A Minimum-Residual Finite Element Method for the Convection-Diffusion Equation

by

Jesse Chan and John A. Evans
We present a minimum-residual finite element method for convection-diffusion problems in a higher order, adaptive, continuous Galerkin setting. The method borrows concepts from both the Discontinuous Petrov-Galerkin (DPG) method by Demkowicz and Gopalakrishnan [1] and the method of variational stabilization by Dahmen et al. [2], and it can also be interpreted as a variational multiscale method in which the fine-scales are defined through a dual-orthogonality condition. A key ingredient in the method is the proper choice of norm used to measure the residual, and we present two alternatives which are observed to be robust in both convection and diffusion-dominated regimes. Numerically obtained convergence rates are given in 2D, and benchmark numerical examples in all space dimensions are shown to illustrate the behavior of the method.
A MINIMUM-RESIDUAL FINITE ELEMENT METHOD FOR THE CONVECTION-DIFFUSION EQUATION
JESSE CHAN, JOHN A. EVANS

Abstract. We present a minimum-residual finite element method for convection-diffusion problems in a higher order, adaptive, continuous Galerkin setting. The method borrows concepts from both the Discontinuous Petrov-Galerkin (DPG) method by Demkowicz and Gopalakrishnan [1] and the method of variational stabilization by Dahmen et al. [2], and it can also be interpreted as a variational multiscale method in which the fine-scales are defined through a dual-orthogonality condition. A key ingredient in the method is the proper choice of norm used to measure the residual, and we present two alternatives which are observed to be robust in both convection and diffusion-dominated regimes. Numerically obtained convergence rates are given in 2D, and benchmark numerical examples in all space dimensions are shown to illustrate the behavior of the method.

1. Introduction. It is well known that the standard Galerkin finite element method performs very poorly for the convection-diffusion equation – in the convection-dominated case, it experiences spurious oscillations in the solution that grow as $\epsilon \to 0.$ The problem is connected back to a loss of discrete coercivity with respect to the standard $H^1$ norm [3]. The concept of stabilized methods was introduced in order to combat such oscillations, the most popular of which is the Streamline Upwind Petrov-Galerkin (SUPG) method [4]. The method can be interpreted as adding a sufficient amount of artificial viscosity in the streamline direction in order to restore discrete coercivity with respect to a new “streamline-diffusion” norm [5]. SUPG is also an example of a residual-based stabilization, where the stabilization mechanism disappears as the strong residual of the equation is satisfied.

A connection can be drawn between residual-based stabilized methods and Petrov-Galerkin schemes, where the trial (approximating) functions and test (weighting) functions are allowed to differ. Specifically, the SUPG method can be interpreted as a modification of standard test functions\(^1\), biasing them in the upwind direction based on mesh size, order of polynomial approximation, the magnitude of convection, and the diffusion parameter. More recently, the concept of Petrov-Galerkin methods has been connected to a novel minimum residual framework – it is shown that the minimization of a specific residual corresponding to a variational formulation naturally leads to the concept of optimal test functions [6].

Optimal test functions resulting from residual minimization were first implemented by Demkowicz and Gopalakrishnan in [1, 7]. The connection between stabilization and least squares/minimum residual methods has been observed previously [8]; however, the DPG method distinguishes itself by measuring the residual of the operator form of the equation, which is posed in the dual space. Soon after, Cohen, Dahmen and Welper introduced an alternative saddle-point formulation of such a minimum residual method in [2], which alluded to a Variational Multiscale (VMS) perspective [9, 10, 11].

The goal of this paper is three-fold. The first is to present a method which borrows concepts from each of these recent works and to derive a more detailed connection between the Petrov-Galerkin, stabilized, and VMS perspectives of minimum-residual methods. The second is to demonstrate that the proposed method is robust in both convection and diffusion-dominated regimes provided the dual norm used to measure the residual is chosen intelligently. The last goal is to show that the method is stable for arbitrary higher order and adaptive meshes, easily implemented using existing finite element codes and technologies, and extendable to three-dimensional convection-diffusion problems.

2. A minimum-residual method. Our starting point is the minimization of some measure of error over a finite-dimensional space. We begin by first introducing an abstract variational formulation

$$\begin{cases}
\text{Given } l \in V^*, \text{ find } u \in U \text{ such that } \\
b(u, v) = l(v), \quad \forall v \in V,
\end{cases} \tag{2.1}$$

\(^1\)We note that one cannot recover the SUPG formulation beginning with the strong form of the equations and the SUPG test functions; the interpretation of SUPG as a Petrov-Galerkin scheme holds only locally, on element interiors.
where \( b(\cdot, \cdot) : U \times V \to \mathbb{R} \) is a continuous bilinear form. Throughout the paper, we assume that the trial space \( U \) and test space \( V \) are real Hilbert spaces, and denote \( U^* \) and \( V^* \) as the respective topological dual spaces. Throughout the paper, we suppose the variational problem (2.1) to be well-posed in the inf-sup sense. We can then identify a unique operator \( B : U \to V^* \) such that

\[
\langle Bu, v \rangle_{V^* \times V} := b(u, v), \quad u \in U, v \in V
\]

with \( \langle \cdot, \cdot \rangle_{V^* \times V} \) denoting the duality pairing between \( V^* \) and \( V \), to obtain the operator form of the our variational problem

\[
(2.2) \quad Bu = l \quad \text{in } V^*.
\]

We are interested in minimizing the residual over the discrete approximating subspace \( U_h \subset U \)

\[
u_h = \arg \min_{u_h \in U_h} J(u_h) := \frac{1}{2} \|l - Bu_h\|^2_{V^*} := \frac{1}{2} \sup_{v \in V \setminus \{0\}} \frac{|l(v) - b(u_h, v)|^2}{\|v\|^2_{V}}.
\]

For convenience in writing, we will abuse the notation \( \sup_{v \in V} \) to denote \( \sup_{v \in V \setminus \{0\}} \) for the remainder of the paper. If we define the problem-dependent energy norm

\[
\|u\|_E := \|Bu\|_{V^*},
\]

then we can equate the minimization of \( J(u_h) \) with the minimization of error in \( \|\cdot\|_E \).

