHO seems to favor that nuclear localization of EGFR might be involved in the STAT-mediated TWIST up-regulation. This notion is not supported by the fact that EGFR-NLS can constitutively activate TWIST promoter (Fig. 4D). Thus, further investigation is required for a role of direct nuclear EGFR in the TWIST up-regulation.
Identification of STAT3-targeted region within the human TWIST promoter. We found, thus far, that STAT3 is involved in EGFR-induced TWIST gene activation and that a 120-bp promoter region may be important in this involvement (Fig. 4). Next, we asked whether the TWIST gene promoter contains STAT3-binding sites. As illustrated in Fig. 5A, the proximal region (−120 bp) of the human TWIST promoter contains two putative STAT3-binding sites. A TATAA box is located at −32 to −28 bp, relative to the transcription start site. To analyze the functionality of the putative STAT3-binding sites A (−116 to −107) and B (−103 to −96), we did site-directed mutagenesis to generate the pTwIST-120/MA mutant with nucleotide substitutions (underlined) at −116 to −104 bp region and the pTwIST-120/MB mutant with nucleotide changes (underlined) at −99 to −96. Additionally, the pTwIST-94 was generated to remove the putative STAT3-binding sites and thus only contains the minimal promoter up to −94 bp. Using these reporters, we found that mutation at either putative STAT3-binding site, A or B, reduced but did not abolish the ability of the human TWIST promoter to respond to EGFR ligands in MDA-MB-468 cells (Fig. 5B, left). Deletion of the STAT3-binding sites reduced its basal level of promoter activity and rendered EGF-irresponsiveness of the TWIST promoter, as indicated by the failure of the pTwIST-94 construct to respond to EGF/TGF-α (Fig. 5B, right).

We further examined the ability of p-STAT3 to bind to the putative STAT3-binding site within the human TWIST promoter using the biotinylated oligonucleotide precipitation/oligo pull-down assay. As indicated in Fig. 5C, EGF activated the binding of p-STAT3 to the consensus STAT3-binding site (STAT3-BS/APRE; refs. 30, 31), the putative STAT3-binding site in the TWIST promoter,
the TWIST-120/MA and TWIST-120/MB oligonucleotides. Consistent with low EGF responsiveness of the TWIST-120/MB promoter (Fig. 5B, left), the TWIST-120/MB fragment was found to contain lowest binding affinity to p-STAT3 (Fig. 5C). We did not detect binding of nuclear EGFR to any biotinylated oligonucleotides that we tested. Furthermore, we examined whether nuclear STAT3 binds to the TWIST gene promoter using the in vivo protein-DNA binding chromatin immunoprecipitation (ChIP) assay, and the results are shown in Fig. 5D. Upon EGF stimulation, nuclear STAT3 binds to the human TWIST gene promoter. In contrast, nuclear EGFR did not associate with the TWIST promoter at a detectable level, consistent with the lack of EGFR binding observed in Fig. 5C. As expected, both nuclear EGFR and STAT3 bind to the c-fos promoter in an EGF-dependent fashion, as we previously reported.
The IgG was used in immunoprecipitation as negative controls and did not yield any band signals, indicating the assay specificity. Input chromatins were also used in these assays to indicate that equal amounts of cell lysates were used from the /C0 EGFand+EGF treatment groups. In summary, we identified and functionally characterized the STAT3-targeted region within the human TWIST promoter.

Positive correlations between EGFR/p-STAT3 and TWIST in a cohort of primary breast carcinomas. We revealed using cultured cells that EGFR activates the human TWIST gene expression via activation of STAT3. Next, we aimed to examine whether such regulation also exists in the primary tumor specimens from cancer patients. To this end, we analyzed TWIST expression via immunochemical staining analysis in a cohort of primary breast carcinomas that have been previously immunostained for EGFR and p-STAT3 (24, 26). Two pathologists independently viewed and scored all slides. All statistical analyses were done using Statistica 6.0 software. Regression analysis indicated a positive correlation between non-nuclear EGFR and TWIST (P = 0.01). Levels of nuclear EGFR do not significantly correlate with those of TWIST (P = 0.6), which is in agreement with the findings in Fig. 5C and D. To further investigate whether p-STAT3 correlates with TWIST expression, we immunostained the same cohort of tumors for p-STAT3 and analyzed the correlation between p-STAT3 and TWIST. We found that levels of TWIST correlate significantly with those of p-STAT3 (R = 0.28, P = 0.0013; Fig. 6C, left). In agreement with the role of EGFR as an upstream activator of STAT3, we found a significant, positive correlation between non-nuclear EGFR and p-STAT3 (R = 0.35, P = 0.00003; Fig. 6C, right). Furthermore, Fig. 6D shows two representative tumors in which the upper case contains high EGFR/p-STAT3/TWIST and the lower tumor contains low EGFR/p-STAT3/TWIST.

