### Abstract

The TSC1/TSC2 complex integrates multiple cues to regulate protein translation and cell growth via a mammalian target of rapamycin complex I (mTORC1). Loss of TSC functions leads to constitutive activation of mTORC1 and uncontrolled mRNA translation. The goal of this research project is to elucidate cis-regulatory elements and trans-acting factors in TSC-mTORC1-mediated translational regulation. We have discovered that the stress-induced preferential translation of Hsp70 mRNA is deficient in cells lacking TSC2. This finding provides a plausible mechanism about how persistent mTOR signaling favors the development of various pathologies of TSC by attenuating stress resistance. We recently discovered that TSC-mTORC1 increased the yield of protein synthesis at the expense of protein quality. By harnessing the power of ribosome profiling, we also discovered post-initiation ribosomal pausing that is subject to TSC-mTORC1 regulation. In addition, we have established a novel approach called Global Translation Initiation sequencing (GTI-seq) to investigate alternative translation. These studies are significant because TSC-mTORC1-controlled alternative translation initiation has never been defined.

INTRODUCTION

Tuberous sclerosis complex (TSC) is an autosomal dominant disease characterized by benign tumors in various tissues. The genes mutated in this disease, TSC1 and TSC2, encode tumor suppressors that are associated in a complex. The TSC1/2 complex, through its Rheb-GAP activity, is a critical negative regulator of mTORC1 under physiological conditions. Activation of mTORC1 positively stimulates cap-dependent mRNA translation via its downstream substrates S6K and 4E-BP. In our previous study, we demonstrated that TSC-mTORC1 signaling regulates the balance between cap-dependent and cap-independent translation. In this project, we aim to elucidate cis-regulatory elements and trans-acting factors in TSC-mTOR pathway-mediated translational regulation.
**Task 1. Define TSC-mediated translational regulation using genome-wide ribosome profiling**

- **Determine the pattern of ribosome pausing in TSC2 KO cells**
  A reliable measure of the translation of cellular mRNA is the degree of its association with ribosomes. Actively translated mRNAs are typically bound by several ribosomes (polysome) and can be separated from individual 40S and 60S ribosomal subunits and 80S monosomes by centrifugation through a linear sucrose gradient. Ribosome profiling, based on deep sequencing of ribosome-protected mRNA fragments (RPF), has proven to be powerful in defining ribosome positions on the entire transcriptome [1, 2]. To investigate the ribosome dynamics during mRNA translation, we have established a modified ribosome profiling technique (Ribo-seq) adapted from the previously published protocol (Fig. 1A). Direct comparison of RPFs from both monosome and polysome fractions afforded us an opportunity to dissect the transition between initiation and elongation.

We built a heat map of RPF density over the entire transcriptome for both TSC2 WT and TSC2 KO cells (Fig. 1B). In addition to the clear enrichment of RPFs at the start of transcripts [3], a significant portion of footprints were also located at several downstream codons, with another prominent peak of reads positioned at +4 codon (Fig. 1C). These results strongly suggest the existence of a post-initiation pausing after the assembly of 80S ribosome at the initiator codon. Interestingly, TSC2 KO cells showed a substantial decrease of RPF density around the initiation codon as compared to the wild type (Fig. 1B, 1C). In particular, the second pause peak at +4 codon was nearly diminished in cells lacking TSC2 (Fig. 1C). Ribosome pausing has long been attributed to the presence of specific sequence features, such as rare codons or RNA secondary structures [4-6]. Our results suggest that the ribosome pausing could also be subject to regulation by nutrient signaling. It appears that mTORC1 not only promotes the ribosome loading via cap-dependent mechanism, but also reduces the initiation pausing of 80S ribosomes, resulting in a faster transition between initiation and elongation.

- **Determine the role of TOP sequence in ribosome pausing**
  By calculating the pausing index across the entire transcriptome (Fig. 1), we found that a subset of transcripts had an exceptionally high initiation pause. Of interest, we observed a strong propensity of initiation pausing on transcripts encoding ribosome proteins (RP) (data not shown). A common feature of RP transcripts is the presence of a characteristic 5'UTR: an uninterrupted sequence of 6-12 pyrimidines at the 5' end called terminal oligopyrimidine (TOP) sequence [7, 8]. Importantly, the TOP motif is necessary for a growth-associated translational regulation of RP mRNAs [8]. However, the underlying molecular mechanism remains controversial. To examine whether the presence of the TOP sequence is sufficient to convey the unique feature of initiation pausing to irrelevant transcripts, we cloned the TOP sequence of Rpl15 into the 5'end of a reporter gene encoding Luc. We also included the Gapdh 5'UTR as a negative control. After ribosome
profiling of transfected cells, we compared the distribution of ribosome density on each Luc transgene bearing different 5'UTR and found positive correlation between the presence of TOP sequence and initiation pausing.

