**Title:** Undersea Node Localization Using Node-to-Node Acoustic Ranges in Distributed Seaweb Network

**Author:** David C. Zinkhon

**Abstract:**
Seaweb is a wide-area network interconnecting a set of distributed underwater nodes through the use of a DSP-based acoustic communications modem at each node and through-water digital acoustic links between neighboring nodes. As a by-product of Seaweb communications, the distances between neighboring nodes are obtained from the round-trip acoustic travel-time measurements. If the network is deployed in an ad hoc distribution, or if an established network is disturbed, the locations of the nodes are unknown to the operator. This thesis uses the node-to-node ranges, which have been compiled at the designated master node, as input to an algorithm for estimating the relative locations of all nodes. Synthetic network geometries serve to evaluate the algorithm with perfect ranges and with imperfect ranges and/or incomplete data. Seaweb networks deployed at sea are the final test of the algorithm.

ABSTRACT

Seaweb is a wide-area network interconnecting a set of distributed underwater nodes through the use of a DSP-based acoustic communications modem at each node and through-water digital acoustic links between neighboring nodes. As a by-product of Seaweb communications, the distances between neighboring nodes are obtained from the round-trip acoustic travel-time measurements. If the network is deployed in an ad hoc distribution, or if an established network is disturbed, the locations of the nodes are unknown to the operator. This thesis uses the node-to-node ranges, which have been compiled at the designated master node, as input to an algorithm for estimating the relative locations of all nodes. Synthetic network geometries serve to evaluate the algorithm with perfect ranges and with imperfect ranges and/or incomplete data. Seaweb networks deployed at sea are the final test of the algorithm.

ACKNOWLEDGMENTS

First I would like to thank my wife, Amy, for the past eleven years of continued love, support, and inspiration, as well as my two beautiful daughters, Grace and Elizabeth.

To my thesis advisor, Professor Joe Rice, for mentoring through the thesis process and allowing me to work with the technologies and opportunities Seaweb presents.

To Chris Fletcher of SPAWAR Systems Center Pacific, for his expeditious retrieval of vital data.

To the numerous professors and staff that made my time at the Naval Postgraduate School the enriching experience it was.

And finally to my fellow students, Chris, Paul, Nevin, Greg, Dave, Chee Wei, Bill, and Jason that helped me through the challenging classes and listened to my ideas.
I. INTRODUCTION

A. PROBLEM STATEMENT

Seaweb is an acoustic communications technology enabling underwater sensor networks. Data packets usually flow from a sensor node to the master node, with command and control packets flowing in the reciprocal path. More generally, a network packet begins at the source node, travels through repeater nodes, and ends at the destination node. The network routes are dictated by routing tables stored in the acoustic modems. Prior to Ong’s development of the Seaweb ad hoc discovery process [1], the routing tables were initialized and maintained by the operator. By using the algorithms developed in [1], Seaweb networks are now capable of self-determining the routing tables, thereby allowing the network to be deployed with an ad hoc distribution. However, with ad hoc deployments, the operator may not know the locations of the nodes within the network. When the routing algorithm from [1] is implemented, the node-to-node ranges are measured through the use of acoustic propagation time delays and assumptions about the speed of sound in water.

This thesis uses the formulas developed in [4] to estimate the relative positions of the nodes using planar trigonometry.

B. SCOPE

1. Objective of Algorithm

The algorithm produced in this thesis uses the range data measured during the Seaweb discovery process to estimate the horizontal positions of the discovered nodes.
This is accomplished by first setting up a horizontal coordinate system that can be used as a frame of reference. The origin is fixed at the location of the master node because it is usually able to self locate by means of GPS. The positive $x$-axis is oriented to intersect with a neighbor node of the master. This node is referred to as the ‘on_X’ node and is preferably located along a known line of bearing from the ‘master’ node to allow the end user to translate the $x$-$y$ coordinate system to a traditional latitude-longitude grid.

Next, range data gathered each time a node conducts a broadcast ping are organized into a time-stamped $N \times N$ matrix. These matrices are compiled into a stack that is sequenced by the time-stamp. The algorithm then looks down each column of the stack and statistically analyzes all the ranges available between a particular pair of nodes, eliminating any ranges that fall outside a ten percent confidence interval from the mean. Next the algorithm uses the filtered mean ranges and localizes the node positions using the formulas outlined in [4]. Due to ambiguous solutions when insufficient ranges are known for a particular node, several solution sets may be possible. The output of the algorithm is the $x$-$y$ position of each node and a visual representation of each ambiguous solution.

2. Limitations Not Addressed

While the algorithm estimates the relative horizontal locations of the network nodes, it does not attempt to then rectify these locations to the traditional latitude-longitude coordinate system. The algorithm also does not attempt to correct for range errors inherent to the method used to derive them; it simply eliminates statistical outliers from the range data in an attempt to find the best solution given all the data.

C. OUTLINE OF THESIS

Chapter II is an overview of Seaweb equipment and operations, including the acoustical method used to measure inter-node ranges. Chapter III then addresses some of the errors inherent with this ranging method. Chapter IV discusses the localization methods used by the algorithm, and Chapter V details their implementation. Chapter VI describes results obtained with various synthetic data, including error-free as well as
incomplete and/or inaccurate data. Chapter VII analyzes the range data from Seaweb sea trial testing. Chapter VIII summarizes the conclusions reached in the thesis, and Chapter IX discusses recommendations and possible further research.
II. BACKGROUND

A. SEAWEB OPERATIONS

Seaweb is a networking technology supporting underwater communication between any number of fixed sensor nodes, repeater nodes, and gateway nodes. It is also configurable to communicate with mobile nodes including submarines and UUVs [5, 6]. Communications through the water with only a single gateway node at the sea surface improves both the stealth and survivability of the network. A representative deployment of Seaweb is shown in Figure 1, where the network includes a submerged UUV, a radio-acoustic communication (racom) buoy acting as the gateway node, and repeater nodes. The UUV uses the network infrastructure while submerged, and the UUV itself can act as a gateway node while on the surface.

![Figure 1. Typical Seaweb configuration consisting of both fixed nodes mounted on the seabed along with UUVs acting as mobile nodes (from [2]).](image_url)
1. **Equipment**

The physical composition of Seaweb consists of three components: the Seaweb server, underwater sensor/repeater nodes, and a gateway buoy that allows interactions between the server and underwater nodes. The Seaweb server is physically located either onboard a control ship or ashore, the only requirement being that radio communications with the gateway buoy are available. If direct radio communications are not possible with the gateway buoy, demonstrated alternatives are an Iridium satellite link or cellular telephone modem. The Seaweb server is used by the operator to command, control and monitor the deployed network [7].