Figure 5. Identification of STAT3-targeted region within the human TWIST promoter. A, schematic illustration of the proximal region of the human TWIST promoter. The human TWIST proximal promoter contains two putative STAT3-binding elements. A TATA box is located at nt −32 to −28, relative to the transcription start site. Site-directed mutagenesis was done to generate the phTWIST-120/MA mutant that contains multiple nucleotide substitutions (underlined) at nt −116 to −107 region and the phTWIST-120/MB mutant with nucleotide changes (underlined) at nt −99 to −96. The pTWIST-94 was additionally generated to remove the putative STAT3-binding sites and thus contains the minimal promoter up to −94 bp. B, mutation at the putative STAT3-binding site II significantly reduced the ability of the human TWIST promoter to respond to EGFR ligands. MDA-MB-468 cells were transfected with phTWIST-120, phTWIST-94, phTWIST-120/MA, and phTWIST-120/MB as previously described. After 48 h, serum-starved transfected cells were stimulated with EGFR (100 ng/mL) for 4 h before determination of luciferase activities. All data represent the mean and SD from three independent experiments. C, biotinylated oligonucleotides precipitation assay. These studies were done to determine the degree of the binding of STAT3 to the TWIST promoter fragments. MDA-MB-468 cells untreated and treated with EGFR (100 ng/mL) for 1 h were harvested, and nuclear lysates were used. Nuclear extracts were then subjected to binding affinity evaluation to a number of biotinylated oligonucleotides, namely, STAT3-BS/APRE (30, 31), TWIST-120/TWIST, TWIST-120/MA, and TWIST-120/MB. Biotinylated oligos were then precipitated by avidin beads, washed and subjected to Western blot analysis for p-STAT3 and EGFR. D, nuclear STAT3, but not nuclear EGFR, binds to the human TWIST gene promoter. A431 cells were serum-starved and stimulated without and with EGFR (100 ng/mL) for 30 min and subjected to the in vivo binding assay ChIP, as we previously described. Briefly, EGFR monoclonal antibody (Neomarkers, Ab13) and STAT3 polyclonal antibody (Santa Cruz, C-20) were used in immunoprecipitation. IgG was used as negative control for immunoprecipitation, whereas input chromatin were used as positive controls for PCR and for equal loading. The c-fos promoter was also amplified as a positive control for both EGFR and STAT3 binding.
Together, we reported here that levels of EGFR and p-STAT3 correlate positively with those of the TWIST gene in breast carcinomas.

**Discussion**

Metastasis is a major obstacle for cancer therapy and is a primary cause of mortality in many cancers, including that of the breast. Understanding the biology of cancer cells with high metastatic potential is, therefore, important in identifying tumors that are likely to undergo metastasis and in improving current anticancer therapy. It has been shown that cancers with the deregulated EGFR pathway possess a high likelihood for local invasion and subsequent metastasis. The specific involvement of EGFR in EMT, an event that takes place during the early stage of tumor invasion, intravasation, and subsequent metastasis to the distant organ sites, remains elusive. The current study was thus undertaken to examine the role of aberrant EGFR pathway in EMT. Here, we report that cancer cells with high EGFR expression/activity undergo EGF/TGF-α–induced EMT, and this phenotypic transition involves EGFR-mediated activation of STAT3 and subsequent STAT3-activated TWIST gene expression.

TWIST is a bHLH transcription factor that has been known as an essential player for proper gastrulation mesoderm formation and neural crest migration (15). More recently, TWIST has been found to express at high levels in a number of human tumors, including those of the breast, prostate, esophagus, lung, uterus, skin, liver, and brain (16–19, 44–46). Importantly, increased TWIST expression is associated with breast cancer metastasis to the lung and increased EMT and intravasation (11). Correlative studies further indicate an association of high TWIST expression with invasion and therapeutic response in other cancer types (17–19, 44, 47–49). Despite frequent reports of TWIST overexpression in human cancers, transcriptional regulation of the human TWIST genes is

![Figure 6. Positive correlations between non-nuclear EGFR/p-STAT3 and TWIST in a cohort of primary breast carcinomas.](image-url)