The first order optimality condition for minimization of the quadratic functional \( J(u_h) \) requires the Gâteaux derivative to be zero in all directions \( \delta u \in U_h \),

\[
(2.3) \quad (l - Bu_h, B\delta u)_{V^*} = 0, \quad \forall \delta u \in U,
\]

which is nothing more than the least-squares condition enforcing orthogonality of error with respect to the inner product on \( V \).

The difficulty in working with the first-order optimality condition (2.3) is that the inner product \( \langle \cdot, \cdot \rangle_{V^*} \), cannot be evaluated explicitly. However, we have that

\[
(l - Bu_h, B\delta u)_{V^*} = (R_{V^*}^{-1}(l - Bu_h), R_{V^*}^{-1}B\delta u)_{V^*},
\]

where \( R_V : V \to V^* \) is the Riesz map mapping elements of a Hilbert space \( V \) to elements of the dual \( V^* \) defined by

\[
\langle R_V v, \delta v \rangle_{V^* \times V} := \langle v, \delta v \rangle_V.
\]

Furthermore, the Riesz operator is an isometry, such that \( J(u_h) = \frac{1}{2} \|l - Bu_h\|^2_{V^*} = \frac{1}{2} \|R_{V^*}^{-1}(l - Bu_h)\|^2_{V} \).

Thus, satisfaction of (2.4) is exactly equivalent to satisfaction of the original optimality conditions (2.3).

2.1. Saddle point formulation. We can translate the optimality conditions (2.4) into a more standard variational problem. First, given some finite dimensional solution \( u_h \in U_h \), we define the error representation function \( e \) such that

\[
\langle e, v \rangle_V = l(v) - b(u_h, v), \quad \forall v \in V.
\]

We recognize this condition as defining \( R_V e = l - Bu_h \); inversion of the Riesz map gives us

\[
e = R_{V^*}^{-1}(l - Bu_h) = R_{V^*}^{-1}B(u - u_h),
\]

from which we can see that \( \|e\|_V = \|u - u_h\|_E \).

Secondly, we need to enforce the orthogonality of the error in equation (2.4), which becomes

\[
\langle e, R_{V^*}^{-1}B\delta u \rangle_V = 0, \quad \forall \delta u \in U_h
\]

\[
\Rightarrow \langle e, B\delta u \rangle_{V^* \times V} = b(\delta u, e) = 0.
\]
Putting these two conditions returns the symmetric saddle-point problem for \((e, u_h) \in V \times U_h\)

\[
(e, v)_V + b(u_h, v) = l(v), \quad \forall v \in V \\
b(\delta u, e) = 0, \quad \forall \delta u \in U_h.
\]

We note that, under the perspective of the minimization of \(J(u_h)\), this system can be viewed as a constrained optimization problem for \(e\), where \(u_h\) are Lagrange multipliers enforcing satisfaction of the variational problem.

At the moment, \(V\) remains an infinite-dimensional space, and will have to be discretized by some \(V_h \subset V\) in order to yield a solution. Under this infinite dimensional setting, the choice of discretization for \(V\) will determine how effectively the solution of the discrete problem will minimize \(J(u_h)\) – inadequate resolution of \(V_h\) may result in a solution which is far from the true minimizer.

\[ \text{Fig. 2.1. Saddle point system for minimization of } J(u_h); \text{ the Schur complement eliminating degrees of freedom for } e \text{ returns the system resulting from optimal test functions.} \]

This formulation was first introduced by Dahmen et al. in [2], where \(V_h\) was determined adaptively. The method proceeded in two steps – first, \(V_h\) was set equal to \(U_h\) on what we will define as the coarse mesh. Next, a posteriori error estimators for \(e\) (based on a specific choice of inner product \((\cdot, \cdot)_V\)) were used to drive adaptivity to determine a fine-scale mesh on which \(V_h\) was supported. We choose a simpler representation – if \(U_h\) is represented by piecewise polynomials of order \(p\), we set \(V_h\) to be piecewise polynomials of order \(p + \Delta p\). We note that these two choices of discretization for \(V\) are not mutually exclusive, and that novel choices for \(V_h\) are likely the key to yielding computationally effective methods under this framework.

2.2. DPG optimal test function framework. The DPG method was introduced by Demkowicz and Gopalakrishnan in 2009, and rapidly applied to a series of problems in computational mechanics [1, 12, 13, 14, 15]. Though the DPG method shares the same variational setting as Dahmen et al. each method followed very different approaches in implementation. Recall the orthogonality of error (2.4); by defining the error representation function \(e\) and undoing the Riesz map acting on \(B \delta u\), we recovered a saddle point formulation. However, it is possible to instead undo the Riesz map acting on the residual instead, to recover

\[
(R^{-1}_V (l - B u_h), R^{-1}_V B \delta u)_V = 0, \quad \forall \delta u \in U_h \\
\Rightarrow (l - B u_h, R^{-1}_V B \delta u)_V = 0 \\
\Rightarrow l (R^{-1}_V B \delta u) - b(u_h, R^{-1}_V B \delta u) = 0
\]

If we define \(v_{\delta u} := R^{-1}_V B \delta u\), then we recover the original variational formulation with a non-standard test space

\[
b(u_h, v_{\delta u}) = l(v_{\delta u}), \quad \forall \delta u \in U_h.
\]
The DPG method with optimal test functions was constructed under this perspective of mini-
mization of $J(u_h)$. While $v_{\delta u} \in V$ must still be solved for approximately, under the assumption
of discontinuous test functions, this solve can be localized to a single element.\(^2\)