The racom gateway buoy is moored at a convenient location within the Seaweb domain, either near the center to maximize the number of underwater nodes that it is in direct contact with, or at the edge to ensure a line-of-sight radio link to the Seaweb server. The buoy is maintained in place by an anchor and swivel system moored on the ocean floor. The surfaced portion of the buoy consists of solar panels, radio communication equipment, satellite communication equipment, and a GPS receiver. Seaweb acoustic communications occur in the 9-14 kHz frequency band through a submerged acoustic transducer married to the mooring line. Figure 2 depicts the racom gateway buoy configuration used at the St. Margaret’s Bay sea trials.

![Figure 2. Racom gateway buoy (from [1]).](image)
Underwater fixed nodes are generally sensor nodes or repeater nodes. The repeater nodes are moored to the seabed and usually consist of anchor, acoustic release module, telesonar modem, and subsurface float. The telesonar modem is commercially available from Teledyne Benthos, Inc. and is programmed with specialized Seaweb networking software and firmware [8]. The acoustic release serves for recovery of the repeater node. Figure 3 shows a typical deployed configuration of a repeater node.

![Seaweb repeater node using a telesonar modem](from [5]).

2. **Network Layout**

Seaweb networks can consist of any number of underwater nodes and gateway buoys, and the network routes are reconfigurable if a node failure occurs. Most Seaweb layouts consist of a single gateway node that is positioned in locations to maximize its survivability, i.e., out of ship traffic lanes and away from other near shore hazards. Often the gateway buoy is identified as the ‘master’ node, since it is in direct radio contact with the server. The term ‘master’ node is also used in the localization process, and since the gateway buoy position at the sea surface is known from GPS, it provides a geographic reference point. Care must be taken when deploying the first underwater node since this is the second reference point used by the localization algorithm, known as the ‘on_X’
node in the localization algorithm. The ‘on_X’ node should be deployed along a known line of bearing from the ‘master’ node thereby allowing the operator to fix the location of these two nodes on a nautical chart.

![Figure 4](image)

Figure 4. Location of Seaweb nodes in June 2008 at St. Margaret’s Bay sea trial. Node 3 (in red) was the gateway buoy and master node (from [1]).

The rest of the network nodes are positioned in the area of interest. Typically, the layout is designed such that multiple communication routes are available for data transfer to each node. This increases the overall reliability of the network by producing
redundant routes. The distance between the nodes can be expected to be one to five kilometers depending on the maximum acoustic communications range for the deployment environment. Significant environmental factors include the sound-speed profile, the background noise level, and transmission loss [9]. Figure 4 shows the network layout used in the St. Margaret’s Bay sea trial in June 2008.

3. Link-Layer Protocols

Seaweb node-to-node communications use a link-layer protocol that allows for addressing, power control, adaptive modulation, and ranging [10]. The protocol uses a request to send (RTS) and clear to send (CTS) to establish first contact between two nodes prior to transferring data between the nodes. Any corrupted data are requested to be resent by the receiving node using a selective automatic repeat request (SRQ). This concept is diagrammed in Figure 5. Following the same handshake strategy, Seaweb also supports a PING/ECHO protocol useful during the ad hoc discovery process.

![Figure 5. Seaweb node-to-node communication scheme (from [10]).](Image)

To determine the range between neighboring nodes, a hyperbolic frequency-modulated (HFM) chirp precedes the PING packet sent by the first node (node $i$ in Figure 6, below). Node $j$ receives the ping and determines the time of arrival by picking the peak of a HFM matched filter. Node $j$ then waits a specified dwell time, $\tau$, prior to
issuing a return echo (with HFM) that follows the same path as the initial ping based on reciprocity. Therefore, the reciprocal sound propagation delays between nodes \( i \) and \( j \) are equal,

\[
d_{ij} = d_{ji}.
\]  

(2.1)

Once the echo is received at node \( i \), the Seaweb modem measures the range between the two nodes based on the total delay time,

\[
t_j - t_o = d_{ij} + d_{ji} + \tau_j,
\]  

(2.2)

and substituting Equation (2.1) and solving for \( d_{ij} \) gives

\[
d_{ij} = \frac{t_j - t_o - \tau_j}{2}.
\]  

(2.3)

Seaweb uses the assumption that the speed of sound in the ocean is \( c_o = 1500 \text{ m/s} \) for determining the node-to-node range,

\[
r = c_o \times d.
\]  

(2.4)

Figure 6. Seaweb ranging process (from [2]).
B. AD HOC DISCOVERY PROCESS

1. Broadcast Ping

Prior to the introduction of the ad hoc discovery process developed in [1], the routing tables were manually determined and maintained by the operator located at the Seaweb server. After a Seaweb network was deployed in the water, the first operation performed was node-to-node ranging to verify that the pre-programmed routing tables were functional. The Seaweb server initiated this process by directing the ‘master’ node to transmit a broadcast ping. When the various repeater nodes detect the broadcast ping, they reply with an echo that confirms that they are within acoustical communications range, the ranges are calculated, and then communicated back to the server. This process is depicted in Figure 7. The operator then sequentially directed each node to repeat the broadcast ping process until all nodes were discovered and all ranges reported to the server. All of this served only to confirm the validity of pre-programmed routes.

![Figure 7. The broadcast ping process (after [11]).](image)

2. Discovery

The discovery process developed in [1] automates the initialization of network routes. A summary of this process is shown in Figures 8, 9, and 10. First the master node conducts a broadcast ping, and then the master node systematically commands each discovered node to conduct its own broadcast ping to potentially discover more nodes. The master node continues to direct all new nodes to conduct their own broadcast ping.
Upon completion, the master node algorithm determines the optimum route to each node according to a cost function that considers the number of nodes that are in the path and the ranges between each node. A by-product of this process are data tables containing the ranges that each broadcast ping measured. The algorithm developed in this thesis uses these range data tables to locate the network nodes.

Figure 8. Left: Ad hoc locations of nodes. Right: Initial broadcast ping by master node, A, which discovers nodes B, C, and D (after [1]).