1b. **Determine the selection of translation initiation sites in response to TSC-mTOR pathway**

- **Established the global mapping of translation initiation sites**
  
  A recent study used an initiation-specific translation inhibitor harringtonine to deplete elongating ribosomes from mRNAs, thereby halting ribosomes at the initiation codons [9]. This approach uncovered an unexpected abundance of alternative TIS codons, in particular non-AUG codons in the 5'UTR. However, these data was “noisy” and required a machine-learning algorithm to identify TIS codons. We develop global translation initiation sequencing (GTI-seq) by utilizing two related but distinct translation inhibitors to effectively differentiate ribosome initiation from elongation.

  While cycloheximide (CHX) freezes all translating ribosomes, the translation inhibitor lactimidomycin (LTM) preferentially acts on the initiating ribosome but not the elongating ribosome (Fig. 2). LTM bears several advantages over harringtonine in achieving the high resolution mapping of global TIS positions. First, LTM binds to the 80S ribosome already assembled at the initiation codon and permits the first peptide bond formation [10]. Thus, the LTM-associated RPF more likely represents physiological TIS positions. Second, LTM occupies the empty E-site of initiating ribosomes and thus completely blocks the translocation. This feature allows the TIS identification at single nucleotide resolution. Third, owing to the similar structure and the same binding site in the ribosome [10], LTM and CHX can be applied side-by-side to achieve simultaneous assessment of both initiation and elongation for the same transcript. With the high signal/noise ratio, GTI-seq offers a direct TIS identification approach with a minimal computational aid.

- **Characterize alternative translation**
  
  From 4,000 transcripts with detectable TIS peaks, we identified a total of 16,231 TIS sites. Codon composition analysis revealed that more than half of the TIS codons used AUG as the translation initiator (Fig. 3A). GTI-seq also identified a significant proportion of TIS codons employing near-cognate codons that differ from AUG by a single nucleotide, in particular CUG (16%). Remarkably, nearly half of the transcripts (42%) contained multiple TIS sites (Fig. 3B), suggesting that alternative translation prevails even under physiological conditions. In addition to validating initiation at the annotated start codon (aTIS), GTI-seq revealed 39% of the transcripts containing downstream initiation sites (dTIS) and 54% of transcripts bearing upstream TIS positions (uTIS). While dTIS codons use the conventional AUG as the main initiator, a significant fraction of uTIS codons are non-AUG with the CUG as the most frequent one. We experimentally validated different translational products initiated from alternative start codons, including non-AUG (data not shown).

Fig. 2. Experimental Strategy of GTI-seq Using Ribosome E-site Translation Inhibitors

Pretreatment of HEK293 cells with either 100 µM CHX, or 50 µM LTM resulted in different patterns of RPFs as revealed by metagene analysis. CHX-associated RPFs are mainly located in the body of coding region. Remarkably, LTM-associated RPFs are enriched at the annotated start codon.

Fig. 3. Global TIS identification by GTI-seq. (A) Codon composition of all TIS codons identified by GTI-seq. (B) Histogram showing the overall distribution of TIS number identified on each transcript.
Task 2. Define the impacts of TSC-mTOR pathway in protein quality and quantity control

2a. Determine how TSC-mTOR pathway the quality of newly synthesized proteins

To investigate how nutrient signaling affects the folding of nascent chains, we used firefly luciferase (Luc) as a reporter because of its high chaperone dependency and stress sensitivity [11, 12]. Cells lacking tuberous sclerosis complex 2 (TSC2) exhibit constitutively active mTORC1 signaling [13, 14]. In spite of the increased protein synthesis, we observed a much lower Luc activity in TSC2 KO cells than in wild type cells (Fig. 4A). Proteasome inhibition by MG132 treatment caused a significant accumulation of Luc (Fig. 4B), indicating the reduced stability of Luc in cells with hyperactive mTORC1 signaling. Remarkably, reducing mTORC1 signaling by specific inhibitor rapamycin was able to rescue the steady-state levels of Luc (Fig. 4B). The reduced protein quality in TSC2 KO cells was not limited to Luc. A significant amount of polyubiquitinated species were also accumulated in these cells after proteasome inhibition as compared to the wild type cells (Fig. 4C). These results strongly suggest that hyperactive mTORC1 signaling increases the yield of protein synthesis at the expense of folding quality.