We can draw yet another connection to the DPG method by considering the discrete problem
which arises from the saddle point formulation. Our discrete saddle point system is

$$
\begin{bmatrix}
A & B \\
B^T & 0
\end{bmatrix}
\begin{bmatrix}
e \\
u
\end{bmatrix}
=
\begin{bmatrix}
f \\
0
\end{bmatrix},
$$

where, for $u_j \in U_h$ and $v_i, v_j \in V_h$,

$$A_{ij} := (v_i, v_j)_V, \quad B_{ij} := b(u_j, v_i),$$

such that $A$ is a square matrix and $B$ is an overdetermined rectangular matrix. Expressing $e = A^{-1} (f - Bu)$ allows us to statically condense out the degrees of freedom $e$ to form the Schur complement

$$B^T A^{-1} Bu = B^T A^{-1} f.$$

The above system is essentially an algebraic least squares system, but preconditioned on the inside with the positive-definite operator $A$, which is precisely the discrete system that arises under the optimal test function framework of DPG. We can see this further by noting that

$$(A^{-1} B)^T B u = (A^{-1} B)^T f$$

is equivalent to

$$b \left( u_h, \sum_k v_{ik} \phi_k \right) = l \left( \sum_k v_{ik} \phi_k \right), \quad i = 1, \ldots, \dim(U_h)$$

where $v_{ik} = (A^{-1} B)_{ik}$ are the degrees of freedom associated with the $i$th approximated optimal test function.

The efficiency of the DPG method lies in that, under the assumption of a localizable norm and optimal test functions, $A$ is block diagonal and can be inverted locally \([6]\). Under the ultra-weak formulation of DPG, one can show that this corresponds exactly to choosing a non-conforming DG space for $V$, where continuity is enforced weakly at element interfaces by requiring that the jump be orthogonal to polynomials of order $p$ \([16]\).\(^3\)

### 2.3. Variational Multiscale Framework

The above saddle point system can also be directly derived from variational multiscale (VMS) principles \([9, 10]\). The key difference between this and standard multiscale methods is the way in which the fine scales influence the coarse; approximating the fine-scale problem is as difficult as approximating the original equation, so analytic approximations or assumptions must typically be made. However, through the proper change of variables, this method converts the fine-scale problem into a symmetric-positive definite one, allowing for a well-behaved subgrid model of fine scale behavior.

We begin again with the variational problem

$$\langle Bu, v \rangle_{V^*, V} = \langle l, v \rangle_{V^*, V},$$

where, as before, $B : U \to V^*$ is the operator form of $b(u, v)$, and $l \in V^*$ is the load. Standard VMS techniques then decompose $U$ into a coarse scale space $U_h$ and fine scale space $U'$, such

\(^2\)In practice, if $U_h(K) = P^p(K)$ is the space of polynomials of order $p$ over the element $K$, then the enriched space $V_h(K)$ is chosen to be $\mathcal{V}_h(K) = P^{p+\Delta p}(K)$, where $\Delta p \geq n$, and $d$ is the spatial dimension.

\(^3\)Such a weakly conforming method was first introduced in \([17]\), where optimal rates of convergence were proved under the assumption that the DG space is at most of order $p+1$.\(^4\)
that the coarse and fine scales $u_h \in U_h \subset U$ and $u' \in U'$ are related through some yet-unspecified orthogonality condition. Decomposing $u = u_h + u'$ gives
\[
  \langle Bu_h, v \rangle_{V^* \times V} + \langle Bu', v \rangle_{V^* \times V} = \langle l, v \rangle_{V^* \times V}
\]
where $U = U_h \oplus U'$. We can now explicitly choose our orthogonality condition defining the fine scales and rewrite the above problem as
\[
  u_h \in U_h, u' \in U, v \in V
  \langle Bu_h, v \rangle_{V^* \times V} + \langle Bu', v \rangle_{V^* \times V} = \langle l, v \rangle_{V^* \times V}
  (u', \bar{w})_E = 0, \quad \forall \bar{w} \in U_h,
\]
where $(u', \bar{w})_E$ is defined through
\[
  (u', \bar{w})_E = (Tu', T\bar{w})_V
  \quad T : U \to V, \quad T := R_V^{-1}B
\]
where $(v, \delta v)_V$ is an inner product on $V$ and $R_V$ is the Riesz map associated with this inner product. DPG literature refer to $T$ as the trial-to-test operator, which, given a basis function $\phi_i \in U_h$, returns the optimal test function for $\phi_i$ [1].

If we define our fine-scale using the above orthogonality condition, we have that
\[
  (Tu', v)_V = (R_V^{-1}Bu', v)_V = (Bu', v)_V
  (u', \bar{w})_E = (Tu', R_V^{-1}B\bar{w})_V = (Tu', B\bar{w})_{V \times V^*}
\]
and can now rewrite our above VMS formulation as
\[
  u_h \in U_h, u' \in U, v \in V
  \langle Bu_h, v \rangle_{V^* \times V} + (Tu', v)_V = \langle l, v \rangle_{V^* \times V}
  (Tu', B\bar{w})_{V \times V^*} = 0, \quad \forall \bar{w} \in U_h.
\]
The saddle point formulation of Section 2.1 can be interpreted as solving not for $u'$, but for $e := Tu'$. The discrete approximation then follows directly from setting $V := V_h$, some finite-dimensional enriched space, which impacts the method only through the approximation of $Tu'$ and the construction of the Riesz map $R_V^{-1}$.

To summarize, the minimum-residual framework motivating both Dahmen’s variational stabilization and Demkowicz and Gopalakrishnan’s DPG method can be characterized as a VMS method under which
\begin{itemize}
  \item Orthogonality of $U_h$ and $U'$ is defined through a nonstandard energy inner product (i. e. $(u', u_h)_E = 0$), and
  \item A change of variables (i. e. solving for $Tu'$ instead of $u'$) symmetrizes the fine-scale contribution and overall system.
\end{itemize}

3. Choices for test norms. As with the DPG method, the primary theoretical difficulty is in defining the norm $\|v\|_V$ such that the method returns good results. This choice of norm defines the measure of the residual which we minimize or the orthogonality condition defining the separation of coarse and fine scales, depending upon whether you adopt the minimum-residual or VMS perspective.