Figure 9. Left: Secondary broadcast pings by node B that discovers M, J, K, and determines range from B to C. Right: Secondary broadcast ping by C that discovers node P and determines ranges from C to B and C to K (after [1]).
Figure 10. Left: tertiary ping by P that discovers node Q. Right: Depiction of routes to all nodes (after [1]).
III. SOURCES OF ERROR

A. ACOUSTIC VARIABILITY

1. Sound Speed Profile

Two significant assumptions are made in the Seaweb estimation of node-to-node ranges, the first of which is that the sound speed, $c_o$, used in Equation (2.4) is 1500 meters per second. Sound speed in the ocean varies from 1480 m/s to 1520 m/s [12], which represents a $\pm 1.3\%$ deviation from the value assumed by Seaweb. For example, if the true sound speed is 1480 m/s and the range between two nodes is 3000 meters, the reported range would be 3040 meters. Assuming that the true sound speed is constant over the entire area of the network, this results in range solutions which are typically larger than the true ranges between the nodes.

The second assumption made by the Seaweb range estimation is that sound travels in straight lines and hence is linearly related to range. However, the variations in temperature, pressure, and salinity in the water column cause significant variability in the speed of sound. This results in refraction as sound passes through the various layers of the water column. To illustrate this, a representative sound speed profile is produced using Munk’s canonical profile [13]

$$c(z) = c_o \left[ 1 + \varepsilon \left( e^{-\eta} + \eta - 1 \right) \right]$$

(3.1)

where

$$\eta = \frac{2(z - z_{axis})}{B}$$

(3.2)

and $c_o$ is the sound speed at the sound channel axis, $\varepsilon$ is the perturbation coefficient, $z_{axis}$ is the depth of the sound channel axis, $B$ is the scale depth, and $\eta$ is the dimensionless distance beneath the sound channel axis. For this example the values of the constants are chosen as $z_{axis} = 1000$ m, $B = 1000$ m, $\varepsilon = 0.0057$, $c_o = 1500$ m/s, and the maximum depth is 4500 m. The resultant sound speed profile is depicted in Figure 11.
If the source and receiver nodes are located at the axis of the sound speed profile, a straight non-refracted path between them exists. When either source or receiver is not located at the sound channel axis, there is no straight line path between them. This is graphically illustrated in Figure 12 using fifteen rays (note: if a ray strikes either the surface or the bottom, it is removed from the analysis). Since the actual ray paths can be longer than the straight line path assumed by the Seaweb ranging estimation, the measured ranges tend to be overestimates of the actual ranges. Using the constraints of this example, for a 5000 meter distance between nodes, the travel time difference could be as great as 0.1 second which equates to a range overestimate of 150 meters, which is an error of 3%.

Figure 11. Representative sound speed profile based on Munk’s canonical profile.
2. Reflected Paths

The previous discussion does not account for rays that interact with either the surface or the bottom, both of which occur in the real world. Interactions with a boundary results in absorption and scattering that reduce the intensity of the sound energy. For the surface, the amount of reduction depends on the roughness of the sea surface and the spectral frequency of the transmitted signal. For a relatively smooth surface with wave heights of approximately 0.3 meters, and a transmitted signal of 25 kHz, each reflection is estimated to cause a 3 dB loss [14]. At the operational frequencies of Seaweb (9-14 kHz) the estimated losses are less since the transmitted wavelengths are...
larger relative to the wavelength of the sea surface [14]. Bottom reflection losses are more difficult to predict because of the large variations in bottom type and characteristics. Additionally, the grazing angle at which the sound strikes the bottom affects the amount of loss in each interaction. However it can be expected that the losses to the bottom are on the order of 8 dB per interaction [14].

Seaweb takes advantage of these losses when determining the node-to-node ranges by using a peak-detector filter which allows the ranging algorithms to select the highest intensity multipath arrival. Since the reflected rays will generally have reduced intensity due to interactions with the boundaries, they are ignored by the filter in favor of the direct path rays.

B. GEOMETRIC ERRORS

Some of the errors that can degrade the node-to-node range data are not a result of acoustics. Rather, these errors arise from the physical geometry of the network nodes.

1. Depth Variance

The sea floor can exaggerate the measured range. Figure 13 depicts a situation where two nodes are located at different depths by virtue of the bathymetry contours. The green arrow is the horizontal range between the two nodes, and the depth difference is $\Delta z$. By the Pythagorean Theorem the measured slant range is

$$r_{\text{measured}} = \sqrt{r_{\text{actual}}^2 + (\Delta z)^2}. \quad (3.3)$$

This results in measured ranges that are greater than horizontal ranges between the nodes.
Figure 13. Range error caused by nodal depth differences.

This difference between slant range and horizontal range is neglected by the algorithm, which analyzes for a 2-D solution where all nodes are assumed to be in the same horizontal plane. This is done not only to simplify the algorithms used, but because the differences in the ranges are typically negligible, being less than 0.1% error in most cases. A 10% slope is required to produce even a 0.5% error in the measured range. Table 1 evaluates the range errors for a few geometries.

Table 1. Summary of measured range errors based on depth differences.
2. Watch Circles

The ocean is a dynamic environment where currents and tides displace the transducers even when the moorings are stationary. These rotations are commonly called watch circles and are well known to a mariner who has spent time at anchor. Based on the schematic layout of a telesonar repeater node depicted in Figure 3, the transducer is approximately 3 meters off the bottom. This results in very little variation in the maximum range difference between two nodes. If both nodes leaned 30 degrees in opposite directions, the difference in range is only 3 meters. The racom gateway buoy ranges are much more influenced by watch circles because of the longer moorings. Based on the diagram in Figure 2, the transducer could experience a watch circle of up to 78 meters from the anchor point for a 30-degree offset from vertical.

3. Geometric Dilution of Precision

The last error considered arises from the relative bearings of the nodes in the 2-D plane and the resulting angles between the nodes. Consider the case illustrated in Figure 14 where the range error ($\Delta r$) is considered to be the same for each pair of nodes. When the two reference nodes are located near each other (Figure 14 a), the triangularized position of the unknown node has a large uncertainty region referred to as geometric dilution of precision (GDOP). As the reference nodes are moved further apart (Figure 14 b) and the angle $\theta_{tr}$ between them increases, the GDOP is reduced until it reaches a minimum when $\theta_{tr}$ is 90 degrees. Since the error is a function of the geometric bearings of the nodes, careful planning of the node locations can minimize GDOP.
Figure 14. Geometric Dilution of Precision (from [15]).

C. EXPECTED ACCURACY

While all of the range errors are present in every scenario, the magnitude of their contributions depends on the location, layout, and environmental conditions. Nevertheless, some generalizations can be made about the localization error budget. The largest sources of error are the ray path assumption - which results in an overestimate of the range - and the watch circle of the racom buoy - which can cause an overestimate or underestimate of the range. The assumption that sound speed is $c_o = 1500$ m/s can result in significant range errors in either direction, and the effects of varying depth are typically small but tend to overestimate the range. Qualitatively, the sum of all of these errors results in an overestimation of range.

