ABSTRACT

A new solar technology with the capability to increase array-level power production is introduced by using simple integrated power converters that connect directly to photovoltaic (PV) panels is investigated. The power converters proposed here are full-bridge DC-DC converters with high voltage gain that operate with an open-loop control scheme. The outputs of these converters could then be directly connected to a grid-tie converter eliminating the need to connect panels in series to achieve the appropriate voltage. With a high-efficiency converter, the total system efficiency would increase even though one panel in the array may be compromised. The simulation results show that a highly-efficient converter is possible. To assist in experimentation, an auxiliary circuit using a microcontroller was implemented to supply power and gate signals to the gate driver of the power converters. The design and construction of a transformer for use with the full-bridge converter is discussed. A novel transformer topology is utilized to increase converter efficiency. The converters were tested both in a laboratory environment and outdoors for solar data collection. Transient response, source regulation and load regulation analysis was performed. The maximum power points of the array were investigated for different insolation levels. Even when insolation differs substantially, the panel output power levels are within their individual maximum power levels when the total output is maximized even without independent power trackers. Analysis of both field data and random insolation indicate that the new approach does increase power generation and therefore system efficiency.
ACKNOWLEDGMENTS

I would like to thank my advisor Dr. Jonathan Kimball for the opportunity to conduct this research. I appreciate all of his contributions and his patience in helping me through my Master’s program. Without his patience and wisdom, completion of the project would not have been attainable.

I would also like to acknowledge the members of my committee, Dr. Mariesa Crow and Dr. Maciej Zawodniok for their interest in my research topic.

I would especially like to thank all my friends and family, particularly Lydia Tucker, Jonathan Homan, and James Summitt. They are my motivation for completing this degree and without their support I would not have reached this level of academic achievement. To all of my friends and family, I dedicate this thesis.

Research was sponsored in part by the Leonard Wood Institute in cooperation with the U.S. Army Research Laboratory and was accomplished under Cooperative Agreement Number W911NF-07-2-0062. The views and conclusions contained in this document are those of the authors and should not be interpreted as representing the official policies, either expressed or implied, of the Leonard Wood Institute, the Army Research Laboratory, or the U.S. Government. 1. INTRODUCTION

1.1. PROBLEM

The number of installation locations with unshaded southern exposure over an area large enough for a conventional photovoltaic (PV) array is limited. If the array’s performance under partial shading could be increased, the number of suitable installation sites would increase significantly.

A typical solar panel generates up to 200 W at about 26 V. A typical inverter is rated for at least 250 V on its input terminals. Conventionally, PV panels are connected in series strings that achieve the desired system voltage, and then these strings are connected in parallel to achieve the desired system power rating. Unfortunately, if one panel is compromised (due to shading, obstructions, damage, etc.) the output power of its whole string is significantly reduced. Since PV system designers and installers are aware of the detrimental effects of shading, they design for as minimal shading as possible.

With the proposed approach, panels can be connected in parallel instead. Then any single compromised panel will only affect that particular panel, rather than the whole array. This will cause the average system output power to increase. While shading should still be avoided or minimized, moderate shading can be tolerated, so more installation sites can be considered.

In the proposed array topology, each individual PV panel has an integrated dc-dc converter which increases the input voltage by a fixed gain. The output of the converter could then be directly connected to a grid-tie inverter that performs maximum power point tracking (MPPT). Good source and load regulation are needed so that individual
panels operate near the same voltage, regardless of system voltage and individual panel power production.

In particular, the converters proposed are full-bridge converters, which are buck-derived isolated converters. The transformers have a ten times gain in order to allow the output voltage to be connected to a grid-tie inverter. A microcontroller, supplied by the PV panel, will be used in order to perform the gate switching for the converter with an open-loop control scheme using pulse-width modulation (PWM).

1.2. LITERATURE REVIEW

A model of a PV panel has been developed using datasheet values [1]. The model uses the single-diode, five-parameters model which takes into account the series and shunt resistance of the panel. With a proper model, simulation could easily be achieved and expected values of current and voltage could be predicted. Simulation and analysis of individual PV cells or modules has been performed [2]. This could also be adjusted to include the converter power stage and extended to comprise added control or other functions. Partial shading simulation of a PV panel is possible as well [3].

The impact of shading on array performance has been investigated [4-6]. There have been efficiency improvements in a series-connected PV array using individual power converters for each panel with partial shading [7]. This allows the maximum power from each panel to be delivered to the string with the use of module-level MPPT. However, the advantage is not as significant as a parallel-connected array. The effects of shading when comparing a series string to a parallel array at varying levels of insolation
corresponding to field data were analyzed and the parallel configurations yielded better performance [8].

There have been studies in different types of converters to use in photovoltaic applications. There has been extensive research of non-isolated converters used in photovoltaic applications [9]. Non-isolated converters could be designed in such a way that high-efficiency is possible regardless of the wide input range from a PV panel or a wide load range [10]. By analyzing the behaviors of the semiconductors, a converter could be optimized in order to achieve high efficiency. With improved semiconductor technologies, new boost converters are being developed for PV applications [11]. Multifunctional converters that integrate energy storage devices for use with PV generation system have been examined [12, 13].

