Breast Density Assessment by Dual Energy X-ray Absorptiometry in Women and Girls

Gertraud Maskarinec, M.D., Ph.D.
Rachel Novotny, Ph.D.

Abstract
Increasing evidence suggests that breast cancer risk is determined early in life. Mammographic density has been used as a biomarker for breast cancer risk because of its strong association with breast cancer. However, use of this screening method is contraindicated in young women and girls because the risk of X-ray based mammograms outweighs potential benefits in that age group. In contrast, Dual Energy X-ray Absorptiometry (DXA) has extremely low radiation and is commonly available. The specific aims of this project among adult women and adolescent girls, who will be recruited as mothers and daughters, will be to 1. Correlate breast density measured by DXA with mammographic density among adult women; 2. Compare the association of known breast cancer risk factors with breast density from DXA scans to their association with mammographic density; 3. Assess DXA breast density by Tanner stage of breast maturation among adolescent girls; 4. Relate DXA breast density to other observable measures of pubertal maturation, e.g., height and menarche; and 5. Examine the relation between breast density measured by DXA in mothers and daughters. During this year, we have recruited 19 mother-daughter pairs plus one additional daughter and obtained DXA scan images from all participants. We project to recruit the remaining 80% (81 mother-daughter pairs) and complete data collection by the end of next year. Upon completion of the study, our multiethnic sample will generate a pilot data on the DXA scan as a method to evaluate breast cancer risks in women and young girls from various ethnic groups.

(5) Introduction

Increasing evidence suggests that breast cancer risk is determined early in life. However, use of mammography as a screening method is contraindicated in young women and girls because the risk of X-ray exposure outweighs potential benefits in that age group. In contrast, Dual Energy X-ray Absorptiometry (DXA) has extremely low radiation and is commonly available. The rationale of this project is that predictors of breast cancer risk may be observed during pubertal development in girls. Our hypotheses are as follows:

1. DXA imaging can provide a valid assessment of breast density in adult women and in young girls.
2. DXA assessed breast density is associated with indicators of pubertal maturation and with known breast cancer risk factors.
3. Due to its strong genetic component, breast density obtained from the DXA scans is correlated between mothers and adolescent daughters.

The specific aims of this project among adult women and adolescent girls, who will be recruited as mothers and daughters, are to:

1. Correlate breast density measured by DXA with mammographic density among adult women.
2. Compare the association of known breast cancer risk factors with breast density from DXA scans to their association with mammographic density.
3. Assess DXA breast density by Tanner stage of breast maturation among adolescent girls.
4. Relate DXA breast density to other observable measures of pubertal maturation (e.g., height and menarche).
5. Examine the relation between breast density measured by DXA in mothers and daughters.

We aim to recruit a total of 100 adult women with daughters between 8-16 years of age. Based on the ethnic distribution of Hawaii’s population, we expect that approximately half of the study subjects will be of Asian (primarily Japanese, Chinese, and Filipino) and Pacific Islander descent.

(6) Body

During this year, we have accomplished the following tasks as outlined in the approved Statement of Work.

Task 1. Study plan and procedures.

Task 1.a. Study manual. We prepared a study protocol describing our recruitment strategy with Kaiser Permanente. After Kaiser IRB’s review and in consultation with the Clinical Research Center at the University of Hawaii where the DXA scans are performed, we made a few modifications to the protocol as requested. One was to perform a urine pregnancy test on all participants including all daughters and to indicate in the consent/assent forms that, if the test is positive, a further follow-up by a doctor is needed to confirm the positive test result. If the daughter is under 14 years old, a positive pregnancy test result will be given to her mother. If the daughter is 14 years or older, the test results will be released only to her. Assenting process with the daughter will be conducted in private and separate from the consenting process with her mother. We also added to the protocol that we mail a study packet containing the consent/assent forms and the Study Questionnaire to all participants prior to their scheduled visits for a thorough review.