To get a feeling for the range error budget, consider a set of nodes that are actually 4,000 meters apart with a 2% slope between the nodes. Additionally assume a sound-speed profile that results in an average sound velocity of 1480 m/s. Since the racom buoy produces the largest watch circle errors, choose this as one of the two nodes. Summing all the range errors, the measured range would be reported as 4278.5 meters which is a 7% error. A breakdown of the contribution of each error type is contained in Table 2.
Table 2. Range Error Budget for two nodes 4000 meters apart with a 2% slope.

IV. LOCALIZATION METHODS

The localization of nodes in a Seaweb network is based on the range-fixing concept of using intersecting circles centered on known locations. For the purpose of this thesis, an ‘unknown’ node is one that has not yet been localized and a ‘known’ node is one that has been localized on the $x$-$y$ plane either by a priori information, or by a range-fixing algorithm. Localization by intersecting circles works well when no node positional errors or range errors are present, but difficulties can arise when errors are introduced. Previous work by [2] and [3] attempted to mitigate these errors by using weighted averages and center of mass method, respectively. Both were tested in [4] and compared with the difference linearization method outlined by [16]. The difference linear method was found to be superior in estimating the position of unknown nodes.

Depending on the number of range measurements between an unknown node and neighboring known nodes, three possibilities exist for the type of solution that can be found for the position of the unknown node. These are one range, which results in no solutions, two ranges, which result in ambiguous solutions, and three or more ranges which result in an exact solution. These cases are discussed in the following sections. Ranges from one unknown to other unknown nodes result in no additional useful information when attempting to localize the unknown node.

A. NO SOLUTIONS

If the unknown node has only one range to a known node, there are infinitely many possible locations for the unknown node. The solution set is a circle centered at the location of the known node with a radius equal to the range from the known node to the unknown node. For this reason, unknown nodes with only a single range are not evaluated and are passed over until the algorithm has localized a second node for which the unknown node has a range, resulting in the case described in the next section.
B. AMBIGUOUS SOLUTIONS

When the unknown node has ranges to two neighboring known nodes, there are two ambiguous solutions that exist where the two range circles intersect. One will be above a line that intersects the two known nodes, and the other is a reflection below the line. This is depicted in Figure 15.

![Figure 15. Two-node, two-range solution set (after [3]).](image)

Determination of the locations of the two ambiguous solutions is made using the law of cosines. Figure 16 demonstrates the locations of the two known nodes, $i$ and $j$, and the two red triangles symbolize the unknown node’s ambiguous solutions. The node-to-node ranges from the known nodes to the ambiguous solutions are represented by $r_i$ and $r_j$, and $r_{ij}$ is the range along the axis of reflection between the two known nodes. The angle from the axis of reflection to the bearing of the unknown node is determined using the law of cosines

$$
\theta = \cos^{-1} \left( \frac{r_i^2 + r_j^2 - r_{ij}^2}{2r_ir_j} \right). \quad (4.1)
$$

The bearing to the ambiguous solution is simply the negative of that angle. Once $\theta$ is determined, the $x$ and $y$ coordinates of the unknown node are given by
\begin{align*}
x &= r_i \cos \theta \\
y &= r_i \sin \theta 
\end{align*} \tag{4.2}

From Figure 15 it is noted that the \( x \) coordinates are the same for both ambiguous solutions and the \( y \) coordinates are reflections about the \( x \)-axis.

![Diagram](image)

Figure 16. Law of cosines used to determine the angle \( \theta \) to the unknown node location from node \( i \), a known node (from [2]).

**C. DIFFERENCE LINEARIZATION METHOD**

When an unknown node has ranges to three known nodes, a single unambiguous solution to the location of the unknown node exists where the three range circles intersect, as seen in Figure 17. This trilateration is the basis for radar navigation and the Global Positioning System.
The difference linearization method is based on the fact that in an $n$-dimensional coordinate system, the location of an object can be found if ranges are known to $n+1$ fixed locations. In a 2-D system, the distance $r_i$ between the $i$th point at a known position and the object located at $(x, y)$ is given by the Pythagorean theorem: $r_i^2 = (x - x_i)^2 + (y - y_i)^2$. Since this is a 2-D system, the distances to three known locations may be written as a system of equations of the form

$$
\begin{bmatrix}
  r_1^2 \\
  r_2^2 \\
  r_3^2
\end{bmatrix} = \begin{bmatrix}
  (x - x_1)^2 + (y - y_1)^2 \\
  (x - x_2)^2 + (y - y_2)^2 \\
  (x - x_3)^2 + (y - y_3)^2
\end{bmatrix}.
$$

(4.3)

The difference linearization method described in [16] is applied to this system of equations. This method first eliminates the square terms and reforms the equality so that it is the sum of a pair of simultaneous equations in $x$ and $y$,

$$
\begin{bmatrix}
  (r_1^2 - r_2^2) \\
  (r_2^2 - r_3^2)
\end{bmatrix} = 2 \begin{bmatrix}
  (x_2 - x_1)(y_2 - y_1) \\
  (x_3 - x_2)(y_3 - y_2)
\end{bmatrix} \begin{bmatrix}
  x \\
  y
\end{bmatrix} + \begin{bmatrix}
  (x_1^2 - x_2^2) + (y_1^2 - y_2^2) \\
  (x_2^2 - x_3^2) + (y_2^2 - y_3^2)
\end{bmatrix}.
$$

(4.4)

Solving for the location of the object $(x, y)$ results in

$$
\begin{bmatrix}
  x \\
  y
\end{bmatrix} = \frac{1}{2} \begin{bmatrix}
  (x_2 - x_1)(y_2 - y_1) \\
  (x_3 - x_2)(y_3 - y_2)
\end{bmatrix}^{-1} \begin{bmatrix}
  (r_1^2 - r_2^2) + (x_1^2 - x_2^2) + (y_1^2 - y_2^2) \\
  (r_2^2 - r_3^2) + (x_2^2 - x_3^2) + (y_2^2 - y_3^2)
\end{bmatrix}.
$$

(4.5)
It is possible for an unknown node to have ranges to more than three known nodes causing Equation (4.3) to be over-determined. Two possibilities then exist for estimating the location of the node. Either the over-determined system of equations can be solved simultaneously using a least-squares procedure, or the ranges can be selected in combinations of three and the position estimated as a weighted average. When the range data contains errors, the latter method was found to be superior by [4] due to its ability to successfully mitigate range errors. For this reason using combinations of ranges and averaging the solutions is implemented in this thesis.
V. ALGORITHM IMPLEMENTATION

The algorithm developed in this thesis is implemented in the MATLAB programming language and consists of four basic stages: operator input, data input, removal of outliers from the data, and determining the locations of the nodes. Each stage is written as a separate function that is called by a master program. The MATLAB code is listed in Appendix A.