The cohort of primary breast carcinoma specimens, previously stained for EGFR (26), was analyzed for p-STAT3 (Y705) and TWIST expression via immunohistochemical staining analysis. All slides were independently viewed and scored by two pathologists. When the scoring discrepancy is >10%, slides were reevaluated and reconciled by two pathologists on a two-headed microscope. All statistical analyses were done using Statistica 6.0 software. A, positive correlation between non-nuclear EGFR and TWIST. Levels of TWIST were correlated with those of non-nuclear EGFR ($P = 0.01$). Regression analysis was done in these analyses. B, lack of correlation between levels of nuclear EGFR and TWIST ($P = 0.6$). Regression analysis was similarly done as in A. C, expression of p-STAT3 correlates with those of TWIST and non-nuclear EGFR. Regression analysis was done to determine $R$ and $P$ values. D, representative tumors immunostained for EGFR, p-STAT3, and TWIST. Top, tumor was stained strongly for EGFR (left), p-STAT3 (middle), and TWIST (right). Bottom, tumor with negative/low expression for all three proteins.
largely unknown. Moreover, regulation of the mouse Twist genes has been investigated to involve tumor necrosis factor-α/nuclear factor κB (NF-κB; ref. 50) and Wnt1/Tcf/β-catenin pathways (51). However, the NF-κB and TCF/β-catenin response elements found in the mouse Twits gene promoters are not present in that of the human TWIST gene. A recent study reported that STAT3 knockdown of mouse 4T1 mammary tumor cells led to altered expression of several genes, including Twist (20). Twist has yet been shown to be a direct transcriptional target of STAT3. We did an extensive search, using TF Search and TESS transcription factor search sites, for the STAT-binding sites within the mouse twist gene promoter and did not find a putative site, suggesting its expression reduction by STAT3 small interfering RNA was likely due to indirect effects. The current study showed that EGFR activated STAT3 sites in the human TWIST promoter and regulates its transcription. Because mouse TWIST promoter does not contain STAT consensus site, this raises an interesting question that the two species may use STAT to regulate TWIST expression through different molecular mechanisms.

The current report strongly supports the notion that EGFR and STAT3 oncoproteins interplay and regulate expression of a series of genes that are involved in aggressive cancer biology. Such regulation, however, seems to be highly complex and not yet fully understood. In the case of TWIST, this study indicates that STAT3 plays a direct transcriptional role by binding to the TWIST promoter and that EGFR seems to be an upstream regulator that phosphorolyses and activates STAT3. Although the responsiveness of EGFR of EGFR-NLS/CHO seems to favor that nuclear localization of EGFR might be involved in the STAT3-mediated TWIST up-regulation. This notion is not supported by the fact that EGFR-NLS can constitutively activate the TWIST promoter. Furthermore, nuclear EGFR does not seem to interact directly with the TWIST promoter, as indicated by the ChiP and oligo pull-down assays. IHC studies showed no significant correlation between nuclear EGFR and TWIST. Together, these evidences suggest that a role of direct nuclear EGFR in the TWIST up-regulation is unlikely. For INOS, nuclear EGFR and STAT3 behave as transcriptional coregulators as the EGFR/STAT3 complex associated with the INOS promoter (24). In the case of cyclin D1, nuclear EGFR seems to bind to the promoter independent of STAT3 (24). On the other hand, STAT3 can be activated by other upstream regulators, independent of EGFR/EGFR, and regulates expression of Myc (52) and p21WAF1/CIP1 (53). Further investigations are indeed needed to further our understanding of EGFR-mediated and STAT-mediated gene regulation and its effect in the biology of cancer cells.

We report here that the human TWIST gene is directly up-regulated by the oncoprotein STAT3 in cancer cells with high levels of EGFR. This correlation was also found in primary breast carcinomas. Given TWIST’s function in promoting EMT, EGFR cooperates with STAT3 to induce TWIST expression leading to EMT. In this context, we observed that chronic EGF/TGF-α exposure promotes EMT in breast and pancreatic cancer cells with high EGFR levels. This finding is supported by the observation that prolonged EGF stimulation leads to loss of E-cadherin and increased invasion in A431 human epithidermoid carcinoma cells (10). Consistent with our findings, tumors with high EGFR and constitutively activated STAT3 contain high potentials to undergo metastasis (1–5). Stat3 controls cell movement in Zebrafish gastrulation via increasing Zinc transporter Liv1 expression (54, 55). In line with our observations, STAT3 knockdown in mouse breast cancer cell line leads to reduced expression of Twist (20). Together, our results and those from other studies highlight an important role of EGFR and STAT3 in promoting cancer EMT via TWIST. Our findings provide important insights into the understanding of the malignant biology of tumors with deregulated EGFR and STAT3 pathways and establish new rationales for using anti-EGFR and anti-STAT3 strategies to target aggressive invasive tumors.

“Targeting signal transducer and activator of transcription 3 (STAT3) as a novel strategy in sensitizing breast cancer to anti-EGFR therapy”

AIM 1: To determine whether increased STAT3 expression/activity confers resistance to anti-EGFR therapy in EGFR-expressing breast cancer cells. AIM 2: To investigate whether suppression of STAT3 expression/activity sensitizes EGFR-expressing breast cancer cells to anti-EGFR therapy. AIM 3: To determine the therapeutic effects of combined use of anti-EGFR and anti-STAT3 treatments in a mammary tumor-bearing animal model.

*Overlap: NONE*
The goal of this study is to determine whether aberrant STAT3 pathway contributes to medulloblastoma biology and if targeting STAT3 leads to significant therapeutic effects.

The goal of this study is to understand the role of STAT3 activation in the resistance of malignant gliomas to anti-EGFR therapy.