2b. Determine how TSC-mTOR pathway affects translation fidelity

Translation fidelity can be thought of a competition between the cognate and near-cognate tRNAs for a given codon. It is conceivable that the increased translation speed under hyperactive mTORC1 signaling generates more error proteins via misreading of genetic codons. We analyzed two different aspects of translation fidelity: nonsense suppression and aa-tRNA selection. To evaluate nonsense suppression we constructed a pGL3-Luc vector with a stop codon at the coding region of Luc (Fig. 5). To evaluate the aa-tRNA selection we made a vector in which the AGA codon of Luc at aa218 was mutated to the near-cognate AGC codon. The R218 residue is a critical amino acid for Luc activity and this mutation potently reduces the luciferase activity. Measuring the Luc activity level of R218A mutant allows us to evaluate the rate of amino acid misincorporation at this position [15]. As expected, both Fluc(Stop) and Fluc(R218A) mutants showed less than 1% of enzymatic activities of the wild type Fluc. Despite such low expression levels, TSC2 KO cells showed an increase in Fluc activity for both Fluc(Stop) and Fluc(R218A) when compared to the wild type cells (2 fold and 1.5 fold increase, respectively) (Fig. 5). These results suggest that the ribosomes in cells with hyperactive mTORC1 signaling have a higher rate of altered aa-tRNA selection.
KEY RESEARCH ACCOMPLISHMENTS

- Genome-wide ribosome profiling reveals regulated post-initiation pausing
- Role of TOP sequence in post-initiation pausing
- Global mapping of alternative translation initiation using GTI-Seq
- GTI-seq reveals prevailing alternative translation
- TSC-mTORC1 increases the yield of protein synthesis at the expense of protein quality
- TSC-mTORC1 controls translational fidelity
REPORTABLE OUTCOMES

Publications:

Manuscript:

Liu B, Han Y, and Qian SB. Co-translational response to proteotoxic stress by early ribosome pausing. (in revision).

Conn CS and Qian SB. Nutrient signaling in protein homeostasis: an increase in quantity at the expense of quality. (in revision).
CONCLUSIONS

The observations described in this study have several implications. First, the critical role of TSC in ribosome dynamics and translation quality extends the molecular linkage between mTORC1 and protein homeostasis. Second, we find distinct roles for mTORC1 downstream targets in maintaining protein homeostasis. Loss of S6 kinases, but not 4E-BP family proteins, diminishes the effects of rapamycin on the quality of translational products. Third, the finding that an increase in protein synthesis is accompanied by a decrease in protein quality provides a plausible mechanism for how persistent mTORC1 signaling favors the development of age-related pathologies. With the most common feature of aging being an accumulation of misfolded proteins derived from erroneous biosynthesis and post-synthetic modification, protein homeostasis is an important mediator of rapamycin in longevity.

So this study expands our knowledge about the role of TSC-mTOR signaling in translational control of gene expression. The distinct roles for mTORC1 downstream targets in maintaining protein homeostasis reveal a mechanistic connection between mTORC1 and protein homeostasis.

Edited by Arthur L. Horwich, Yale University School of Medicine, New Haven, CT, and approved June 20, 2012 (received for review May 14, 2012)

How the ribosome-bound nascent chain folds to assume its functional tertiary structure remains a central puzzle in biology. In contrast to refolding of a denatured protein, cotranslational folding is complicated by the vectorial nature of nascent chains, the frequent ribosome pausing, and the cellular crowdedness. Here, we present a strategy called folding-associated cotranslational sequencing that enables monitoring of the folding competency of nascent chains during elongation at codon resolution. By using an engineered multidomain fusion protein, we demonstrate an efficient cotranslational folding immediately after the emergence of the full domain sequence. We also apply folding-associated cotranslational sequencing to track cotranslational folding of hemagglutinin in influenza A virus-infected cells. In contrast to sequential formation of distinct epitopes, the receptor binding domain of hemagglutinin follows a global folding route by displaying two epitopes simultaneously when the full sequence is available. Our results provide direct evidence of domain-wise global folding that occurs cotranslationally in mammalian cells.