We began recruiting participants in the second half of this year. Subsequently, we made a modification to the study protocol to allow participation of mothers and daughters who were not Kaiser members but biologically related. We had a case in which an eligible woman had a biological daughter who was not a Kaiser member (not covered by her mother’s health plan). We anticipate the same could happen to eligible daughters whose biological mothers are not a Kaiser member. Thus, allowing these mothers and daughters to participate will expand our potential participant pool and enhance our recruitment efforts. If the biological mothers are not Kaiser members, an additional Mammogram Release Authorization Form will be signed to access their mammogram films at non-Kaiser clinics/hospitals.

Furthermore, we added a participant weight limit of 300 pounds because the DXA machine cannot perform a body scan beyond this weight limit. Due to concerns by the Kaiser IRB, the lower age limit for girls was raised to 10 years. These modifications have been reported to and approved by all three IRBs: the U.S. Army Medical Research and Material Command, the University of Hawaii Committee on Human Subjects, and Kaiser Permanente.

Task 1.b. Subcontracts. Subcontracts have been established with the University of California at San Francisco (UCSF) and with Kaiser Permanente Hawaii.
**Task 1.c. DXA procedures.** The DXA Operator’s Manual was prepared by a research staff member at UCSF Breast Bone Density Group (BBDG); it includes step-by-step description of DXA scan procedures, as well as instructions on how to send DXA scan images to UCSF BBDG. The same staff member came to Hawaii to train the x-ray technician at the Clinical Research Center in operating the Lunar Prodigy DXA Bone Densitometer (DF+12484) in a research mode specified for the current study and performing DXA scans of the breast and a custom phantom developed by USCF BBDG.

**Task 1.d. Plan recruitment strategy with Kaiser.** Recruitment strategies were developed with Kaiser based on our previous successful projects with girls and adult women. We made a modification previously described in Task 1.a. Updated strategies are described in the approved Study Protocol.

**Task 1.e. Train DXA technician.** A licensed x-ray technician at the Clinical Research Center, University of Hawaii, was trained in performing DXA scans as described in Task 1.c. After several study meetings with staff from CRCH and Kaiser to train all personnel in study procedures, a number of trial sessions with volunteers were conducted and the correct DXA scanning procedures were practiced by the technician while the study coordinators observed the process and made suggestions on how to obtain images of optimal quality.

**Task 1.f. Establish study database.** A password-protected, study database was created by research personnel at the Cancer Research Center using Microsoft Excel 2003 to enter participants’ data by study ID number; it will contain demographic data, health and menstrual/reproductive information, anthropometric measures, and Tanner stages for girls. This database will be merged with mammographic and DXA scan data after completion of the data collection from all 100 participant pairs.

**Task 1.g. Purchasing study supplies.** Pregnancy-test kits were purchased from Fisher Scientific and R. Weinstein, Inc. Gift cards for the participants were purchased from Ala Moana Shopping Center. Encrypted USB memory drive and recordable CDs were purchase from Office Depot to be used for the shipment of DXA scan data to UCSF BBDG.

**Task 2. Subject recruitment.** From the Kaiser membership database, women who had received a mammogram during the last year and had a daughter aged 10-16 years were identified. This year, a total of 424 invitation letters were mailed to eligible women and their daughters. In compliance with privacy regulations, Kaiser Permanente sent out the invitations that contain a postage-paid return envelope. Upon receipt of the return envelop from interested members, a trained Kaiser research staff member made prescreening phone calls to explain the study, screen for eligibility, and schedule a study visit. Nineteen mother-daughter pairs plus one additional daughter have been recruited for the study by June 2008. We project to complete recruitment of the remaining 81 mother-daughter pairs within the next year.