The full-bridge converter can be designed in various ways. The typical conversion process in power electronics usually requires the use of magnetic components (such as inductors and transformers) that are frequently the heaviest and bulkiest item in the converter. These have a significant effect upon the overall performance, efficiency, size, and cost of the converter. Some studies have investigated the design and analysis of zero-voltage switched (ZVS), PWM converters [14-16]. This leads to a reduction in switching losses at higher frequencies. With higher frequency operation, the size and cost of the magnetic components, the inductors and transformers, in the circuit will be reduced. There has also been some investigation of zero-current switching (ZCS) to further reduce switching losses [17-20]. For higher power levels, high efficiency can be achieved with soft switching [21, 22]. From a lower power-scale prototype, a higher power converter could be designed. The converter could be designed for a flat efficiency
curve over a wide load range[23]. A current-fed full-bridge converter comparable in power level and efficiency has also been developed [24].

1.3. CONTRIBUTIONS OF THE THESIS

The main contributions of this thesis are:

- development and experimentation of an auxiliary circuit to supply gate drivers with power from a step-down circuit and gate signals from a microcontroller,
- development and implementation of a Labview interface to control devices and take measurements,
- development of the full-bridge buck-derived, isolated converter with novel parallel input, series-output transformer topology,
- presenting the simulation results to verify the design is sufficient,
- acquiring hardware bench-testing results, and
- obtaining outdoor solar-testing results.

1.4. THESIS ORGANIZATION

This thesis is organized into four sections. Section 1 provides a general introduction with a problem statement, literature review and contributions of the thesis. Section 2 describes the methodology used for the research, which covers the hardware and software design of a microcontroller circuit used for control, the development of a Labview interface to set an electronic load and measure input and output currents and voltages, and a discussion of the use of pyranometers and thermocouples. Section 3
presents the full-bridge converter used for experimentation, which explains the design and simulation of the full-bridge converter, the design and construction of the transformers used in the converter, and the experimental results from bench testing. Section 4 explains the setup and experimentation of the full-bridge converters with solar panels. Section 5 concludes the thesis and describes future work.

Following the solar testing conclusions, Appendix A contains the schematics and board layouts for the printed circuit boards used for collecting the experimental data. Appendix B includes the microcontroller code written to produce the pulse-width modulation gate signals. Appendix C illustrates the block diagram for the Labview interface and the human-machine interface screen used to capture data. Appendix D includes the data tables for solar testing at different isolation levels as well as the figures of the I-V and P-V curves for each isolation level, similar to Section 4 but more extensive.
2. METHODOLOGY

In this section the methods used to assist the project will be detailed. These include the methods to develop a microcontroller, a Labview program for data acquisition, and the use of a pyranometer and thermocouple.

2.1. MICROCONTROLLER

2.1.1. Hardware Design. The full-bridge converter is used in conjunction with another circuit which provides the voltage and the gate signals for the gate drivers. The schematic of this circuit is in Appendix A along with the printed circuit board (PCB) layout. This circuit has two step-down circuits, one to power the gate driver and the other to power the microcontroller. A buck converter, a TL2575-ADJIKTTR from Texas Instruments, with a variable gain is used in order to obtain the desired voltage for the gate drivers. The recommended circuit can be seen in Figure 2.1 [25].

The output voltage is determined by resistors $R_1$ and $R_2$ according to

$$V_{out} = \left(1 + \frac{R_2}{R_1}\right)V_{ref}$$  

where $V_{ref} = 1.23$ V. Resistors $R_1$ and $R_2$ were chosen to be $1\,k\Omega$ and $6.8\,k\Omega$ respectively to get an output voltage of $9.594$ V. Capacitors $C_1$ and $C_2$ were recommended to be $100\,\mu F$ and $330\,\mu F$, respectively. These are EEE-FP1V101AP and EEE-FP1C331AP, respectively, aluminum electrolytic capacitors from Panasonic. The diode $D_1$ was chosen to be a surface mount schottky diode, SSA34-E3/61T from Vishay. The inductor $L_1$ was recommended to be $330\,\mu H$. The inductor chosen is a MSS1260-334KLB from Coilcraft.
This voltage is then connected to a LD1117S33CTR low drop voltage regulator (LDO), from STMicroelectronics, in order to get a fixed 3.3 V to power the microcontroller, a MSP430F1222IDW from Texas Instruments. The recommended circuit can be seen in Figure 2.2 [26].

The input capacitor and output capacitors to the LDO are ceramic capacitors of 0.1 μF and 10 μF respectively. The output is connected to \( V_{cc} \) of Figure 2.3 [27], which shows the circuit design for in-circuit programming. Resistor R1 has a value of 47kΩ. Capacitors C1, C2 and C3 are ceramic capacitors with values of 2.2 nF, 10 μF and 0.1 μF respectively. The microcontroller was programmed with a debugging/programming interface, a MSP-FET430UIF from Texas Instruments. This is a USB to JTAG interface.
For programming when the power to the microcontroller is supplied by the board, connect J1. For programming when the power of the microcontroller is supplied by the programming adapter, connect J2.