Results and Discussion

During translation elongation, the positions of ribosomes on a given mRNA, and hence the length of the synthesized polypeptide chain, can be determined by deep sequencing of the ribosome-protected mRNA fragments (RPFs) (10, 11). FactSeq is based on enriching ribosomes bearing nascent chains with recognizable structural features, followed by sequencing of the associated RPFs. Direct comparison of RPF distribution before and after ribosome enrichment provides sequence-specific structural information associated with the nascent chain. To pilot this technique, we generated a HEK293 cell line stably expressing the flag-rapamycin binding domain (FRB) was fused to the NH2 terminus of GFP (Fig. 1). After collecting the ribosome fractions from the whole-cell lysates by sucrose gradient sedimentation, we converted polysomes to single ribosomes by RNase I treatment to digest mRNAs not protected by the ribosome. We enriched ribosomes bearing the NH2-terminal Flag-tagged nascent chain by immunoprecipitation (IP) using anti-Flag mAb-coated beads. After extracting Flag-tag-associated RPFs as well as total RPFs from the same sample, we constructed a cDNA library suitable for Illumina high-throughput sequencing (Fig. 1).

The sequencing results of RPFs obtained with or without Flag IP were of similar quality (Fig. S1). As expected, the majority of RPFs were approximately 30 nt in length. The 5’ end positions of RPF showed a strong 3-nt periodicity, confirming that the RPF accurately captures the ribosome movement along mRNAs. By using RPFs derived from the entire transcriptome, we built a ribosome density map on the Flag-FRB-GFP transcript (Fig. 2). Consistent with the nonuniform rates of translation elongation, the transcript was punctuated with multiple ribosome pausing sites with a skewed number of reads located at the start codon region. Notably, the linker region between FRB and GFP showed the least RPF reads, possibly because of our selection of commonly used codons in creating the construct. Over four independent RPF deep-sequencing replicates, the ribosome distribution pattern on individual transcripts was highly reproducible (Fig. S2).

As the NH2-terminal Flag tag is present at the start of the nascent chain, the Flag mAb-associated RPFs should capture nearly all the ribosome footprints during elongation. Alignment of RPF reads on Flag-FRB-GFP transcript before and after Flag IP revealed a nearly identical pattern of ribosome density except the first 50 codon region (Fig. 2, Lower). As ~40 aa of the}

The growing polypeptide chain are buried within the ribosome exit tunnel, this corresponds well to the minimal length of 10 aa required for antibody binding (i.e., the full length of Flag tag). Notably, there was little reduction of Flag IP-associated RPF reads relative to total RPFs along the remaining part of the transcript, indicating that the Flag tag remains intact during the synthesis of Flag-FRB-GFP. This argues that cotranslational degradation is minimal in this multidomain fusion protein. Thus, the FactSeq approach allows tracking of the behavior of nascent chains with high accuracy and sensitivity.

We next extended the FactSeq approach to evaluate cotranslational folding of the FRB domain before the complete synthesis of GFP. To probe the folding status of FRB domain, we took advantage of its binding partner FKBP (FK506 binding protein). The dimerization of FKBP and FRB relies on their 3D structures and the presence of rapamycin or rapalog (12, 13). As expected, recombinant FKBP synthesized in Escherichia coli specifically pull down the Flag-FRB-GFP fusion protein in a rapalog-dependent manner (Fig. S3). Thus, FKBP-rapalog can be used as a bait to probe the folding status of FRB before the full-length fusion protein is released from the ribosome. Consistent with the high specificity of rapalog-mediated FRB–FKBP interaction, very few RPF reads were recovered in the absence of rapalog (Fig. 2B). By contrast, adding rapalog selectively restored a significant number of RPFs starting at the 150 codon position of the Flag-FRB-GFP transcript. Given 10 aa from the Flag tag and 40 aa buried in the ribosome tunnel, the appearance of RPF reads after 150 codon position corresponds to the minimal length of 100 aa at which the FRB domain starts to create the rapalog binding site and associate with FKBP. Thus, FRB domain is able to fold when the corresponding amino acid sequence immediately emerges from the ribosome.

Fig. 1. Schematic for FactSeq approach. The polysomes from HEK293/Flag-FRB-GFP are converted into monosome by RNase I treatment, followed by IP using anti-Flag or recombinant FKBP in the presence or absence of rapalog. The RPFs are extracted and mixed with spike-in control before cDNA library construction. The deep sequencing results of RPFs are analyzed by transcriptome mapping. (Inset) Circle depicts structure of FKBP (blue, PDB 1A7X) and FRB (red, PDB 1AUE) dimerization in the presence of rapamycin (green).