From this point on, we will focus specifically on $H^1$ standard Galerkin formulation for the scalar convection-diffusion problem on domain $\Omega$
\[
  \nabla \cdot (\beta u) - \epsilon \Delta u = f,
\]
which represents the convection of some quantity \( u \) subject to a convection field \( \beta \in \mathbb{R}^n \) and diffusion of magnitude \( \epsilon \in \mathbb{R} \), where \( \epsilon > 0 \). We impose inflow and outflow boundary conditions

\[
\begin{align*}
    u|_{\Gamma_{\text{in}}} &= u_{\text{in}} \\
    u|_{\Gamma_{\text{out}}} &= u_{\text{out}}
\end{align*}
\]

where the following boundaries are defined as

\[
\begin{align*}
    \Gamma_{\text{in}} &:= \{ x \in \partial \Omega \text{ s.t. } \beta \cdot \vec{n}(x) < 0 \} \\
    \Gamma_{\text{out}} &:= \{ x \in \partial \Omega \text{ s.t. } \beta \cdot \vec{n}(x) > 0 \}
\end{align*}
\]

where \( \vec{n}(x) \) is the outward normal at a point on the boundary \( \partial \Omega \). If it is non-empty, we may also define \( \Gamma_{0} := \{ x \in \partial \Omega \text{ s.t. } \beta \cdot \vec{n}(x) = 0 \} \) as the boundary with outward normal orthogonal to the streamline.

Under \( u, v \in H^1_0(\Omega) \), Our weak formulation becomes

\[
(\nabla u, \beta v + \epsilon \nabla v)_{L^2(\Omega)} = (f, v)_{L^2(\Omega)}.
\]

A norm based on the symmetric part of the bilinear form was explored in [2], but yielded approximations which degnerated in \( \epsilon \). We present here two different methods based on alternative choices for test norms on \( V \) for the convection-diffusion equation that both yield good results as \( \epsilon \to 0 \).

3.1. Weighted streamline diffusion norm. Our first method is motivated by previous results for the DPG method in [18], which achieved good results through a modification of the test norm. We set

\[
\| v \|_{V,w}^2 := \frac{L}{|\beta|} \| \sqrt{w} \beta \cdot \nabla v \|_{L^2(\Omega)}^2 + \epsilon \| \nabla v \|_{L^2(\Omega)}^2 + \alpha \| v \|_{L^2(\Omega)}^2,
\]

where \( L = |\Omega|^{\frac{1}{2}} \) is the length measure of \( \Omega \) in \( d \) spatial dimensions, \( |\beta| = \max_{\Omega} |\beta|_{L^2} \), and we have introduced the scaling \( \frac{L}{|\beta|} \) on the streamline diffusion term for unit consistency\(^4\). \( \alpha \geq 0 \) is a user-specified constant with units of inverse time\(^5\), and \( w(x) \) is some smoothly varying positive weighting function. Specifically, we require \( |w(x)| \) to be of magnitude \( O(\epsilon) \) for \( x \in \Gamma_{\text{in}} \), but \( O(1) \) away from the inflow boundary\(^6\).

A second motivation behind the weighting function can also be found in [19, 3, 5], which refer to \( w(x) \) as a cut-off function. A theoretical issue with the convection-diffusion problem is that \( \| u \|_{H^1_0} \) and \( \| u - u_h \|_{H^1_0} \) do not remain bounded as \( \epsilon \to 0 \), due to the fact that \( u' = O(\epsilon^{-1}) \) in the region of boundary or internal layers. These cut-off functions were introduced in order to yield \( \epsilon \)-independent bounds on the error by localizing error estimates away from layers.

We can demonstrate the need for the weight/cut-off function \( w(x) \) in the test norm – Figure 3.1 shows the result of two simulations on a uniform 16 element piecewise-linear mesh. The error representation \( e \) is approximated by quadratics over the same mesh. Without the weight, the solution degenerates near the inflow; a similar phenomenon was observed in [2, 1, 16].

Physically speaking, the weight can be interpreted as a cutoff function for the adjoint solution [20], which displays a boundary layer near the inflow due to the fact that the direction of convection is reversed for the adjoint equation. Mathematically speaking, it can also be interpreted as restoring a sense of directionality to the test norm (which is sign of \( \beta \)).

\(^4\)In all problems considered, \( \frac{L}{|\beta|} = O(1) \).

\(^5\)In the case where \( \alpha = 0 \), the seminorm remains a norm due to equivalence with the \( H^1 \) seminorm, which is norm on \( H^1_0 \). Specifying \( \alpha > 0 \) does not change the results dramatically; however, it does appear to improve conditioning of \( A \).

\(^6\)Specific restrictions on \( w \) are derived in [18] in context of the DPG method.
Fig. 3.1. Comparisons of $u$ and $e$ for $\epsilon = 10^{-3}$, $f = 1$ and $\alpha = 0$. The solution when $w = 1$ is in red, and the solution for when $w = x + \epsilon$ is given in blue. The exact solution is given in black.

3.2. Streamline norm with weak boundary conditions on $e$. While the above norm appears to give improved results, the issue of constructing a weighting function for complex geometries in higher dimensions can be fairly nontrivial. One possibility would be to solve a Laplace’s equation for $w$ on the domain, enforcing that $w(x) = \epsilon$ at inflow boundaries; however, the behavior of such a computationally determined weight has not been examined, and incurs additional complexity that is avoided by other methods.

Under this saddle-point framework, however, it is possible to avoid the use of a weight altogether. Currently, we seek $v, e \in H^1_0(\Omega)$; however, if we seek instead $v, e \in H^1_{\text{out}}(\Omega)$:

$$\text{such that } v|_{\Gamma_{\text{out}}} = 0,$$

we modify our variational formulation to be

$$(\nabla u, \beta v + \epsilon \nabla v)_{L^2(\Omega)} - \epsilon \int_{\Gamma_{\text{in}}} \frac{\partial u}{\partial n} v = (f, v)_{L^2(\Omega)}.$$

Under this modification of the variational formulation, we can set $w = 1$ and use the test norm

$$\| v \|^2_{V,w} := \frac{L}{\beta} \| \beta \cdot \nabla v \|^2_{L^2(\Omega)} + \epsilon \| \nabla v \|^2_{L^2(\Omega)} + \alpha \| v \|^2_{L^2(\Omega)}$$

without experiencing the issues displayed for $e \in H^1_0(\Omega)$ in Figure 3.1.