The outputs of the microcontroller are two signals connected to TA1 and TA2 which are used for the gate signals. Additionally, there are connections for alternative uses of the circuit. There is a connection to use a crystal oscillator on pins XIN and XOUT of the microcontroller. These would be used if the microcontroller internal oscillator is not sufficiently accurate. There are connections for the use of two push buttons on input pins P3.0 and P3.1 of the microcontroller. Two analog to digital converter (ADC) inputs are connected to pins P2.0 and P2.1 of the microcontroller that could be used for closed-loop control. A USART or UART mode can be used with pins UTXD0, which transmits data, and URXD0, which receives data. These additional connections can be seen in the PCB schematic shown in Appendix A. The present work did not use these extra features.

Figure 2.2. Recommended Circuit for LDO
2.1.2. **Software Design.** The microcontroller program was designed such that it will produce two gate signals with the same duty cycle and switching frequency but with a phase shift of 180 degrees. The desired switching frequency is 100 kHz. The program turns off unnecessary peripherals and the CPU enters a low power mode after the program is loaded in order to minimize power consumption.

The program first turns off the watchdog timer. The primary function of the watchdog timer (WDT) module is to perform a controlled system restart after a software
problem occurs or if the selected time interval expires. Since there is no need for a system reset or interrupt routine, the watchdog timer is disabled.

Next the program will set two different registers, the DCOCTL and BCSCTL, in order to adjust the internal clock frequency. The DCOCTL register sets the DCO value to 7 and the BCSCTL register sets the RSEL value to 7. From the datasheet[28], the maximum value of the internal clock frequency is 5.4 MHz.

The program then sets the pins P1.2 and P1.3 to be PWM output pins using Timer A in up/down mode. The P1DIR register sets the pins as output pins and P1SEL designates the use of Timer A. The value of TACCR0 defines half of the PWM period and the values of TACCR1 and TACCR2 the PWM duty cycles. Using the system clock of 5.4MHz as Timer A clock, the value of TACCR0 can be determined with

$$ TACCR0 = \frac{f_{CLK}}{2 \times f_{sw}} - 1 $$

For a desired switching frequency of 100 kHz and the maximum clock frequency of 5.4 MHz, the value of TACCR0 is 26. However through experimentation the value of switching frequency was measured as 93.3 kHz. The lower than expected value is attributed the tolerance in clock frequency but based on the switching frequency, the estimated clock frequency is 5.038 MHz.

In order to achieve the phase shift necessary, TACCR1 is set to toggle/set mode and TACCR2 is set to toggle/reset mode, using the TACCTL1 and TACCTL2 registers respectively. The value of TACCR1 was set to 15 and the value of TACCR2 was set to 11. This gives each signal an effective duty cycle of 42%. An example of the operation of the PWM signals can be seen in Figure 2.4[29].
The last thing done in the program is to set the microcontroller into low-power mode. In this mode, the central processing unit and the master clock are disabled. The entire microcontroller program can be seen in Appendix B.

2.2. LABVIEW

The Labview interface was developed using Labview 10.1 in order to measure the input voltages, input currents, output voltages and output currents of the converters for specific load points. The block diagram can be seen in Appendix C. The electronic load, an Agilent N3300A, uses two modules in order to be within voltage ratings. Each module can handle 240 V and 30 A. One module is used as a voltage source to handle large voltages while the other module is used as a current or resistive load. There are three main parts to the visual interface. These include an initialization routine, the main routine and a shutdown routine.

For the initialization routine, the multimeters (Fluke 8845A) and the electronic load are configured. The multimeters are set to their specific function, whether that be
measuring dc voltage or dc current, and individual ranges were also set. The multimeters connected to the inputs of the converters were set with a 10 A range for the input current and a 100 V range for the input voltage. The multimeters connected to the outputs of the converters were set with a 3 A range for the output current and a 1000 V range for the output voltage. The first module on the electronic load is set to a current load with a 1 A range and a value of 1 mA. The range is set in order to receive a better degree of precision on the value of the current. The particular ranges are 48, 480, or 4800 ohms. The second module is set to a voltage load with a value of 100 V. This is in order to protect the first module in case the output voltage of the converter is greater than 240 V. This circuit is shown in Section 4.

The main routine takes the values of the maximum current and the step size that the user inputs into the visual interface to run a for-loop. This determines the amount of times the for-loop runs. The commanded current is determined by the step size and that value is sent to a text builder. The text is a program command to the electronic load. After a short time delay, the multimeters will measure the input voltages and input currents for each converter. There are some time delays inserted in this process to avoid software crashes. The electronic load will measure the output voltage and output current for the paralleled output of the converters. The output voltage data is sent to a voltage selector to determine a safe value of voltage for the voltage mode module of the electronic load. It is also used for determining the proper resistive load when the electronic load switches from a current load to a resistive load. When the commanded current is greater than 0.4 A, the program commands change the electronic load from a current load to a resistive load. Resistance is determined according to
\[ R = \frac{V[k-1] - V_{\text{OFFSET}}}{I[k]} \]  

(3)

where \( I[k] \) is the commanded current value, \( V[k-1] \) is the measured output voltage from the previous measurement, and \( V_{\text{OFFSET}} \) is the voltage offset on Channel 3. The range for the resistive load is also set in order to increase precision for the resistance commanded.