Fig. 2. Monitoring cotranslational behavior of Flag-FRB-GFP polypeptide in mammalian cells. (A) Comparison of RPF distribution on Flag-FRB-GFP transcript before and after anti-Flag IP. Both the total and Flag IP-associated RPFs are aligned based on the sequence position of Flag-FRB-GFP. Lower: Pattern analysis using single codon peak ratio (dot plot) and significance (P value) of RPF density vs. background in a 10-codon sliding window (field plot). The line plot represents the LOESS-smoothed trend line for single codon peak ratio (sampling proportion, 0.2). The colored areas represent regions of nascent chains that inaccessible to anti-Flag antibody. Cutoff line was set at \( P = 0.001 \) (green dashed line). (B) Comparison of RPF distribution on Flag-FRB-GFP transcript before and after FKBP affinity purification. (Upper) Alignment of RPFs associated with total and FKBP binding in the presence or absence of rapalog. Lower: Pattern analysis using single codon peak ratio (dot plot) and significance (P value) of RPF density vs. background in a 10-codon sliding window (field plot). The line plot represents the LOESS-smoothed trend line for single codon peak ratio (sampling proportion, 0.2). The colored areas represent regions of nascent chains inaccessible to FKBP. Cutoff line was set at \( P = 0.001 \) (green dashed line).
Fig. 3. Monitoring cotranslational folding of HA in influenza A-infected cells. (A) Epitope sites on the RBD domain of HA. The structure of monomeric HA is shown as a ball-and-stick model with HA1 in light brown and HA2 in light blue (PDB 1RU7). The Sa site recognized by Y8-10C2 is shown in red, whereas the Sb site by H28-E23 is dark blue. The RBD domain is identified from R53 to E276. (B) Comparison of RPF distribution on HA transcript derived from PR8 H1N1 influenza A before and after IP. Polysome fractions were prepared from influenza A-infected HeLa cells. IP was performed by using a panel of antibodies, followed by deep sequence of RPFs. Lower: Pattern analysis after IP with Y8-10C2 (red) and H28-E23 (blue) using single codon peak ratio (dot plot) and significance (P value) of RPF density vs. background in a 10-codon sliding window (field plot). The line plot represents the LOESS-smoothed trend line for single codon peak ratio (sampling proportion, 0.2). The colored areas represent regions of nascent chains inaccessible to antibodies. Cutoff line was set at P = 0.001 (green dashed line). (C) Comparison of RPF distribution on HA transcript derived from CV1 mutant that escapes the Y8-10C2 recognition. Lower: Pattern analysis after IP with H28-E23 (blue) using single codon peak ratio (dot plot) and significance (P value) of RPF density vs. background in a 10-codon sliding window (field plot). The line plot represents the LOESS-smoothed trend line for single codon peak ratio (sampling proportion, 0.2). Cutoff line was set at P = 0.001 (green dashed line). (D) A model of domain-wise global folding of the HA nascent chain attached to the ribosome. Rapid cotranslational folding occurs only after the full RBD domain sequence is available. The blue ovals represent possible binding partners of nascent chains, such as molecular chaperones.
Intriguingly, there was a significant reduction of FKBP-associated RPF reads after 200 codon position of the Flag-FRB-GFP transcript relative to total RPFs \( (P = 6.256 \times 10^{-5}; \text{Fig. 2B, Lower}) \). We cannot attribute this to cotranslational degradation, because the NH2-terminal Flag tag was continuously present (Fig. 2D). Rather, the appearance of GFP polypeptide could partially prevent folded FRB from interacting with FKBP, possibly by associating molecular chaperones or other binding partners (5).

Having successfully monitored the cotranslational folding of FRB domain, we next applied FactSeq to evaluate the cotranslational folding process of influenza A hemagglutinin (HA). Influenza presents a serious public health challenge, and HA is a prime candidate for vaccine design and drug development (14). HA is a type I transmembrane glycoprotein with multiple folding domains. The protein is cotranslationally glycosylated in the endoplasmic reticulum. After posttranslational trimerization, the HA trimer then traffics to the cell surface. The crystal structure of HA reveals a globular ectodomain sitting atop an extended stalk (Fig. 3A). The HA mediates attachment to cells via its receptor binding site in the ectodomain (i.e., receptor-binding domain (RBD)), which also contains most of the epitopes for neutralizing antibody recognition (15). All known neutralizing anti-HA mAbs recognize conformational determinants, i.e., their epitopes are formed by folding of the primary sequences. For instance, the Y8-10C2 mAb recognizes an epitope on the HA comprising residues from E158 to Y168 [Puerto Rico/8/34 (PR8)], whereas the H28-E23 epitope is principally formed by residues from N187 to E198 (16) (Fig. 3A). As these mAbs are capable of binding HA monomers based on local folding of their respective domains, we used them to probe cotranslational formation of distinct epitopes during the biosynthesis of HA. As a negative control, we used the H17-L2 mAb, whose binding is dependent on trimerization, as its epitope is formed by residues on each side of the trimer interface (17).