A. OPERATOR INPUT

The first stage requires the operator to provide the parameters associated with the Seaweb network to be analyzed. The operator identifies the address of each node in the network, and specifies the ‘master’ node and the ‘on_X’ node. The ‘master’ node is usually the gateway buoy that supports interface between the underwater network and the operator. A useful attribute of the gateway buoy is its on-board GPS receiver. The ‘on_X’ node is the only other node in the network that must be specially designated. It must be close enough to the ‘master’ node to ensure that a range measurement is available and the operator must be able to specify what the true bearing is from the ‘master’ node to the ‘on_X’ node. This permits the operator to orient the solution produced by the algorithm to a geo-referenced coordinate system, such as latitude-longitude.

The next thing the operator specifies are the names of the text files that contain the node-to-node range data. The format of the text data files is shown in Table 3, below.
Table 3. Example of the node-to-node range data format used by the algorithm. The red column is the node address that initiated the communication, the blue column is the node address that responded, and the black column is the calculated range between the two nodes in meters. Zeros indicate that the initiating node did not receive a response.

### B. STACK BUILD

The Stack_Build.m function takes the input data and sorts it into a single 3-D matrix, referred to as a range stack, in a form suited for analysis. The range stack consists of the same number of layers as the number of files loaded by the operator. Each layer is a square matrix where the node addresses comprise the first row and first column of the matrix and serve as headers for indexing the range data. For convenience, the ‘master’ node is assigned to the second row/column and the ‘on_X’ node is assigned to the third row/column.

Each node-to-node range data file is loaded and its contents are organized as a layer in the stack with each range datum stored in the row of the node that initiated the communication and in the column of the corresponding node. Once a layer is completed, it is placed on the stack and the next data file is loaded. A graphical representation of the range stack appears in Figure 18, below.
C. STACK SIFT

The range stack is passed to the function Stack_Sift.m, where it is distilled to determine the mean range between each pair of nodes. Each node pair is statistically evaluated and the resulting mean ranges are stored in a single 2-D array.

The first step is for all the ranges for a particular node pair to be loaded into a single vector. This is done by “looking down the stack” for the particular node pair for all the range measurements made during the discovery process (e.g., node 3 to node 7). Simultaneously the reciprocal combination is found by looking “up the stack” (e.g., node 7 to 3). This process is depicted in Figure 19.
The vector is statistically analyzed in an iterative manner to derive a good range between the selected nodes by progressively eliminating outlier ranges that fall outside a ten percent confidence interval for the data. Initially the mean and ten-percent confidence interval of the data ranges are calculated and data that fall outside the confidence interval are flagged. The flagged datum falling furthest from the mean is eliminated. The mean and confidence interval are then recalculated and the process is repeated until no data fall outside the confidence interval. The final calculated range estimate for the node pair is then stored in the appropriate element of the 2-D array. Once all node pairs have been analyzed, the resulting output is a 2-D square array that is symmetric about the main diagonal, with node pairs that lack a range estimate denoted by ‘NaN’ (“Not a Number”).

---

**Figure 19.** Example of building the vector of range data for a node pair.
Now that the range data are filtered, averaged, and organized, the Solver.m function estimates the locations of the nodes. The first step is to establish a frame of reference based on the known locations of ‘master’ and ‘on_X’ nodes. The master node location is set to be at the origin (0,0) of a horizontal Cartesian grid. The positive x-axis is forced to intersect the location of the ‘on_X’ node, such that the coordinate of this node is $(r_{master}, 0)$. Once a node is localized within the grid, it is considered to be a known node. With these known nodes in place, the algorithm evaluates each remaining node to determine how many ranges it has to known nodes in the grid. Three distinct possibilities exist: one range, two ranges, or three or more ranges. If only one range exists to a known node no attempt is made to localize that node since the solution set is a circle centered at the known node’s location with a radius equal to the range.

If a node has ranges to only two other known nodes, there are two ambiguous solutions to the location of that node. Since no solutions can be eliminated without knowing some geographical constraints, all possible solutions are tracked. This means that there are potentially $2^{(# of nodes - 2)}$ different possible solutions that must be stored. To account for all these possibilities, a binary system is employed that tracks each time a node has ranges to only two nodes. For example, in a five-node network there are eight
possible solutions. The first two nodes, the ‘master’ and ‘on_X’ nodes are in fixed locations, and the third node has ambiguous solutions that are labeled 00000 and 00100 respectively. If the fourth node also has only two ranges to nodes with known locations, there are four possible solutions: 00000, 00100, 00010, and 00110. (These solutions are alternately identified by their base-ten values 0, 4, 2, and 3). When a previously unknown node becomes known, the program also sets a flag to cause it to cycle through all the nodes again since a node that had previously been bypassed may now have sufficient ranges to known nodes to make its localization possible.

When a node has ranges to three known nodes, the program then finds a single solution using Equation (4.5). If this is the first time a solution has been determined for this node, the program sets the flag to cause the program to loop through all nodes again and also has that node evaluated in all possible ambiguous solution sets. If it not the node’s first solution, the location determined by this particular iteration of the algorithm is checked against the previous solution. If either the x-coordinate or the y-coordinate are greater than some range difference threshold from the previous solution, the new solution is considered improved and the program sets the flag to have every node in every ambiguous solution set evaluated again.

This process continues until the all nodes have been located within the specified tolerances of the previous solutions. The output of the program is a list of all the ambiguous solutions, i.e., 00000, 00100, 00110, etc., as well the locations of each node for each ambiguous solution set.

E. EXAMPLE OF A FIVE-NODE LAYOUT

This section provides an example of the algorithm process for a simple five-node layout for illustration purposes. The nodes are generated randomly on a 5000-meter by 5000-meter grid, the ‘master’ node is node 4, and the ‘on_X’ node is node 2. The true node locations and the actual node-to-node ranges are given in Table 5. These true node locations are plotted in Figure 20. Figure 21 is a plot of the same five nodes with the frame of reference translated such that the origin is at the ‘master’ node and the positive x-axis intersects the ‘on_X’ node.