**Task 3. Conduct study visits.** Study visits were conducted by trained research staff members at the Clinical Research Center including a licensed x-ray technician. These staff members were trained in explaining the study procedures, performing final eligibility check, obtaining informed consent/assent, administering the study questionnaire, and collecting anthropometric measurements. In addition, the x-ray technician had previously been trained in conducting Tanner-stage assessments of pubertal development (breast and pubic hair), and has performed the assessments of all 20 girls participated in our study this year.

**Task 4. Perform DXA scans.** A licensed x-ray technician who received training for this study as described previously in Task 1.c performed scans of the whole body and breasts on a Lunar Prodigy DXA Bone Densitometer (DF+12484). DXA scans were obtained from all participants. Scanned images were saved on a password-protected USB memory drive each day as directed by the DXA Operator’s Manual. At the end of each month, these images were burned to a CD, protected by password, and mailed to UCSF BBDG via FedEx by the project coordinator.
Task 5. **Perform Breast Density Analysis.** We plan to proceed with this task in 2009 after completion of data collection from all 100 mother-daughter pairs next year.

Task 6. **Data Management and Analysis.** All current participants’ data collected during the study visits have been entered in the study database by the project coordinator at the Cancer Research Center. This includes demographic data, health and menstrual/reproductive information, anthropometric measures, and Tanner stages for girls. The mean age of the mothers was 48.4±4.1 years, and that of the daughters’ was 13.6±1.7 years. Self-reported ethnicities (Table 1) reflect the diverse population of Hawaii.

(7) **Key Research Accomplishments** None to date.

(8) **Reportable Outcomes** None to date.

(9) **Conclusions**

This year, we established study procedures and obtained human subjects approval from the University of Hawaii, Kaiser Permanente Hawaii, the University of California at San Francisco, and the Department of Defense. The efforts to create one study protocol acceptable to all institutions consumed several months. Input from the Clinical Research Center at the University of Hawaii where the DXA scans are performed was also incorporated into the study protocol. Each additional change that had to be submitted to all IRBs delayed the study for a number of weeks. As to the actual study, we created a study database, trained study personnel, purchased all necessary supplies, created a data transfer protocol with the University of California at San Francisco, and proceeded with the recruitment of the study subjects.

By June 17, we had recruited 20% of the total participants so far. We project to recruit the remaining 80% (81 mother-daughter pairs) and complete data collection by the end of next year. We experienced a lower-than-expected response rate from Kaiser members (4.5% vs. 10%) this year. Thus, we may need to make further modifications to our recruitment strategy to improve our recruitment efforts.

Composition of the current participants represents the multiethnic population of Hawaii. Upon completion, this study will generate pilot data on the DXA scan in mother-daughter and provide more information about the heritable aspects of breast density from a diverse population. Moreover, the current study will develop a technique that will provide a unique tool to screen for breast cancer risk in early life and aid in developing prevention strategies.

(10) **References** None cited

Breast density, the radiographically opaque fraction of the breast in a mammogram, is one of the strongest biomarkers of breast cancer risk. However, younger populations do not typically have mammograms due to radiation concerns. This study explored a commercially available dual-energy X-ray absorptiometer (DXA) system as a low-dose method to measure breast fibroglandular density in adolescent girls. Eighteen girls (13-14 years old) indicated their breast development according to Tanner and underwent three dedicated DXA scans, two of their left and one of their right breasts. Total projected breast area was manually delineated on each image and percent fibroglandular volume density (%FGV), absolute fibroglandular volume (FGV), total breast area, and volume were computed. It was possible to image breasts representing all five Tanner stages; %FGV ranged from 31.9% to 92.2% with a mean of 71.1 ± 14.8%, whereas FGV ranged from 80 to 270 cm³ with a mean of 168 ± 54 cm³. Left and right breast %FGV were highly correlated ($r_p = 0.97$, $P < 0.0001$) and of the same magnitude ($P = 0.18$). However, left total volume and FGV were larger than the right by 38 cm³ ($P = 0.04$) and 19 cm³ ($P = 0.02$), respectively. Total volume and FGV increased by Tanner stage, whereas %FGV did not. Our method had excellent precision for %FGV and moderate precision for FGV (root mean square SDs of 2.4% and 16.6 cm³). These pilot data indicate that dedicated DXA breast scans may be useful in studies exploring breast density in girls.