The values of the input and output voltages and currents are sent to various plotting blocks and a block that records the data into an excel spreadsheet. This is for verification by the end-user to see if the data is correct and sufficient based on what is expected.

The shutdown routine starts by setting the voltage module of the electronic load to 100 V. The electronic load is also set back to a current load. The routine then runs through a for-loop designed to ramp down the current on the load from the maximum current to 500 mA and then dropping down by 100 mA increments to 100 mA. There is a time delay between steps in order to limit software crashes.

### 2.3. PYRANOMETER/THERMOCOUPLES

A Li-Cor pyranometer is used in order to measure the solar radiation flux density (in watts per meter square) on the solar panel surface. The pyranometer was connected to a Fluke 115 hand-held digital multimeter in order to measure the DC voltage signal produced. The conversion from the DC voltage to solar radiation flux density is given by the manufacturer as 

\[ 1mV = 100 \frac{W}{m^2}. \]

A thermocouple is a device consisting of two different conductors that produce a voltage proportional to a temperature difference between either end of the pair of conductors.
conductors. A K-type thermocouple, from Newport, was attached to the bottom of the solar panel and the signal was measured on a Metex M-3850D digital multimeter to measure the temperature in Fahrenheit or Celsius.

2.4. SUMMARY

The devices and programs described here were used to supplement the design and experimental process. The microcontroller circuit was developed to supply the gate drivers with power and gate signals. The Labview program was created to control the multimeters and electronic load in order to make changes to the equipment and take measurements at a higher rate than by hand. The thermocouples and pyranometers were utilized to determine the temperature on the individual PV panel and the insolation levels being received.
3. FULL-BRIDGE CONVERTER

3.1. DESIGN

The converters proposed are full-bridge converters, which are buck-derived isolated converters. This can be seen in Figure 3.1. The converter used a high-reliability, high-ripple-current capacitor on the input terminals (C1); four MOSFETs arranged in an H-bridge; two transformers connected in an input-parallel, output-series topology; a full-bridge rectifier composed of ultrafast diodes; and an output filter composed of an inductor (L1) and a capacitor (C2). The converters have been built with the circuit parameters shown in Table 3.1. The interface between the controller and the MOSFETs used dielectric-isolated gate drivers. The designed operating frequency was chosen to be 93 kHz to minimize transformer size.

![Diagram of Full-Bridge Converter Topology](image)

Figure 3.1. Full-Bridge Converter Topology

To limit the effect of the primary winding losses on the transformer, two transformers were connected in parallel on the primary and in series on the secondary, as
may be seen in Figure 3.2. With the series connection, the secondary currents were forced to be equal, so the primary currents were equal by necessity. The MOSFETs are controlled with a microcontroller, set to generate PWM waveforms with an effective duty ratio (after rectification on the secondary) of 84%, as described in Section 2.1.

Toshiba TCPA8048 MOSFETs were chosen for the bridge because of their exceptionally low on-state resistance and reasonable gate charge and output capacitance. These are packaged in an enhanced (for low thermal resistance and low on-state resistance) version of an SO-8, a surface-mount package measuring 6 mm × 5 mm.

Figure 3.2. Input-parallel-output-series transformer connections
The gate drivers used in the first revision of the board were International Rectifier IR2110 dual drivers. In the second revision, these were replaced with IR2101 drivers, which are smaller and less expensive but with otherwise similar specifications. The IR driver chips have one channel that is referred to the input common and one channel that is floating, suitable for driving the high-side MOSFET in one leg of the full-bridge.

The output rectifier bridge used ES3J diodes in the first revision and PDU540 diodes in the second revision. Both types are ultrafast (with reverse recovery times of 35 ns) with suitable voltage ratings. The PDU540 was chosen because of a lower on-state conduction loss.

The PCB schematics and board layouts of the complete converter circuit with auxiliary circuit can be seen in Appendix A.

3.2. TRANSFORMER DESIGN AND CONSTRUCTION

For the initial design of the transformers using the $K_g$ core geometry approach (from McLyman [30]), the design specifications can be seen in Table 3.2.

The regulation and power-handling ability of a core is related to the core geometry. In order to calculate the appropriate core geometry, \( K_g \), the regulation, the apparent power \( (P_t) \), and the electrical conditions \( (K_e) \) need to be determined. The regulation is determined from the specifications in Table 3.2. The transformer apparent power, \( P_t \), is determined using

\[
P_t = P_o \left( \frac{1}{\eta} + 1 \right)
\]

where the output power and the expected efficiency can be seen in Table 3.2. The calculated value of the apparent power is 406.19 W. \( K_e \) is determined by the magnetic and electric operation conditions, which are related by

\[
K_e = 0.145 \left( K_f \right)^2 \left( f_{sw} \right)^2 \left( B_{ac} \right)^2 \left( 10^{-4} \right)
\]

where the waveform coefficient, \( K_f \), has a value of 4 due to a square wave gate signal. The electric conditions equaled 23200. The core geometry, \( K_g \), is calculated using

\[
K_g = \frac{P_t}{2K_e \alpha}
\]

The core geometry equaled 0.004377 cm\(^5\) where the constant \( \alpha \) has a value of 2 and not its percentage value of 0.02.