Table 6. Node-to-node range matrix after 4000-meter maximum range cutoff is applied.

Solver.m produces the following ambiguous solutions: 0, 1, 2, and 3, all of which are depicted in Figure 22. Comparing these solutions to Figure 21, it is apparent that...
ambiguous solutions 0 and 1 are on the wrong half-plane based on nodes 1 and 5 being below the x-axis in Figure 21 and nodes 1 and 5 being above the x-axis in solutions 0 and 1. Solution 2 is eliminated due to nodes 1 and 5 being in nearly a straight vertical line in Figure 21, while solution 2 has these nodes canted. Thus, solution 3 is the most accurate solution. Also of note is that node 3 is not featured in any solution set because it has only a single range to other nodes after the 4000-meter range cutoff is applied.

Figure 22. Plotted results of all ambiguous solutions of example nodes.
VI. SYNTHETIC DATA ANALYSIS

Synthetic data for testing the algorithm are created in MATLAB using the built-in random number generator functions. For the node locations, the function `unidrnd` gives a uniformly distributed random number for both the $x$ position and the $y$ position. Error-free ranges are calculated for the node pairs. Simulated range error is introduced by multiplying the error-free range by a normal distribution, and then adding five percent of the actual range multiplied by a chi-squared distribution,

$$r_{\text{reported}} = \text{Normdist}(\mu, \sigma) \times r_{\text{actual}} + 0.05 \times r_{\text{actual}} \times \chi^2(\nu).$$ (6.1)

The normal distribution introduces some variability to the reported ranges to account for sound speed assumption errors which tend to be small and proportional to the range between the nodes. The mean, $\mu$, is set to one, and the standard deviation, $\sigma$, is 0.1 to ensure that most reported ranges will be near the actual range. The chi-squared distribution is chosen as the model for the additive factor to account for refracted ray path errors and depth variance errors which tend to be larger, but also proportional to the range between the nodes. The parameter $\nu$ is set to one for this evaluation, resulting in an expected value of one, with a standard deviation of two. When this is multiplied by 5% of the error-free range, it results in an approximate 5% overestimation of the range. This method typically yields a reported range greater than the actual range. This reflects the fact that most range errors result in an overestimation of the range as established in the error analysis performed in Chapter III. Watch circle errors are not addressed since they normally only affect the racom node and will typically average out over the course of a network’s operations.

For analysis of the algorithm performance, fifteen nodes are randomly placed in an eight-kilometer by six-kilometer region, since this is the approximate area of the St. Margaret’s Bay sea trial. For each simulation, the node-to-node range calculations are performed fifty times with different realizations of the range errors. Each set of ranges is entered as a separate layer in the range stack. To match realistic acoustic communication range limitations, ranges exceeding 4000 meters are omitted. For consistency across all
simulations, node 1 is set as the ‘master’ node and node 2 is set as the ‘on_\text{X}’ node. The algorithm is allowed an arbitrary maximum of 50 iterations to achieve convergence of the node coordinates. For the simulation cases considered in this thesis, 50 iterations is sufficient for convergence of the node positions. Increasing the number of allowed iterations was found to not significantly increase the accuracy of the solutions.

A. OUTLIER RANGE REJECTION

Simulation testing confirms that the Stack\_Sift.m program rejects ranges that fall outside the confidence interval and estimates a good range between nodes. For the analysis in this section, the 4000-meter range cutoff is removed to maximize the number of ranges evaluated in each pass. The analysis is performed for 100 realizations of the fifteen-node network, resulting in 19,600 ranges being evaluated. The percent error between the actual ranges and the ranges with offsets is recorded, and then the ranges are analyzed by the Stack\_Sift.m function. The percent error between the output of the function and the actual ranges are then computed.

The mean percent range error for the ranges not run through Stack\_Sift.m is 4.7\%, and the largest percent error is 5.0\%. After the ranges are processed by Stack\_Sift.m, the mean error is reduced to 3.7\%, and the single largest error is 4.3\%. This filtering gains over a 1\% increase in the accuracy of the range data, which is substantial when localizing nodes. In absolute terms, the accuracy of a 4000-meter range estimate is improved by 40 m. The results are summarized in Table 7.

B. ERROR-FREE RANGES

Error-free testing is performed to verify the ability of the algorithm to correctly determine the positions of all nodes with perfect range data. Several statistics are
computed for each network realization. The number of iterations required by the algorithm to position all nodes within 25 meters accuracy is recorded because this is indicative of the processing time required. The program also tracks how many of the fifteen nodes have been localized to ascertain how many of the nodes are beyond the maximum cutoff range to more than one node. Thirdly, the algorithm counts the total number of ambiguous solutions caused by an unknown node having ranges to just two known nodes. This count is important because it indicates how many ambiguous solutions the operator must evaluate for redundant or impossible solutions, such as those that result in a node being located on land when translated to a navigation chart. Lastly, the true positions of all the nodes are translated and rotated to place the ‘master’ node at the origin and the ‘on_X’ node on the x-axis. The positions of each node in each ambiguous solution are then compared to these true positions, and the ambiguous solution that has the lowest total range error is recorded. This total error is divided by the number of nodes that were localized for that particular node set, to give the mean error per node for that set.

One-hundred realizations are simulated to yield an adequate sample size. In four of these 100 sets, the algorithm is unable to determine the location of a third node due to no nodes being within the maximum cutoff range (4000 meters) of both the ‘master’ node and ‘on_X’ node. These four realizations are excluded from analysis since they would skew the statistics of interest.

The first statistics analyzed are how many of the fifteen nodes are able to be localized and how many iterations of the program are required to converge all nodes to within 25 meters of its previous solution. The mean number of nodes localized is 14.8 of the possible 15. The mean number of iterations is 19.1, but this result is bi-modally skewed by the large number of times the program required less than five iterations and the number of times it required all 50 allowed iterations. More indicative statistics are the median number of iterations (6.5) and the mode (3). Figures 23 and 24 provide histograms of the results as well as the statistical values of interest.
The number of ambiguous solutions is also evaluated. The mean number of ambiguous solutions is 11.1, and the maximum is 64. For a fifteen-node network the minimum number of solutions is 2, with a theoretical maximum of 8192 solutions. The results are summarized in Figures 25.
The most telling statistic is how well the algorithm is able to localize the nodes when compared to the actual positions. This is done by finding the mean error for each node for a particular solution set. The mean nodal localization error is 5.8 meters with a maximum of 242 meters. The minimum, mode and median of the localization errors are all less than one. Figure 26 presents the data as a histogram. It is unclear at this point why range errors are incurred when the known ranges between nodes are exact. It is presumed that the maximum number of allowed iterations and acceptance criteria for the algorithm to not flag an ambiguous solution for another iteration play major roles.
C. ERROR-INDUCED RANGES

The same analyses that are performed on the error-free realizations are repeated for ranges that include errors introduced with Equation (6.1). The results of the algorithm show that in 35 of the node sets no solutions are achieved due to no nodes being within the maximum cutoff range of both the ‘master’ and ‘on_X’ nodes. The greater number of node sets that the algorithm was unable to localize is partly due to the fact that the range errors introduced resulted in a greater number of nodes that had ranges above the 4000-meter cutoff to the ‘master’ and ‘on_X’ nodes.