We purified ribosomes 5 h after viral infection of HeLa cells with PR8 (Fig. S4). The ribosome fractions were then immunoprecipitated using each of the mAbs followed by deep sequencing of RPFs. Total RPF reads aligned to the full length of HA transcript exhibited typical pausing sites (Fig. 3B). Trimer-specific H17-L2 set the background level of reads. In contrast, both Y8-10C2 and H28-E23 recovered a large number of RPFs over background. Thus, FactSeq could be used to investigate the cotranslational folding of endoplasmic reticulum proteins. Intriguingly, Y8-10C2 exhibited an almost 110-codon delay in the appearance of RPFs relative to the emergence of its epitope (Fig. 3A). These results indicate that Y8-10C2 and H28-E23 epitopes are not formed sequentially. Although we could not exclude the possibility of mAb binding-induced nascent chain folding, our previous study suggests that it is unlikely for such an event to contribute to the specific RPFs revealed by FactSeq (15). First, refolding of denatured HA by antibody binding occurs over days, not within 1 h. Second, mAb binding-induced HA folding, if rapid, would lead to continuous enrichment of mAb-associated RPFs along with elongation. However, similar to cotranslational folding of the FRB domain, the HA exhibited reduced accessibility of Y8-10C2 after its initial epitope formation. The discontinuous antibody accessibility to the continuously elongated nascent chain could represent a previously unrecognized feature of cotranslational folding pathway. Thus, the coappearance of distinct epitopes after the full ectodomain is available is consistent with a model of global folding pathway that occurs rapidly when the RBD sequence has emerged from the ribosome (Fig. 3D).

To validate the cotranslational folding propensity of HA revealed by FactSeq, we performed \[^{35}S\]methionine pulse-chase of influenza A virus-infected cells coupled with IP. Pulse-chase was performed at 20 °C to slow down elongation and trimerization of HA polypeptides. Y8-10C2 recovers HA fragments in addition to the full-length polypeptide. In contrast, HA trimer-specific antibody H17-L2 recovers only full-length HA. Y8-10C2-binding fragments completely resolve during the chase into full-length HA, demonstrating a precursor–product relationship and indicative of the ability of HA fragments to generate the Y8-10C2 conformational epitope (Fig. S5A). Remarkably, the pattern of HA fragments matches well with that revealed by FactSeq (Fig. S5B). For instance, the smallest fragment from each assay was approximately 30 kDa. Despite relatively low resolution, pulse labeling analysis confirms the discontinuous nature of mAb binding during elongation. These data support the conclusion that the high resolution pattern offered by FactSeq represents the true behavior of nascent chain synthesis.

We next asked how mutation of an epitope affects the default folding pathway of the HA globular domain. To this end, we chose a PR8 escape mutant CV1, whose single K165E substitution reduces Y8-10C2 avidity more than 100-fold (18) (Fig. S6). Only background levels of RPF reads were recovered by Y8-10C2 from CV1, providing an important confirmation of the specificity of the FactSeq method (Fig. 3C). Interestingly, whereas CV1 maintained the similar codon lag as WT HA in the generation of H28-E23 epitope, the full extent of epitope formation was delayed, indicating that the single K165E substitution alters the kinetics of the cotranslational folding of HA (Fig. 3C and D).

Conclusion

It is widely believed that cotranslational folding is a universal feature of newly synthesized polypeptides (1, 2). However, monitoring this dynamic process is challenging, in particular inside mammalian cells. By harnessing the power of the ribosome profiling technique with the folding-sensitive affinity reagents, FactSeq provides a unique view of the folding competency of the nascent chain during its elongation. The acquisition of the functional FRB and the HA RBD immediately after their sequences emerge from the ribosome exit tunnel strongly favors a domain-wise global folding pathway. Despite the limitations of FactSeq in providing real-time kinetics of folding pathway, the snapshot taken by FactSeq consists of continuous frames of ribosomes with varied length of nascent chains. FactSeq also requires folding-sensitive affinity reagents to capture specific folding status of ribosome-attached nascent chains. With the increasing number of available conformation-specific antibodies or binding factors for various gene products (19), FactSeq is readily applicable to endogenous proteins thanks to the high throughput of deep sequencing that covers the entire transcriptome. In addition, taking advantage of the intrabodies that are designed to be expressed intracellularly (20, 21), FactSeq has the potential to capture cotranslational folding in live cells before cell lysis. Beyond cotranslational folding, the prototype of FactSeq can also be applied to other cotranslational events. For instance, by using an NH2-terminal tag, the same concept can be adapted to investigate cotranslational degradation by comparing the loss, rather than the gain, of RPFs. Finally, FactSeq can also be expanded to study cotranslational chaperone interaction with nascent chains (7, 22). The applicability of FactSeq is not limited to studying cotranslational events. The basic principle can be used to design in vivo folding reporter to investigate cellular factors influencing cotranslational folding. We envision that this
approach will provide novel insights into protein triage decisions under physiological as well as pathological conditions.