The next step is to select an appropriate core that meets or exceeds this minimum required core geometry, \( K_g \). Also in the selection of the core is to find one with the proper core material. For this design, an ETD-29 ferrite core was chosen with a core material of 3C90. The ETD-29 core geometry value is 0.0517 cm\(^5\) which is higher than the calculated value. This means the ETD-29 core is suitable for the transformer design. Although a smaller core could have been chosen, the ETD-29 core was chosen for ease of
transformer construction. The design specifications for the ETD-29 can be seen in Table 3.3.

Next, the parameters of the primary winding are determined. These are the number of turns on the primary, current density, calculated input current, primary bare wire area, the resistance of the primary winding, and the power loss on the primary winding. The number of primary turns, $N_p$, can be expressed using Faraday’s Law

$$N_p = \frac{V_{in}(10^4)}{K_f B_0 f_{sw} A_c}$$  \hspace{1cm} (7)

The number of primary turns was calculated to be 8.7385 turns and was rounded down to 8 turns. The current density, $J$, was calculated using

$$J = \frac{P(10^4)}{K_f K_u B_{sw} f_{sw} A_p}$$  \hspace{1cm} (8)

The current density was calculated to be 235.06 A/cm$^2$. The input current, $I_{in}$, was evaluated to verify what is expected using
The calculated input current was 7.751337 A, which is within the expected range of input current. The primary bare wire area, $A_{wp(B)}$, was calculated using

$$A_{wp(B)} = \frac{I_{in}}{J}$$

The calculated primary bare wire area was 0.032975 cm$^2$. The appropriate wire size was selected from [30] to be 12 AWG. 12 AWG has a bare wire area of 0.03308 cm$^2$ and is larger than the calculated value, making it suitable for use. The primary resistance, $R_p$, was calculated using

$$R_p = MLT \left( N_p \right) \left( \frac{\mu \Omega}{cm} \right) \left( 10^{-6} \right)$$

where $\left( \frac{\mu \Omega}{cm} \right)_{\text{was given as 52.1}}$. The primary resistance was 2.668mΩ. The primary copper loss, $P_p$, was predicted using

$$P_p = I_p^2 R_p$$

The primary copper loss was predicted to be 0.1603 W.

Next, the parameters of the secondary winding are determined. These are the number of turns on the secondary, secondary bare wire area, the resistance of the secondary winding, and the power loss on the secondary winding. The number of secondary turns, $N_s$, was calculated using

$$N_s = \frac{N_p V_s}{V_{in}} \left( 1 + \frac{\alpha}{100} \right)$$
The number of secondary turns was calculated to be 81.6 turns and was rounded down to 80 for a ten times gain on the transformer. The secondary bare wire area, \( A_{ws(B)} \), was calculated using

\[
A_{ws(B)} = \frac{I_o}{J}
\]

The calculated secondary bare wire area was 0.003199 cm\(^2\). The appropriate wire size was selected from [30] to be 22 AWG. 22 AWG has a bare wire area of 0.003243 cm\(^2\) and is larger than the calculated value, making it suitable for use. The secondary winding resistance, \( R_s \), was calculated using

\[
R_s = MLT \left( N_s \right) \left( \frac{\mu \Omega}{cm} \right) \left( 10^{-6} \right)
\]

where \( \left( \frac{\mu \Omega}{cm} \right) \) was given as 531.4. The calculated secondary resistance was 0.27208Ω.

The secondary copper loss, \( P_s \), was predicted using

\[
P_s = I_o^2 R_s
\]

The secondary copper loss was predicted to be 0.15382 W.

The last step is to calculate the total system parameters. These include the total primary and secondary copper loss, the transformer regulation, the core loss, the total loss and the calculated window utilization. The total primary and secondary copper loss, \( P_{cu} \), was calculated using

\[
P_{cu} = P_p + P_s
\]

The total primary and secondary copper loss was calculated to be 0.31412 W. The transformer regulation, \( \alpha \), was calculated using
\[ \alpha = \frac{P_{cu}}{P_o} \times 100 \]  \hspace{1cm} (18)

The calculated transformer regulation was 0.15706 \%. In order to determine the core loss, a watts per kilogram value must be determined. The watts per kilogram, W/kg, was calculated using

\[ \frac{W}{kg} = k \left( f_{sw} \right)^m \left( B_{ac} \right)^n \]  \hspace{1cm} (19)

where \( k \) equals 0.001983, \( m \) equals 1.36 and \( n \) equals 2.86 based on material properties of the chosen core [30]. The calculated core loss power density was was 17.2712 W/kg.