As expected, the performance is poorer than in the error-free cases. The mean number of nodes localized declines to 8.9 nodes per set. Also the number of iterations required increases to nearly the maximum in almost every simulation, rising to a mean of 47.5 passes. The data are presented in Figures 27 and 28.
Figure 27. Total number of nodes localized for 100 realizations of 15-node networks in an 8-km by 6-km area, with range errors.

Figure 28. Total number of iterations for 100 realizations of 15-node networks in an 8-km by 6-km area, with range errors.

The number of ambiguous solutions also increases over the error-free case. The mean number of ambiguous solutions increases to 226.2 with a maximum of 4096 ambiguous solutions. Figures 29 shows these results.
Figure 29. Total number of ambiguous solutions for 100 realizations of 15-node networks in an 8-km by 6-km area, with range errors.

Obviously, the mean best localization per node also increases. The mean value is 511 meters with a maximum of 3811.7 meters. However the median is 312 meters, meaning that the localization error tends to be less than a quarter of a nautical mile. Figure 30 summarizes the results.

Figure 30. Mean localization error for 100 realizations of 15-node networks in an 8-km by 6-km area, with range errors.
VII. ST. MARGARET’S BAY EXPERIMENT

In June of 2008, Naval Postgraduate School conducted a test of the firmware upgrade of the ad hoc discovery scheme developed in [1] at St. Margaret’s Bay, Halifax, Nova Scotia, Canada as part of the 2008 TTCP Unet sea trials.

A. SETUP

Nineteen nodes were deployed in this experiment, including a single racom buoy that served as the master node and which was located near the center of the Seaweb network. Figure 31 shows the physical components of the Seaweb network. Table 8 tabulates the recorded deployment location of each node as determined by GPS fixes. Figure 4 shows a chart of St. Margaret’s Bay and the location of each node.

The water where the nodes were deployed varies from 30 to 70 meters deep, with the bottom type characterized as sand or gravel. Wind speed was typically less than 8m/s as observed at CFAV Quest, and shipping traffic was observed to be light.

Figure 31. Seaweb network components: Seaweb server, racom gateway buoy, and Seaweb repeater node (after [1]).
Table 8. GPS coordinates of 19 nodes involved in June 2008 Seaweb ad hoc network discovery experiment.

B. ACOUSTIC ENVIRONMENT

Seaweb communications between the acoustic modems occur in the 9-14 kHz frequency band. Environmental observations during the sea trial, permit analysis of the communication channel during the experiment.

1. Transmission Loss

As sound energy propagates away from the source, its intensity decreases due to geometric spreading and attenuation. Geometric spreading is frequency independent and is best described as wavefront expansion as the sound travels away from the source. Initially the expansion begins as spherical spreading with intensity decreasing as a function of the range from the source squared. As the wavefront begins to interact with the seafloor and surface, and the water medium begins to act as a duct, the spreading shifts to a cylindrical model where the intensity decreases in proportion to the range from the source [14].

In addition to geometric spreading, sound energy is also absorbed as it travels through a medium. The attenuation is due to the conversion of the sound energy into heat, and the rate at which this conversion takes place is frequency-dependent. As frequency increases, the rate at which the sound is attenuated increases. Based on work by Francois and Garrison in [17 and 18], the expected rate at which sound attenuation
occurs in the ocean at Seaweb frequencies is approximately 1 dB/km. Figure 32 shows the operating frequencies of Seaweb and the corresponding attenuation coefficient.

![Graph showing attenuation coefficient](image)

**Figure 32.** Attenuation coefficient $\alpha$ in dB/km versus transmission frequency in kHz, based on Francois and Garrison [17 and 18] for salinity $S = 35$ ppt, acidity $pH = 8$, and depth $D = 50$ m.

### 2. Noise Level

The background noise levels in the ocean have several major constituents that each contribute differently depending on the frequency of interest. At very low frequencies, below 20 Hz, the noise is dominated by tidal and wave noise. From 20 Hz to 500 Hz, man-made shipping noise is the main contributor. At 500 Hz, wind noise is dominant until approximately 100 kHz, when thermal noise dictates the background noise levels [14]. Thus, at the Seaweb operating frequencies, wind-driven noise is the main component of the background noise. This is seen in Figure 33 derived from Coates [19].
Figure 33. Noise spectrum level based on empirical formula by Coates (after [19]).

NLwind is for 5 m/s (10 kts) wind speeds.

Since wind-driven noise is the limiting component of the total background noise in the frequency range of interest for Seaweb, and the wind noise is dependent on the wind speed, Coates’ formulas can be expounded upon to give Figure 34. This figure demonstrates the variation in noise level with wind speed. From the figure it is estimated that 50 dB re 1 µPa ambient noise existed at the operating frequencies of Seaweb for the wind speeds observed during the trial.
3. Multipath Propagation

As discussed in Chapter III, the shape of the vertical sound speed profile dictates the path that sound travels from the source. Figure 35 shows the sound-speed profiles taken at the outset and prior to the conclusion of the trial near the gateway node. The average sound-speed profile is analyzed using code from Torres [20] that determines the channel impulse response based on eigenray traces employing a Bellhop Gaussian beam-tracing propagation model. Figure 36 shows the results for nodes at 55 meters in depth at a frequency of 12 kHz, in 57 meters of total water depth. These figures demonstrate that the direct-path arrivals are greater in amplitude than any multipath, and therefore the matched filter used by Seaweb to measure node-to-node ranges should be effective at determining the direct-path arrivals.
Figure 35. Sound-speed profiles from St. Margaret’s Bay.