Physically speaking, the replacement of $H^1_0(\Omega)$ with $H^1_{\text{out}}(\Omega)$ can be viewed as releasing the strong imposition of a boundary condition at the inflow. The addition of the term $\epsilon \int_{\Gamma_{\text{in}}} \frac{\partial u}{\partial n} v$ is akin to a penalty term that weakly enforces a homogeneous boundary condition on $e$ at the inflow; the orthogonality condition for $e$ under this additional term is

$$(\nabla \delta u, \beta e + \epsilon \nabla e)_{L^2(\Omega)} - \epsilon \int_{\Gamma_{\text{in}}} \frac{\partial \delta u}{\partial n} e = 0, \quad \forall \delta u \in U_h$$

If $U_h$ is taken to be a polynomial space of order $p$, the first term enforces orthogonality of $\beta e + \epsilon \nabla e$ to polynomials of order $p - 1$ on the interior, while the second term enforces orthogonality of $e$ to polynomials of order $p - 1$ on the subset of the boundary $\Gamma_{\text{in}}$. If $e$ is represented by a polynomial of order $p - 1$, then this condition reduces to strong enforcement of $e|_{\Gamma_{\text{in}}} = 0$ [17]. This boundary condition is released in the limit as $\epsilon \to 0$; as a result, for small $\epsilon$, the contribution $(e, v)_V$ no longer provides an extraneous stabilization at the inflow for under-resolved meshes, improving the resulting solution $u$. However, for large $\epsilon$, the boundary condition activates and $e$ recovers homogeneous boundary conditions over the entire space $V$. The choice of weight $w(x)$ in the previous section can be seen as similarly removing the contribution of $e$ near the inflow for small $\epsilon$, but allowing it to return for large $\epsilon$.

A comparison between the weighted norm $\| v \|^2_{V,w}$ with $e \in H^1_0(\Omega)$ and unweighted norm with $e \in H^1_{\text{out}}$ in one dimension is given in Figure 3.2.
Remark 1. We remark that this inclusion of \( \epsilon \int_{\Gamma_{\text{in}}} \frac{\partial u}{\partial n} v \) is a variational crime under the assumption that \( u \in H^1_0(\Omega) \); the proper way to include such a term in a conforming manner (without introducing additional regularity assumptions on \( u \)) would be to introduce \( \epsilon \frac{\partial u}{\partial n} \) as an additional unknown on the boundary, similar to the work done using DPG under the ultra-weak formulation [1, 21]. We note that Broersen and Stevenson have also achieved good results by making use of the space \( H^1_{\text{out}}(\Omega) \) in their application of the DPG method to the mixed mild-weak formulation for convection-diffusion [22]. The mild-weak formulation effectively enforces the orthogonality of \( e \) to polynomials of lower order on \( \Gamma_{\text{in}} \), in a conforming manner, by introducing an additional flux unknown representing \( \epsilon \frac{\partial u}{\partial n} \).

For many flow problems, activity near the inflow is typically very smooth and can thus be represented using a minimal number of elements under an effective adaptive mesh refinement scheme, implying that the cost of introducing such additional unknowns on \( \Gamma_{\text{in}} \) can be minimized. However, since the codebase we currently use does not feature unknowns with support only on element edges/faces, we continue to operate under this variational crime, in hopes that we can implement a conforming version in the near future.

Remark 2. Various other methods of implementing a weak boundary condition on \( e \) at the inflow \( \Gamma_{\text{in}} \) were implemented; for example, the inner product \( (e, v)_{V^h} \) was modified by adding the a weak penalization term

\[
\epsilon C(h, p + \Delta p) \int_{\Gamma_{\text{in}}} e v
\]

to enforce the boundary condition at \( e \big|_{\Gamma_{\text{in}}} \), where \( C(h, p+\Delta p) = p^2/h \), which is a common choice of penalization parameter in high order finite element literature [23, 24]. However, the inclusion of the nonconforming term \( \epsilon \int_{\Gamma_{\text{in}}} \frac{\partial u}{\partial n} v \) in the bilinear form still resulted in the best solutions for all our numerical tests.

Thus, the full formal characterization of the second method can be given as follows - solve for \( u \in U_h \subset H^1_0(\Omega) \cap H^{3+\delta}(\Omega) \) (where \( \delta \) is an positive real number), \( e \in V_h \subset H^1_{\text{out}}(\Omega) \) such that

\[
(e, v)_{V^h} + (\nabla u, \beta v + \epsilon \nabla v)_{L^2(\Omega)} - \epsilon \int_{\Gamma_{\text{in}}} \frac{\partial u}{\partial n} v = (f, v)_{L^2(\Omega)}, \quad \forall v \in V_h
\]

\[
(\nabla \delta u, \beta e + \epsilon \nabla e)_{L^2(\Omega)} - \epsilon \int_{\Gamma_{\text{in}}} \frac{\partial \delta u}{\partial n} e = 0, \quad \forall \delta u \in U_h
\]

where

\[
(e, v)_{V^h} := (\beta \cdot \nabla e, \beta \cdot \nabla v)_{L^2(\Omega)} + \epsilon (e, \nabla v)_{L^2(\Omega)}.
\]

We will utilize this second version of the method for all following numerical examples.
Remark 3. We note that, when the Peclet number \( \text{Pe} = \frac{|\beta| L}{\epsilon} \gg 1 \), the boundary term \( \epsilon \int_{\Gamma_{\infty}} \frac{\partial u}{\partial n} v \) effectively disappears, and numerically speaking, we can use \( \epsilon, v \in H^1_{\Gamma_{\infty}}(\Omega) \) without including the additional boundary term in the variational formulation.