The core loss, \( P_{fe} \), was calculated using

\[ P_{fe} = \left( \frac{W}{kg} \right) \left( W_{fe} \right) \times 10^{-3} \]  \hspace{1cm} (20)

The calculated core loss was 0.48359 W. The total loss, \( P_\Sigma \), was calculated using

\[ P_\Sigma = P_{cu} + P_{fe} \]  \hspace{1cm} (21)

The total power loss of the transformer was calculated to be 0.7977 W. The total calculated window utilization, \( K_u \), was determined using

\[ K_u = \frac{N_p A_{wp(\beta)} + N_s A_{wil(\beta)}}{W_a} \]  \hspace{1cm} (22)

The total calculated window utilization was 0.366. This value is the percentage of the window area that is being utilized by bare wire cross-sectional area (which is 36.6\%). An example diagram of the transformer windings can be seen in Figure 3.3.
From the initial transformer design, early attempts used larger ETD cores (ETD34, ETD44, ETD49 and ETD54) with a foil winding for the primary and round-wire winding for the secondary for ease of construction. At 93 kHz, the skin depth in copper ($\epsilon$), calculated using

$$\epsilon = \frac{6.62}{\sqrt{f_{sw}}}$$

is 0.02171 cm. This value needs to be doubled to determine the proper wire size. The wire diameter would need to be 0.04342, which is approximately the diameter of 26 AWG wire. To minimize skin and proximity effect, a wire size with a radius equal to the skin depth is desired. However, to achieve the proper current density, the equivalent of 12 AWG is needed on the primary, 22 AWG on the secondary. To approximate 12 AWG, copper foil of a width similar to the bobbin width and 813 $\mu$m thickness was used. The copper foil was wrapped in insulating tape. For the secondary, 22 AWG wire was used as a reasonable compromise.

Unfortunately, manufacturing a transformer with low-resistance termination connections using the foil was unattainable. Therefore, a different approach was used.
The largest component of power loss was the copper loss on the primary winding. Thus to decrease the power loss in the primary winding, two transformers with parallel primaries were designed. This would decrease the magnitude of primary current by a factor of two and the overall resistance of the parallel-input would decrease by a factor of two. To ensure current sharing, their secondaries were connected in series, as shown in Figure 3.2. With the series connection, the secondary currents were forced to be equal, so the primary currents were equal by necessity. With the reduced primary current, 15 AWG equivalent was needed, so the transformers were constructed with $2 \times 18$ AWG in parallel on the primary. Again 22 AWG was used on the secondary. Since power handling decreased, the size of the core could be decreased to an ETD29. This approach was much easier to construct, and therefore achieved better results despite the theoretical advantage of foil windings.

3.3. SIMULATION

In order to assist in part selection and feasibility, a simulation was developed using Simulink and PLECs. The simulation was helpful in determining if the ratings of the components chosen were sufficient. In a simulated environment, the currents on surface mount components (MOSFETs, rectifier diodes, inductors, etc.) could be measured whereas on the physical board this was not possible. Figure 3.4 shows the simulation model built in PLECs.
Along with this model an m-file was used to input component values into the simulation model. In this way, the converter parameters could easily and conveniently be changed. The initial constructed transformers were connected to a Hewlett Packard 4284A Precision LCR Meter in order to measure the inductance of each of the windings. This was done by connecting the LCR meter to the respective winding and leaving the other winding in an open-circuit. For leakage values, the LCR would be connected to the appropriate winding and the other winding would be shorted. The resistance values received from the LCR were either exceptionally high or negative values. Thus the calculated winding resistance values were used because of error in measurement of the resistance with the LCR meter. The values of the components (given in Table 3.1), the expected value of the on-state resistance, the measured values of the transformer were put into a ideal transformer model (coupled inductors) and the calculated winding resistance values were were put into the m-file.

The values of on-state resistance, transformer winding inductances, and calculated transformer values can be seen in Table 3.4.
From the values for the transformer inductances, the mutual inductance can be approximated using

\[ M = L_p \left( \frac{N_s}{N_p} \right) \]  \hspace{1cm} (24)

This value would need to be included in the coupled inductor matrix as

\[
\begin{bmatrix}
L_p & M \\
M & L_s
\end{bmatrix}
\]  \hspace{1cm} (25)

With the values in MATLAB, the simulation was ran and a high efficiency (greater than 95%) was verified along with expected voltages and currents of the converter. The simulated results of the power and efficiency can be seen in Figure 3.5.

From the results we can see where the value of input power (approximately 203 W) is about what is expected (205 W). The output power ripple is within a reasonable amount of tolerance with less than 1 W of ripple. The simulated efficiency is nearly 98%.

Table 3.4. Simulation Model Values
3.4. EXPERIMENTAL RESULTS

There were multiple experiments ran in order to measure the capabilities of the converters. There was a transient response experiment to ensure that the converter could respond to a change in the input within a reasonable amount of time. Source and load
regulation were measured as well. The current and voltage on the input and output was measured in order to produce relevant graphs to what is expected for outdoor testing.

Figure 3.6 shows the transient response to a step in current load from 100 mA to 150 mA. The input voltage is shown on Channel 1 with 10 V per division and the output voltage is shown on Channel 2 with 5 V per division and a voltage offset.