Materials and Methods

Cells and Reagents. HEK293 cells stably expressing Flag-FRB-GFP were maintained in DMEM with 10% (vol/vol) FBS. Rapalog AP21967 was provided by Aried. Anti-Flag and anti-HA antibodies were purchased from Sigma, and protein A/G beads from Santa Cruz. TRIzol reagent was purchased from Invitrogen.

Influenza A Infection. HELa cells were infected with Influenza A/PR8 strain at a multiplicity of 20 pfu/cell in A50 medium, pH 6.6. After adsorption at 37 °C for 1 h, infected monolayers were overlaid with DMEM containing 7.5% FBS, and incubated for an additional 5 h.

Ribosome Profiling. Sucrose solutions were prepared in polyisum gradient buffer [10 mM Hepes, pH 7.4, 100 mM KCl, 5 mM MgCl2, 100 µM glycine, 5 mM DTT, and 20 mU Superase In (Ambion)]. Sucrose density gradients [15–45% (wt/vol)] were freshly made in SW41 ultracentrifuge tubes (Fisher) using a BioCimp Gradient Master (BioCimp) according to the manufacturer’s instructions. HEK293/Flag-FRB-GFP cells were plated to four 10-cm dishes before ribosome profiling. Cells were first treated with cycloheximide (100 µg/mL) for 3 min at 37 °C to freeze the translating ribosomes, followed by ice-cold PBS solution wash. Cells were then harvested by ice-cold polyisum lysis buffer [10 mM Hepes, pH 7.4, 100 mM KCl, 5 mM MgCl2, 100 µg/mL cycloheximide, 5 mM DTT, 20 mU Superase In, and 2% (vol/vol) Triton X-100]. After centrifugation at 4 °C and 10,000 × g for 10 min, approximately 65% of supernatant was loaded onto the holo ribosome gradients followed by centrifugation at 100,000 × g for 120 min at 4 °C. The ribosomal pellets were then washed with 4% BSA for 1 h. The mAb-coated beads were then incubated with the precleared ribosome samples at 4 °C for 1 h, followed by washing with polyisum lysis buffer for three times. For KFB binding assay, 20 µg recombinant HA-FKB proteins purified from E. coli (BL21) were first immobilized on protein A/G beads using anti-HA antibody. After blocking with 4% BSA for 1 h, the beads were then incubated with the precleared ribosome samples at 4 °C for 1 h in the absence or presence of 1 µM rapalog. After washing with polyisum lysis buffer three times, total RNA extraction was performed by using TRIzol reagent.

cDNA Library Construction of Ribosome-Protected mRNA Fragments. Purified RNA samples were first mixed with 1 nM of synthetic 28-nt random RNA (5′-AUGUAUAcGGAGGACGGACGCAGACGGCATACGATTTTTTTTTTTTTTTTTTTTVN-3′; HT025, 5′-pTCGATCGTCGGACTGTAGACGTTCAACGTACAGGAGGCTATACGATTTTTTTTTTTTTTTTTTTTTTVN-3′). In brief, the tail RNA product was mixed with 0.5 µM dNTP and 2.5 µM synthesized primer and the gel was incubated at 65 °C for 5 min, followed by incubation on ice for 5 min. The reaction mix was then added with 20 mM Tris (pH 8.4), 50 mM KCl, 5 mM MgCl2, 10 mM DTT, 40 mU RNaseOUT, and 100 U SuperScript III (Invitrogen). RT reaction was performed according to the manufacturer’s instructions. RNA was eliminated from cDNA by adding 1.8 µL of 1 M NaOH and incubating at 98 °C for 20 min. The reaction was then neutralized with 1.8 µL 1 M HCl. Reverse transcription products were separated on a 10% polyacrylamide TBE-urea gel as described earlier. The extended first-strand product band was expected to be approximately 100 nt, and the corresponding region was excised. The cDNA was recovered by using DNA gel elution buffer (300 mM NaCl, 1 mM EDTA).