4. Numerical examples. We present several numerical examples, demonstrating rates of convergence and performance of the method on several benchmark problems in 2D. All numerical examples were implemented in the Python-based FEniCS codebase [25] to demonstrate that, unlike previous methods based upon the minimization of dual residuals, this method is easily implemented in most standard high-order finite element codes.

A remaining choice to be specified is the discretization of \( V_h \): if \( U_h \) is given to be polynomials of order \( p \), the enriched space \( V_h \) under which the fine-scales are approximated is set to be polynomials of order \( p + \Delta p \) – in other words, we use a simple polynomial enrichment scheme over a fixed mesh to approximate the fine-scale error representation function \( e \). In all experiments, \( \Delta p = 1 \) has been found to be sufficient, and larger \( \Delta p \) has not been found to have a significant effect on the behavior of the method. This is in contrast to the original DPG method, which also adopts a polynomial enriched space (where enrichment is done locally over each element) – results by Gopalakrishnan and Qiu in [26] suggest that only \( \Delta p \geq d \), where \( d \) is spatial dimension, is guaranteed to yield optimal convergence rates for Laplace’s equation.

We report only \( L^2 \) errors for each example, due to the fact that \( H^1 \) error is not a well-defined quantity as \( \epsilon \to 0 \). As a consequence, during adaptive refinement, the error does not always monotonically decrease or behave as expected, since adaptive refinement is driven by the quantity \( \|u - u_h\|_E = \|e\|_V \), which we expect to be equivalent (possibly with equivalence constants depending on \( \epsilon \)) to the \( H^1 \) norm. We do expect \( \|u - u_h\|_E \) to decrease monotonically for all \( \epsilon \) (though not uniformly in \( \epsilon \)) due to the minimum-residual nature of our method.

4.1. Ericsson-Johnson model problem. We adopt a problem first proposed by Ericsson and Johnson in [27] and later used in [18, 20] to determine the robustness of DPG with respect to the diffusion parameter \( \epsilon \). For the choice of \( \Omega = (0, 1)^2 \), \( f = 0 \), and \( \beta = (1, 0)^T \), the convection diffusion equation reduces to

\[
\frac{\partial u}{\partial x} - \epsilon \left( \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} \right) = 0,
\]

which has an exact solution by separation of variables, allowing us to analyze convergence of DPG for a wide range of \( \epsilon \). For boundary conditions, we impose

\[
\begin{align*}
    u &= u_0, \quad x = 0, \\
    u &= 0, \quad x = 1, y = 0, 1
\end{align*}
\]

In this case, our exact solution is the series

\[
u(x, y) = \sum_{n=0}^{\infty} C_n \frac{e^{r_1,n(x-1)} - e^{r_2,n(x-1)}}{e^{-r_1,n} - e^{-r_2,n}} \sin(n \pi y)\]

where

\[
\begin{align*}
    r_{1,2,n} &= \frac{1 \pm \sqrt{1 + 4 \lambda_n}}{2 \epsilon}, \\
    \lambda_n &= n^2 \pi^2 \epsilon.
\end{align*}
\]

We take for the exact solution the first mode, such that \( C_0 = 1 \), and \( C_n = 0 \) for \( n \neq 1 \).

\[
u(x, y) = \frac{e^{r_1(x-1)} - e^{r_2(x-1)}}{e^{-r_1} - e^{-r_2}} \sin(\pi y),
\]

\[
r_{1,2} = \frac{1 \pm \sqrt{1 + 4 \epsilon^2 \pi^2}}{2 \epsilon},
\]
The problem is driven solely by inflow boundary conditions, and develops a boundary layer of width $\epsilon$ at the outflow $x = 1$. The resulting solution is shown in Figure 4.1 for $\epsilon = 10^{-2}$, along with convergence rates of $L^2(\Omega)$ error under uniform mesh refinement for both $p = 1$ and $p = 2$. Optimal rates of convergence are not expected due to the pre-asymptotic nature of the mesh relative to the solution – typically, $h$ must be $O(\epsilon)$ in order to observe optimal rates of convergence [28].

For large diffusion – $\epsilon = 1.0$, we do observe optimal $p + 1$ rates of convergence in Figure 4.2. Likewise, when $\epsilon \ll h$, we observe a sub-optimal rate of $\frac{1}{2}$, the same as the rate suggested by theory and observed numerically in [22] due to the strong boundary layer present under small $\epsilon$.

\end{subfigure}
\caption{Erikkson-Johnson model problem for $\epsilon = 1$ and $\epsilon = 10^{-4}$, along with convergence rates under uniform refinement.}
\end{figure}
5. Adaptive mesh refinement. We experimented also with an adaptive refinement scheme. Since $\|e\|_V$ is localizable\textsuperscript{7}, we can evaluate it element-wise to get element error indicators $e_K := \|e\|_{V(K)}$. We implemented a bulk-chasing refinement strategy, where, given some factor $\theta \in [0, 1]$, we refine the top $\lceil \theta N \rceil$ elements with the largest error indicators $e_K$. A greedy refinement scheme was also implemented, where all elements with $e_K > \theta \max_K e_K$ are refined; however, this refinement scheme tended to place refinements more conservatively, requiring many more refinement iterations to achieve a qualitatively good resolution. In all following experiments, $\theta$ is set to be .25.

5.1. Eriksson-Johnson model problem. We continue to verify our method using the Eriksson-Johnson with $\varepsilon = 10^{-3}$. The solution $u$ and the convergence/rates of $L^2(\Omega)$ error under adaptive mesh refinement for $p = 2$ are given in Figure 5.1. The energy error $\|u - u_h\|_E$ is also displayed for comparison.