(Cancer Epidemiol Biomarkers Prev 2008;17(7):1709–13)
Breast DXA in Girls

there is great interest in studying cancer biomarkers in early life, such as breast density in girls. Little is known about when a girl reaches her peak breast density and how density relates to genetics and early life habits such as diet. In this article, we report on the characteristics of our DXA method to measure breast fibroglandular density in adolescent girls at different pubertal stages of breast development.

Materials and Methods

Subjects. Eighteen girls (13-14 years old) were recruited as a convenience sample from the Adequate Calcium Today study (13), a multisite trial that examined the influence of a multimedia intervention on calcium intake and bone health of sixth grade girls (principal investigator: D. Savaiano). These subjects underwent a full-body DXA scan and consented to be recontacted. Therefore, the girls and their families were familiar with DXA scans and understood the very low level of exposure to radiation. The project was approved by the Committee on Human Studies at the University of Hawaii and by the Institutional Review Board of Hawaii Pacific Health, where the DXA machine is located. All girls signed an assent form and their parents signed an informed consent form. After weight and height measurements and confirming the absence of pregnancy by a urine test, participants underwent two dedicated DXA scans of their left breast and one of their right breast.

DXA Data Acquisition. All scans were acquired using the research scan protocol and software version 9.3 on a GE Lunar Prodigy Bone Densitometer (GE Healthcare). The scan options were set to research mode, standard X-ray technique, and scan width equal to 20 cm and length of 30 cm. The pixel dimensions were 1.0 \times 1.5 \text{ mm}^2.

After removing all clothing, and wearing cotton hospital gowns, the participants were positioned for dedicated decubitus mediolateral scanning of each breast. For imaging the left breast, the girls lay on their left side with their left arm resting below their head. Their left breast rested on the DXA surface and their right hand was used to hold their right breast out of the DXA scanning path. Standard radiolucent positioning wedges were used to support their back as well as the left breast to put the nipple in profile. The gown was pulled to lay smoothly over the image area with few folds. No breast compression was used. Each scan was manually stopped after scanning the entire breast length to minimize dose. After scanning the left breast, the girls were asked to roll over and were repositioned to scan the right breast. Lastly, the subjects were asked to get up and off the DXA machine, and then to remount the DXA, when they were repositioned for a second DXA scan of the left breast. The repositioning was to simulate the differences that would occur between repeated examinations. The X-ray dose per breast scan was estimated to be 15 \mu Sv. A single DXA technologist performed the DXA scans for all participants.

Low-energy and high-energy attenuation images were saved for each scan using the options available from GE Lunar for the research scan mode. Data analysis was done on the University of California at San Francisco Breast Density Workstation (14). The scans were calibrated to a two-compartment model of fat (steric acid) and fibroglandular tissue density using a variety of custom phantoms as described previously (11). Briefly, calibration phantoms of a known range of breast composition and thickness are scanned. A “ratio value” (R value) is defined as the ratio of the low-energy to high-energy attenuation for density and thickness. The paired R value and high-energy attenuation value are unique for each density and thickness. We define two polynomial functions to convert the R values and high-energy attenuations to either %FGV or breast thickness for each pixel. The dense breast volume in pixels is the product of the %FGV and the calculated volume of tissue in the pixel (thickness \times pixel area).

In vivo repeatability of the density measurements using the GE Lunar Prodigy DXA machine, we performed three scans of the density step phantom everyday for 2 wk. The phantom varied in thickness (2, 10, and 20 cm) and contained three %FGV values of 28%, 65%, and 100%.