Figure 3.6. Transient Response
Figure 3.7 shows the source regulation ($SR$), defined as

$$SR = \frac{\left| \frac{V_{out}}{V_{in}} \right|_{V_{in}=20} - \left| \frac{V_{out}}{V_{in}} \right|_{V_{in}=25}}{\left| \frac{V_{out}}{V_{in}} \right|_{V_{in}=25}}$$

(26)

The objective of the source regulation experiment is for the gain of the converter, output voltage ($V_{out}$) divided by input voltage ($V_{in}$), to remain constant regardless of input voltage. This is essentially a gain error. The mean source regulation for output currents above 100 mA (where the converter entered continuous conduction mode) was approximately 2%.

Figure 3.8 shows the load regulation for two different values of input voltage. For very low load currents, the converter enters discontinuous conduction mode and the output voltage floats up. Measuring from the point where the converter enters continuous conduction mode (an output current of 100mA) to full load, the load regulation was 7.71%.

The current versus voltage (I-V) waveforms for the two converters can be seen in Figure 3.9 and Figure 3.10. Figure 3.9 shows the input current versus input voltage waveforms and Figure 3.10 shows the output current versus output voltage waveforms. This shows how well the two converters perform in relation to each other. Ideally the waveforms would be identical and the converters would behave similarly. The difference in transformer construction is at fault for the small differences seen.
Figure 3.7. Source Regulation

Figure 3.8. Load Regulation
Figure 3.9. Input I-V Waveforms

Figure 3.10. Output I-V Waveforms
The power versus voltage (P-V) waveforms for the two converters can be seen in Figure 3.11 and Figure 3.12. Figure 3.11 shows the input power versus input voltage waveforms and Figure 3.12 shows the output power versus output voltage waveforms. As in the I-V waveforms, this shows how well the two converters perform in relation to each other. Ideally, the waveforms would be identical and the converters would behave similarly. The difference in transformer construction is at fault for the small differences seen.

![Figure 3.11. Input P-V Waveforms](image)

The efficiency versus output current can be seen in Figure 3.13. The peak efficiency for Board 1 was 90.98% at approximately 450mA output current. The peak efficiency for Board 2 was 90.16% at approximately 450mA output current. This was almost entirely
due to construction of the transformer. With a better manufacturing process, a highly efficient transformer could be constructed and high efficiency converters could be achieved.

The efficiency graphs are nearly identical which is expected from the I-V and P-V waveforms. The very low efficiency at the beginning can be attributed to a constant control current of 1mA for the commanded output current. This was a safety constraint of Labview to give a low control value for measurement.
Figure 3.13. Efficiency Waveforms
4. SOLAR TESTING

4.1. SETUP

Experimental data was obtained through outdoor solar testing of the full-bridge converters with parallel connected photovoltaic array as shown in Figure 4.1. Shown in the electronic load block is the different modules used as described in Section 2.2. Each solar panel is connected to a full-bridge converter. For the tests described in this chapter, Kyocera KD215GX-LPU multicrystalline panels were used. The experimental setup for outdoor solar testing is shown in Figure 4.2. For our experiments, Board 1 was connected to Panel 1 and Board 2 was connected to Panel 2. The bench results of Board 1 and Board 2 can be seen in Section 3.4.

Figure 4.1. System Topology
There are two high-precision multimeters, Fluke 8845As, either used as both a voltmeter and an ammeter on the input of a single full-bridge converter. The individual full-bridge converters are connected in parallel to an electronic load, an Agilent N3300A, which is also used to measure the output voltage and output current.

For the solar testing, Blue Hawk 4 mil thick, heavy-duty plastic sheeting was cut into smaller sheets. These were placed on top of the solar panels in order to provide varying levels of insolation to the solar panels. There were six different levels of insolation tested where there were unshaded, some partial shading, and full shading of an
individual panel. Figure 4.3 shows the physical setup to simulate a uniform insolation over a solar panel.

![Physical Setup of Uniform Insolation](image)

**Figure 4.3. Physical Setup of Uniform Insolation**

### 4.2. EXPERIMENTAL RESULTS

In this section, the results for unshaded, partial shading and full shading are shown. These include the current versus voltage (I-V) and power versus voltage (P-V) waveforms along with maximum power point data tables. More results may be found in Appendix D.
Figure 4.4 shows the current versus voltage (I-V) curves for the unshaded condition. Figure 4.5 shows the power versus voltage (P-V) curves for the unshaded condition. These figures demonstrate that the two converter outputs are nearly identical for unshaded conditions.

The values of the maximum power, the voltage at the maximum power point, and the current at the maximum power point can be seen in Table 4.1. Included are the insolation of the unshaded panel, the temperature of each panel, the current, voltage and power at the total maximum power point for each panel.
The data shows that the two panels with their individual converters operate nearly the same. Also the data shows that the maximum power point of each individual panel is near the maximum power point of the entire system. This is expected from the results in Section 3.

Figure 4.6 shows the power vs. voltage relationship for the inputs of the two converters and the paralleled output of the converters for unshaded conditions. From the plots, the total maximum power point can easily be determined and occurs at the same instance as the maximum power points of each individual panel.