![Eriksson-Johnson problem with $\varepsilon = 10^{-3}$ under 16 refinements.](image)

As a result of the saddle point formulation, we can also examine the fine-scale error representation function $e$. Figure 5.2 displays a comparison between the error representation function after the first iteration of adaptive mesh refinement and the 16th iteration. Recall that the main contribution to the energy error is the streamline derivative of $e$; $\|u - u_h\|_E^2 = \|e\|_V^2 = \|\beta \cdot \nabla e\|_{L^2(\Omega)}^2 + \epsilon \|\nabla e\|_{L^2(\Omega)}^2$. Thus, variation in the streamline direction is picked up by $\|\beta \cdot \nabla e\|_{L^2(\Omega)}^2$ and is the primary contribution to the total error. After sufficient refinement and resolution of the outflow layer, the error representation function becomes smooth in the region of the boundary layer, and refinements will be placed according to the viscous error $\epsilon \|\nabla e\|_{L^2(\Omega)}^2$.

One open question concerning this method is the energy norm $\|u\|_E$ which is induced by our choice of bilinear form and inner product on our choice of test space $V = H^1_{\text{out}}$. Figure 5.3 displays both $L^2$ and energy errors over a range of $\varepsilon$. We observe that the energy error appears to be, like the $L^2(\Omega)$ error (but unlike $H^1(\Omega)$ or error in the streamline diffusion norm), independent of $\varepsilon$ – convergence does not appear to be in a norm that is equivalent to the $H^1$ norm with constants independent of $\varepsilon$.

Numerical experiments indicate that the measure of energy error is fairly insensitive to the degree of enrichment of $V_h$, so we expect that only a moderately finer resolution of $V_h$

\textsuperscript{7}A localizable norm $\|v\|_{V(\Omega)}$ can be written in the form

$$\|v\|^2_{V(\Omega)} = \sum_{K \in \Omega_h} \|v\|^2_{V(K)},$$

where $\|v\|_{V(K)}$ is a norm over each element $K$ in the mesh $\Omega_h$. 

11
Fig. 5.2. Comparison of the fine scale error representation $e$ under the Ericsson-Johnson problem with $\varepsilon = 10^{-3}$ for the mesh at the first and 16th refinement steps.

with respect to $U_h$ is sufficient to capture fine-scale effects. More investigation is necessary to determine the nature of the energy norm induced by this method.

5.2. Discontinuous forcing and advection skew to mesh. We consider next a slight variant of a model problem introduced by Hughes and Sangalli in [11]. The domain $\Omega$ is again taken to be the unit square, $\beta$ is taken to be $\beta = [.5, 1]$, and $\varepsilon = 10^{-3}$. Homogeneous Dirichlet boundary conditions are taken over the entire boundary, and the problem is driven by a discontinuous forcing term $f(x, y)$, where

$$f(x, y) = \begin{cases} 
1 & \text{if } y > 2x \\
0 & \text{otherwise}
\end{cases}$$
Under such an example, a boundary layer develops at the outflow boundaries \( x, y = 1 \), and an internal layer develops due to the fact that the discontinuity in \( f \) is parallel to the streamline. Figure 5.4 displays the solution and mesh resulting from 16 automatic mesh refinement iterations. Figure 5.5 displays a zoom of the solution and convergence history of the energy error.

![Model problem with \( \epsilon = 10^{-3} \) and discontinuous forcing \( f \).](image)

**Fig. 5.4.** Model problem with \( \epsilon = 10^{-3} \) and discontinuous forcing \( f \).

![Zoom on the upper right-hand corner of the mesh for \( f \) discontinuous, along with convergence of energy error \( \| u - u_h \|_E \).](image)

**Fig. 5.5.** Zoom on the upper right-hand corner of the mesh for \( f \) discontinuous, along with convergence of energy error \( \| u - u_h \|_E \).

We can similarly examine advection skew to the mesh, another common benchmark problem for convection-diffusion. We adopt a modification of the standard problem parameters – here, \( \epsilon = 10^{-7}, \beta = [0.5, 1] \), and \( f = 0 \). Boundary conditions are set such that

\[
  u = \begin{cases} 
    1 & \text{if } y = 0, x < 0.5 \\
    1 - y & \text{if } x = 0 \\
    0 & \text{otherwise}.
  \end{cases}
\]

Mathematically speaking, the considered problem is ill-posed for the standard Galerkin method in the continuous setting – the boundary condition implies a discontinuity in \( u \), such that the
solution cannot lie in $H^1$. The boundary condition is then convected in a manner that is skew to the mesh and forms a boundary layer on part of the outflow.

![Fig. 5.6. Advection skew to mesh on a uniform quadratic 32 x 32 grid of triangles. The fine scale error representation function $e$ is also shown; note that the multiscale contribution of $e$ is dependent on the form of $(e,v)_V$, which involves streamline derivatives.](image)

![Fig. 5.7. Advection skew to mesh after iterations 18 of adaptive mesh refinement.](image)

We note that the standard boundary condition for advection skew to the mesh is

$$u = \begin{cases} 1 & \text{if } x = 0 \text{ or } y = 0 \text{ and } x < .5 \\ 0 & \text{otherwise,} \end{cases}$$

which produces a discontinuity at the upper left hand corner as well. However, under automatic mesh refinement, extraneous refinements are placed at this corner’s discontinuity. It is possible to avoid such an issue either by tailoring a mesh refinement scheme to avoid the corner or by adopting a regularized boundary condition by introducing a mesh-dependent “ramped” boundary condition which approximates the discontinuity. This was done for for the lid-driven cavity flow problem under Stokes flow in [15].

We avoid both the above “fixes” in order to more cleanly demonstrate the behavior of automatic adaptive mesh refinement; however, we note that under the uniform meshes in Figure 5.9, or under adaptive refinement schemes that avoids the corner singularity, the method appears to deliver similar results to SUPG.
5.3. A 3D model problem. We conclude by applying the method to a simple model problem in 3 space dimensions. We solve on the unit cube $\Omega = [0, 1]^3$ with $\beta = [1, 1, 1]$, $f = 1$ and $u = 0$ on $\partial\Omega$. A boundary layer develops on the outflow boundaries $x, y, z = 1$. Figure 5.10 displays slices of the domain along the streamline direction to illustrate the formation of such a boundary layer.