Tanner Staging. All girls in the study were shown a diagram of breast development depicting the five Tanner stages (15) of breast development (Fig. 1) and were asked to select their current appearance. This method has been shown to be valid when compared with clinical staging done by health professionals (16).

The five stages describing the development of the breast by Tanner are as follows:

1. Same as in childhood; small elevated nipple with no significant underlying breast tissue.
2. Breast buds become visible. There is elevation of the breast and nipple as a small mound; the areola begins to enlarge. Milk ducts inside the breast begin to grow.
3. Further enlargement and elevation of the breast and areola occurs. The areola begins to darken in color. The milk ducts give rise to milk glands that begin to grow.
4. The areola rises above the rest of the breast and forms a secondary mound.
5. Only the nipple projects although in some woman the areola continues to form a secondary mound.

Statistical Analysis. All data management and analyses were done using the SAS statistical software package, version 9 (SAS Institute, Inc., 2001). In vivo repeatability was assessed using the repeat DXA scans of the left breast. The repeatability (precision) of the measures was calculated as SD and percent coefficient of variation (%CV) for each subject. For a representative precision value of the population, we define precision as the root mean square SD (RMS SD) and root mean square percent coefficient of variation (RMS %CV) as done commonly elsewhere (17).
RMS SD = \sqrt{\frac{\sum_{j=1}^{m} SD^2_j}{m}} \quad (A)

and

RMS %CV = \sqrt{\frac{\sum_{j=1}^{m} \%CV^2_j}{m}} \quad (B)

where SD\(_j\) and CV\(_j\) represent the values for the \(j\)th participant, and \(m\) is the total number of participants in the precision study. Comparisons between left and right breast measures were done by calculating the Pearson’s Correlation coefficient \(r_p\). Mean levels of breast total volume, projected area, \%FGV, and FGV tissue were computed as a function of Tanner pubertal breast stage, and the associations to Tanner stage described by the Spearman’s rank correlation coefficient \(r_s\). The density step phantom was analyzed using a template of seven regions of interest. The stability of the DXA system was determined by plotting the phantom results over time and checking for breaks in the calibration using standard process control methods and Shewhart rules (18).

**Results**

This study included 18 girls of ages 13 to 14 years. Of these, 11 reported Japanese ancestry, 3 were mixed Japanese/Chinese, 2 were Chinese, and 1 each reported Filipina and Korean ethnicity. All girls, except one, had reached menarche. The mean body weight was 47.4 ± 7.1 kg. The breast development in the girls was classified into the following Tanner stages: one as stage 1, three as stage 2, eight as stage 3, five as stage 4, and one as stage 5.

The DXA images showed the breast tissue separate from the pectoral muscle and rib cage. However, there was not much detail in the fibroglandular tissue. Figure 1 shows typical scans as a function of Tanner pubertal stage. Left and right measures for \%FGV, FGV, total area, and total volume were all highly correlated (Table 1). Total breast volume and FGV are larger, on average, for left than for right breasts \((P = 0.04\) and \(P = 0.02\), respectively). Breast volumes (mean of right and left) ranged from 113 to 670 cm\(^3\) with a mean of 254 cm\(^3\). FGV ranged from 80 to 270 cm\(^3\) with a mean of 168 ± 54 cm\(^3\). Percent FGV ranged from 32\% to 92\% with a mean of 71 ± 14.8\%. Body mass index (BMI) showed a significant relation with \%FGV \((r_p = -0.68, P = 0.003)\) and total volume \((r_p = 0.56, P = 0.02)\) but not with FGV \((P = 0.95)\).

As shown in Fig. 2, the total breast volume and FGV increased significantly by Tanner stage \((P = 0.003)\) whereas \%FGV showed an inverse trend but was not statistically significant \((P = 0.90)\). The respective FGV means by Tanner stage were 104, 124, 161, 210, and 214 cm\(^3\).