![Figure 4.6. Total P-V Waveforms Unshaded](image)

Figure 4.7 shows the power vs voltage relationship from Figure 4.6 with maximum power points added for each of the inputs and the paralleled output of the converters. The maximum power points all occur at the same output voltage on the curve, which is expected.
Figure 4.8 shows the efficiency vs. the output current for the unshaded conditions. The peak efficiency was 92.41%. The average efficiency was 90.25% after the first measurement.

Figure 4.9 shows the input current vs. input voltage when one panel is partially occluded, resulting in approximately 50% insolation. Figure 4.10 shows the power vs. output voltage relationships for the inputs of the two converters and the paralleled output of the converters for partially shaded case.
As above in Table 4.1, the values of the maximum power, the voltage at the maximum power point, and the current at the maximum power point can be seen in Table 4.2. Included are the insolation of the unshaded panel, the temperature of each panel, the current, voltage and power at the total maximum power point for each panel.

Figure 4.11 shows the power vs voltage relationship from Figure 4.9 with maximum power points added for each of the inputs and the paralleled output of the converters. At the output voltage where the output power reaches its maximum, the unshaded panel is within 2.02% of its maximum power and the shaded panel is within 1.28% of its maximum power. This shows that the individual panel outputs are well within 5% of their individual maxima when the array power is maximized, despite differing insolation.
Figure 4.12 shows the efficiency vs. the output current for the partially shaded conditions. The peak efficiency was 92.25%. The average efficiency was 89.96% after the first measurement.

Figure 4.9. Input I-V Waveforms with Partial Shading
Figure 4.13 shows the input current vs. input voltage when one panel is fully shaded, resulting in approximately 30% insolation. Figure 4.14 shows the power vs. output voltage relationships for the inputs of the two converters and the paralleled output of the converters for fully shaded case.

At the output voltage where the output power reaches its maximum, the unshaded panel is within 0.5% of its maximum power and the shaded panel is within 11.2% of its maximum power.

As the insolation is decreased past 50%, the shaded panel drops out of the 5% range desired. The difference in power from the maximum power point at full shaded conditions is 11.19%, which is over double the objective. At insolation levels where the
shaded panel is out of the 5% range, the characteristics of the unshaded panel dominate the total system power characteristics.

The difference in power from the maximum power point is less than 2.05% for the unshaded panel for all shading conditions on the other panel.

Figure 4.15 shows the power vs voltage relationship from Figure 4.13 with maximum power points added for each of the inputs and the paralleled output of the converters.
As above in Table 4.1, the values of the maximum power, the voltage at the maximum power point, and the current at the maximum power point can be seen in Table 4.3. Included are the insolation of the unshaded panel, the temperature of each panel, the current, voltage and power at the total maximum power point for each panel.

Figure 4.16 shows the efficiency vs. the output current for the partially shaded conditions. The peak efficiency was 92.44%. The average efficiency was 89.92% after the first measurement.

5. CONCLUSIONS AND FUTURE WORK

A new approach to PV arrays was investigated. Each panel has an integrated module-level power converter with a fixed voltage gain. The output of the converters may be directly connected to a grid-tie inverter. This will allow individual panels to operate much closer to their respective maximum power points than panels in a conventional series-connected array.

The design of an auxiliary circuit to supply gate drivers with gate signals and power is presented. The design and implementation of a Labview interface for automating the experimental process of setting the electronic load and taking measurements was discussed. The use of supplementary devices such as the pyranometer and thermocouples was discussed.

The design of a full-bridge, buck-derived, isolated converter is presented. The design and construction of a transformer for use with the full-bridge converter is covered, as well as the novel topology utilized to increase converter efficiency. The simulation results show that a high efficiency converter is possible if skin and proximity effects are limited and transformer construction is improved.

Analysis of both field data and random insolation indicate that the new approach does increase power generation and therefore system efficiency. Solar testing shows that the topology does improve system performance overall independent of insolation levels on one of the panels. With a higher efficiency converter, the individual maxima will more closely coincide with the total maximum power point of the system. Even with less efficient converters, the unshaded panel’s characteristics govern the total system’s characteristics, rather than the shaded panel limiting outputs.
Future work should include the introduction of two new gate signals to control Q3 and Q4 as seen in Section 3.1. These new gate signals would have a phase shift from the gate signals on Q1 and Q2. This would allow the voltage on the MOSFETs to reach zero and achieve zero-voltage switching, possibly increasing efficiency. Further experimental testing could then be done to measure the increase in efficiency. If bench testing proves successful, the next step would be to do solar testing and measure the efficiency increase on both converters. Also, checking the difference in power from the maximum for both converters at maximum output power to ensure that the converters are operating at their individual maxima independent of insolation levels. Finally, the system should be scaled to a large PV array and connected to a grid-tie inverter.
APPENDIX A.

PRINTED CIRCUIT BOARD DESIGN
This appendix includes the schematics and board layouts of the printed circuit boards described in Section 2.1 and Section 3.1. The schematic diagram is broken into multiple sections and shown in Figures A.1 through A.4 for clarity.