Figure 36. Bellhop eigenray traces for June 2008 St. Margaret’s Bay trial show a downward-refracting channel with multipath propagation. Direct-path arrivals are in red. Left: 1 km spacing. Right: 4 km spacing. Note the time-scale and amplitude-scale changes on the channel impulse response plots.
C. DATA

The Seaweb experiments of interest in St. Margaret’s Bay were conducted June 23 thru June 25, 2008. During this time the ad hoc discovery method of Ong [1] was exercised on five separate occasions. The node-to-node range measurements were saved into separate files for each discovery process, and all of these files were input into the localization algorithm for analysis. Node 3 was the racom buoy and master node. For the analysis, node 20 was selected as the ‘on_X’ node for its proximity to the master node and due to it having a large number of neighboring nodes. Figure 37 plots the node locations as determined by GPS at the time of deployment relative to the ‘master’ node. This figure corresponds to Figure 4, which shows the charted positions of the nodes. Figure 38 plots the same node locations with the axes rotated such that ‘on_X’ node lies on the x-axis.

Figure 37. Locations of St. Margaret’s Bay nodes referenced to node 3.
D. RESULTS

Using the range data from the five ad hoc discoveries, the algorithm converges the node locations to within 25 meters in six iterations. The algorithm produces 16 ambiguous solutions. The ambiguous solution that is closest to the actual node positions is solution 71936, which has a mean nodal position error of 80.8 meters. Figure 39 plots the locations of this solution. Appendix B contains plots for all of the ambiguous solutions that are generated.

Additionally an analysis for redundancy is conducted. Using a 25-meter threshold between each node location to call an ambiguous solution redundant, two of the solutions are declared redundant. Namely, ambiguous solution 4096 is redundant to solution 2048 and solution 67480 is redundant to solution 71936, which is the solution with the smallest mean nodal localization error.
Figure 39. Ambiguous solution exhibiting the smallest mean error per node (80.8 m) compared with the recorded node locations.
VIII. HORTEN EXPERIMENT

A second experiment was conducted off the coast of Horten, Norway in September 2008, but on a smaller scale with fewer nodes and a smaller area. The network deployment area, as seen in Figure 40, was approximately 500 meters by 600 meters and includes nine nodes. Due to the shallow bathymetry and sound speed profile that resulted in most of the sound energy being refracted to the boundaries during the trial, the maximum acoustic range was limited to less than 1500 meters. During the experiment, 32 ad hoc discoveries were conducted over the course of six days. Node 3 was the racom buoy and ‘master’ node, and node 10 is selected as the ‘on_X’ node for analysis.

Figure 40. Horten Seaweb network layout (from [1]).
The algorithm yields two ambiguous solutions, the better of which has a mean node localization error of 35.7 meters and requires three iterations for the solutions to converge. Figure 41 displays the node locations translated such that node 3 is the origin and node 10 is on the x-axis. Figure 42 shows the two ambiguous solutions, of which ambiguous solution 0 is the more accurate one. A visual comparison of solution 0 to the rotated actual node locations reveals that the solution for node 21 is farther away from the ‘master’ node than the actual location. This follows the general assumption from Chapter III, that the measured ranges will typically exceed the actual ranges, and that these errors compound as the distance from the master node increases.

Figure 41. Horten experiment nodes rotated with node 3 as the ‘master’ node and node 10 as the ‘on_X’ node.
Figure 42. Ambiguous solutions of the Norway sea trial data.
IX. CONCLUSIONS

A. SUMMARY OF RESULTS

The Seaweb ad hoc discovery process provides node-to-node range measurements that can be used to localize the positions of the network nodes. The results from the synthetic data and experimental data demonstrate that the algorithm implemented in this thesis is capable of localizing the nodes of a Seaweb network. This is especially important for sensor nodes, for which geo-localization is vital to operationally exploit the sensor data gathered.

B. RECOMMENDATION

In view of the fact that the algorithm is capable of localizing nodes, it should be added to the Seaweb field kit. It should be further refined and tested, with the eventual goal of incorporating it into the master node for automated operations.

C. FURTHER RESEARCH

The opportunities for further research stemming from this thesis fall into two broad categories, improving the algorithm to make it more accurate and efficient and having the algorithm interact with the Seaweb network to provide better data input by using system feedback.

1. Pruning Ambiguous Solutions

An improvement would be for the algorithm to selectively determine which unknown node should be evaluated first after the ‘master’ and ‘on_X’ nodes have been localized. The candidates for the third node would require ranges to both the ‘master’ and ‘on_X’ nodes. The recommended criteria for selecting the best third node from those that qualify would be the node that has the most ranges to other nodes also having ranges
to the ‘master’ and ‘on_X’ nodes. The benefit would be that secondary nodes chosen in this manner would not have ambiguous solutions. This would reduce the total number of ambiguous solutions.

Another improvement that would reduce the number of ambiguous solutions is to incorporate operator-provided constraints on the network geometry, such as boundaries, shorelines and known node locations. These constraints could be used to test hypothetical solutions.

2. **System Feedback**

When the algorithm processes the range data, it is unable to localize any node that has only a single range to known node. To proactively localize these single-range nodes, the algorithm could request of the Seaweb operator that these nodes issue another broadcast ping in an attempt to measure a range to a second known node. The new broadcast ping could be at a higher power level to attempt to overcome background noise, or the system could wait some time interval to allow noise levels and propagation conditions to improve. This same principle could also be applied to nodes having ambiguous solutions. If a third range is found to a known node, the solution becomes exact and eliminates the ambiguity.

The use of a mobile node, such as a UUV or simply a repeater node hung over the side of a ship, provides many avenues for augmenting the range data which are delivered to the algorithm. Assuming the mobile node is capable of determining its own location via GPS, it is an ideal choice as the ‘on_X’ node, because all of the nodes could be geolocalized once the algorithm was complete. The mobile node could also be used to eliminate ambiguous solutions by positioning itself as a known node such that a third range would be available for otherwise ambiguous node solutions. For nodes that have only a single range to a known node, the mobile node could provide ranges from multiple stations. The mobile node could also search for nodes that were deployed but not discovered. To accomplish this, the mobile node could transit to areas where the localization failed to show a node and conduct broadcast pings.
The program Stack_Sift.m could also be modified to detect the migration of nodes over time. Nodes could potentially be moved by bottom-trawling fishermen which would alter the node layout. If the Stack_Sift.m function noted a persistent change in the ranges between nodes, it could either request a complete repeat of the ad hoc discovery process to reset all of the ranges for every node, or it could begin to use the new ranges and disregard the old ones.