The precision is shown both as RMS CV and RMS SD for \%FGV and FGV in Table 1. The RMS SD was 2.4\% for \%FGV and 16.6 cm\(^3\) for FGV. These values are comparable to the phantom precision values that ranged from 1.5\% (10 cm in thickness and 100\% composition) to 2.4\% (2 cm in thickness and 28\% composition). There were no observed changes in the systems calibration over time observed from the density step quality control phantom.

**Discussion**

Our pilot study to test the feasibility of using a standard bone densitometer to capture images of adolescent girls (Fig. 1) found that it was possible to image all Tanner stages and that breast volume and FGV density were related to Tanner stages. The total and dense volumes of the breast increased by Tanner stage, whereas we found no relation between \%FGV and Tanner stage. However, we only had one girl with Tanner 1 and Tanner 5. Thus, our ability to make definitive statements about density and pubertal development was limited.

*Pearson’s correlation coefficient.
† P < 0.05.
‡ Note that taking the percent of a percent value is not standard practice.

The repeatability was high for %FGV (2.5%) but only moderate for FGV (12%). In our previous work with women, we found the repeatability of %FGV from similar DXA scans to be 1.2% (14). We believe that some of this difference in precision between girls and women to be breast size, but we plan to further develop and standardize subject positioning and automated outlining of the breast area to improve the precision on girls. A sign of overall accuracy was that the percentage of fat using the GE Lunar DXA analysis was highly correlated with the breast phantom percentage fibroglandular density reported by the phantom’s manufacturer (r > 0.998).

BMI was inversely correlated to %FGV. Other studies have also found breast density measured from mammograms inversely corrected to BMI for postmenopausal women (19). However, the correlation of BMI and breast density has not precluded breast density as an independent risk factor. Barlow showed in a multivariate model that BMI and breast density were both strongly associated with breast cancer in postmenopausal women (20). After controlling for breast density, breast cancer risk was 47% higher for women with a BMI of ≥35 when compared with women with a BMI of <25. At the same time, the risk association to breast density was 3-fold higher for women in the highest breast density category compared with the lowest.

These results are comparable to the DXA study among 17 women (14) that also reported a high correlation for left and right measures. We found the left breasts to be, on average, higher in total volume and FGV than the right breasts. This is consistent with the findings in women that left breasts are larger in general (21). Hussain et al. (22) found that the average difference was 39.7 cm³ in 22 women using a magnetic resonance imaging technique. Interestingly, we observed a difference of 38 cm³ although our sample was very small. A lower percentage density with larger breasts is consistent with the findings in women; on average, larger breasts have more fatty tissue and lower percent density (23). The increase in FGV with Tanner stage is also consistent with developing breasts, although our study was limited by few girls in the Tanner 1 and Tanner 5 categories.

We also showed in this study that our DXA breast scanning technique is generalizable across DXA hardware. This study was done on a GE Prodigy whereas our previous work was on a Hologic Delphi/A. However, the analysis algorithms and calibration standards were the same. Thus, we would expect indistinguishable results if the present study were to be reproduced on a Hologic system.

Although these preliminary findings look promising, data on a larger sample of girls and a more thorough understanding of breast density are necessary before DXA scanning can be applied in longitudinal or intervention studies. A method to monitor breast composition in young women and girls is currently not available because of the risk of X-ray based mammograms outweighs potential benefits in that age group (24). Novel techniques to obtain images of the developing breast are also of interest because there is an interest to develop low-radiation methods for adult women to monitor breast density for individualized risk prediction (25). Magnetic resonance imaging has been suggested as useful for breast density measurements in young women (26, 27) and is currently being used in studies involving young women. However, DXA has many advantages over magnetic resonance imaging or mammography: It is widely available, inexpensive compared with magnetic resonance imaging, already a commonly used and accepted measure for whole-body and regional soft tissue composition, does not entail breast compression, gives results that are objectively interpreted, and uses an X-ray dose 10 times lower than mammography (11).