First-strand cDNA was normalized in 20 µL of reaction containing 1× Circularise buffer, 2.5 mM MnCl2, 1 M Betaine, and 100 U Circilgase II (Epicone). Circularization was performed at 60 °C for 1 h, and the reaction was heat-inactivated at 80 °C for 10 min. Circular single-strand DNA was relinearized with 20 mM Tris-accept, 50 mM potassium acetate, 10 mM magnesium acetate, 1 mM DTT, and 7.5 U APE 1 (NEB). The reaction was carried out at 37 °C for 1 h. The linearized single-strand DNA was separated on a Novex 10% polyacrylamide TBE-urea gel (Invitrogen) as described earlier. The expected 100-nt product bands were excised and recovered as described earlier.

Deep Sequencing. Single-stranded template was amplified by PCR by using the Phusion High-Fidelity enzyme (NEB) according to the manufacturer’s instructions. The oligonucleotide primers qNTI200 (5′-CAAGAGAAAGCCGCACTA-3′) and qNTI201 (5′-AATGCATCGGGCCACCGACAGTTCCAGTCGACACG-3′) were used to create DNA suitable for sequencing, i.e., DNA with Illumina cluster generation sequences on each end and a sequencing primer binding site. The PCR contains 1× HF buffer, 0.2 mM dNTP, 0.5 µM oligonucleotide primers, and 0.5 U Phusion polymerase. PCR was carried out with an initial 30 s denaturation at 98 °C, followed by 12 cycles of 10 s denaturation at 98 °C, 20 s annealing at 60 °C, and 10 s extension at 72 °C. PCR products were separated on a nondenaturing 8% polyacrylamide TBE gel as described earlier. Expected DNA at 120 bp was excised and recovered as described earlier. After quantification by Agilent BioAnalyzer DNA 1000, equal amount of barcoded samples were pooled to a single lane. Approximately 3–5 pm mixed DNA samples were used for cluster generation following by sequencing using sequencing primer 5′-CAAGAGGTCGA- GAGTTCCACAGTCCGACGACTG-3′ (Illumina Genome Analyzer 2 or HiSeq).

Data Analysis. The deep sequencing data of ribosome footprints was processed and analyzed by using a collection of custom Perl scripts. The barcoded multiplex sequencing output files were separated into individual sample datasets according to the first 2-nt barcodes. Second, the 3′ polyA tails allowing one mismatch were identified and removed. After that, the high-quality reads of length ranging from 25 to 35 nt were retained whereas other reads were excluded from the downstream analysis. The sequences of the longest transcript isoform for each human gene were downloaded from the Ensembl database to construct a human transcriptome reference. In addition, the sequence of the 5′-UTR of barcoded samples from the National Center for Biotechnology Information database and the plasmid sequence of Flag-FRB-GFP were used as the reference. The trimmed reads were aligned to the corresponding reference transcripts by SOAP 2.0, allowing as many as two mismatches, and only unique mapping hits were retained. Last, the 5′ end positions of aligned reads were mapped into the coding frame and the number of reads was counted at each codon ranging from −20 codon 5′ UTR to the stop codon for the downstream analysis. The reproducibility of the RPF distribution on individual transcripts was evaluated by Pearson correlation. The replicates were clustered by Cluster 3.0, and heat maps were produced by Treeview. To compare the RPF distribution on transcript before and after the affinity purification, the reads in the first 30-codon window were considered as the background because the poly-peptides are still buried within the ribosome exit tunnel and cannot be accessed by binding partners. The significance (i.e., P value) of the RPF density vs. background within a 10-codon sliding window in the pull-down sample was calculated by Fisher exact test across the transcripts compared with the total sample. The first position at which the P value was less than 0.001 was considered as the folding start point. Based on the number of reads after the folding start point, the total and pull-down data were normalized to the same scale. To control the counting error, only the positions with reads above the mean reads density in the total sample were treated as comparable sites. Subsequently, the single codon peak ratio was calculated by dividing the normalized reads of pull-down sample to those of total
sample at the same codon. The trend line of the single codon peak ratio was determined by locally estimated scatterplot smoothing (LOESS) by using SigmaPlot 11.0 (Systat).

ACKNOWLEDGMENTS. The authors thank the Cornell University Life Sciences Core Laboratory Center for performing deep sequencing and Dr. Yuxin Mao for help in preparing the hemagglutinin structure shown in Fig. 3A.