We examined the behavior of the method with respect to a small $\epsilon$, in this case $\epsilon = 10^{-6}$. 8 adaptive refinements were done beginning with a uniform linear mesh of 8 elements per side; Figure 5.11 shows the resulting solution and mesh along a cut orthogonal to the streamline direction. All experiments indicate that the method appears to behave qualitatively the same as in 2 dimensions, modulo increased computational cost.

6. Conclusions and future direction. We have presented a higher order adaptive $H^1$-conforming method for convection-diffusion problems for very small $\epsilon$, and have made connections to both the DPG method as well as the method of Cohen, Dahmen and Welper. The
method has also been shown to be derivable in the Variational Multiscale framework as well, and is distinguished from traditional VMS methods in its definition of the fine-scale space and problem. Unlike standard stabilized $H^1$ methods, there are no stabilization parameters. However, unlike the DPG methods of both Demkowicz and Gopalakrishnan, as well as the method of Broersen and Stevenson, this method is easily implementable within current finite element codes in arbitrary spatial dimensions.

We note that, while the method displays similarities to SUPG, we do not observe nodal exactness in 1D. The two methods differ in that we do not work directly with coarse scales defined by the $H^1$ inner product; unless we can induce an energy inner product such that
\[ (u_h, u')_E = (u_h, u')_{H^1_0}, \] then we should not expect nodal exactness in 1D. However, in higher space dimensions, the behavior of the method is qualitatively very similar to SUPG.

We hope to explore in future research both additional improvements on the method and the application of this method to other problem frameworks and settings, a few of which are described in the following sections.

6.1. \textit{hpr}-refinement. Since this method is derived from the same variational principles as DPG, it should likewise be automatically inf-sup stable for arbitrary \( hp \) meshes as well. \( hp \)-refinement is of interest due to the fact that, under proper choices between \( h \) and \( p \) refinement, exponential convergence rates are possible, and have been observed for several model problems [29]. Intelligent \( hp \)-adaptive strategies could also offer more mathematically motivated alternatives to CFD approaches such as flux limiters, which effectively limit the order of approximation in areas of singularities and high gradients.

Additionally, the method automatically extends to incorporate anisotropic elements and \( r \)-refinement as well, similar to ALE methods. The combination of these two methods has been shown to produce very fine-resolution results at a competitive computational cost for flow problems with very small viscosity [30].

6.2. Computational feasibility. The main obstacle to making this method computationally competitive is the doubling of the number of fully coupled degrees of freedom in solving the problem in saddle point system formulation. While a larger number of degrees of freedom is often cited as a detriment, it is often accompanied by an advantageous underlying structure – for example, discontinuous Galerkin methods are also often criticized for their “explosion of degrees of freedom” compared to continuous Galerkin methods [31], but their local nature aids significantly in parallelization, adaptivity, and explicit time integration, as opposed to methods based on continuous discretizations.

The cost of explicitly discretizing the fine scale error representation \( e \in V_h \) roughly amounts to the cost of discretizing an additional coupled PDE under a higher resolution. The idea of solving an additional PDE for the purposes of stabilization is not unheard of [32]; however, the additional discretization cost must be minimized. We propose several preliminary ideas for doing so:

- Recall in Section 2.1 that the saddle point system is reducible to

\[ B^T A^{-1} B u = B^T A^{-1} f. \]

where \( f \) and \( B \) are the load and overdetermined stiffness matrix under \( V_h \), and \( A \) is the Gram matrix/discrete Riesz map associated with the inner product \( (v, \delta v)_{V'} \). One approach is to explore possibilities for rapid inversion of \( A \). For example, it is possible to choose \( V_h \) to simply be the space of piecewise linears enriched with bubbles – higher order degrees of freedom could be condensed out, resulting in a system for \( e \) with the same number of unknowns as \( u \). The resulting matrix-vector products required to form the Schur complement could be parallelized as well.

One additional possibility would be the exploration of iterative methods for the Schur complement – the matrix is positive definite, and assembling a matrix-vector product could be done efficiently under a good preconditioner for the symmetric positive-definite matrix \( A^{-1} \). Preliminary results demonstrate effective speedup for uniform meshes of piecewise linears in 2D using standard preconditioners (ILU, block Jacobi, AMG), and suggest that a discretization of \( V_h \) using a \( h \)-refined fine mesh could be possible; however, more work would be required to develop preconditioners for high order adaptive meshes.

- Another possibility would be to solve the saddle point problem using an Uzawa method [33], which would decouple the saddle point system into two problems, each involving only degrees of freedom for \( e \) or for \( u \). The solution of these two problems feeds an iterative procedure which can converge to the solution of the saddle point problem. Again, effective use of an Uzawa algorithm would require a good preconditioner for \( A \) under high-order refined meshes.
• We hope to explore alternative discretizations for both $U_h$ and $V_h$ in order to minimize degrees of freedom or solution for in the overall system. A few examples of nonstandard discretizations include higher order continuity basis functions (splines and NURBS [34]), and discontinuous functions (DG). Preliminary experiments have yielded promising results in 1D under the combination of higher-continuity and $C_0$ bases for $U_h$ and $V_h$, respectively. We hope to further explore intelligent mixing of discretizations for trial and test spaces in future experiments.

• The DPG method achieves computational efficiency by block-diagonalizing $A$ using discontinuous test functions. The same method could be applied to the $H^1$ setting for convection-diffusion problems at the cost of introducing inter-element fluxes representing the trace on the boundary of an element resulting from integration by parts of the viscous term. An alternative along the same lines would be to consider block diagonalization of $A$ under a patch-based decomposition, such as FETI or one of its variants [35, 36].

7. Acknowledgements. The authors would like to acknowledge the help of Truman Ellis and Dr. Leszek Demkowicz for fruitful discussions and perspective. Jesse Chan was supported by the Department of Energy [National Nuclear Security Administration] under Award Number [DE- FC52-08NA28615]. John A. Evans was partially supported by the ICES Postdoctoral Fellowship at the Institute for Computational Engineering and Sciences, and by a grant from the Office of Naval Research [N00014-08-1-0992].
