**Title:** The purpose of this research program is to develop an imaging-based protocol to improve diagnosis and outcome prediction of mild traumatic brain injury (mTBI). It includes the development of a modern technology for processing susceptibility maps to evaluate the presence of bleeding and deoxyhemoglobin and the study of sensitivity of new MR imaging technology in detecting mild TBI. Our major findings relate directly to our specific aims. First, we have demonstrated that these new advanced MRI methods nicely complement conventional imaging methods in their ability to detect mTBI in the acute setting. Second, susceptibility weighted imaging and mapping (SWIM) are able to delineate venous structures and microbleeds making it possible to quantify and monitor evolution of pathological changes. Third, we have developed the process by which to evaluate DTI data throughout the entire brain to look for local variations in ADC and FA values to assess tissue damage. And fourth, we have begun to collect imaging and neuropsychological data for both volunteers and mTBI patients during the last quarter of this year. The significance of this work to date is that we are now able to find evidence of damage in mTBI where that has heretofore been difficult with cMRI.

**Subject Terms:** Mild traumatic brain injury, susceptibility weighted imaging and mapping,

INTRODUCTION

**Background:** Traumatic brain injury (TBI) has been labeled as a “signature wound” in the anti-terrorism wars in Iraq and Afghanistan. 15% - 25% of surveyed returning service members have been reported to have possible long-term mild traumatic brain injury (mTBI) or concussion. In the civilian sector, the prolonged neuro-cognitive and functional symptoms following mTBI affects over 1.2 million Americans annually. However, our understanding of the neuropathology of mTBI and its recovery process is still very limited due to the lack of sensitive clinical and diagnostic tools. First, current TBI classification scales are mainly based on results from computed tomography (CT) scans of moderate to severe TBI patients, and thus can hardly be applied to mTBI cases. Secondly, current laboratory biological markers, clinical CT and conventional magnetic resonance imaging (MRI) are either insensitive or not specific to the subtle abnormalities in mTBI and poorly predict patient’s long-term outcome. It is in urgent need of developing a set of advanced MR imaging biomarkers that can: i) be sensitive enough to differentiate mTBI patient population from normal healthy ones, ii) have the potential for outcome prediction; and iii) assist in management of mTBI patients in acute settings.

**Objective/Hypothesis:** The overall goal of the current research is to develop imaging-based biomarkers to improve diagnosis and outcome prediction of mTBI. Advanced MRI techniques reveal many more details than conventional imaging. For example, susceptibility weighted imaging (SWI) and susceptibility mapping (SWIM) can detect and quantify temporal reduction of hemorrhagic lesions associated with mTBI patients’ functional outcome and diffusion tensor imaging (DTI) can detect axonal injury at the acute stage and possible changes over time. As the next generation of SWI developed in our lab, SWIM will be used to quantify iron in microbleeds and oxygen saturation in major veins throughout the brain. Our central hypothesis is that axonal injury (measured by DTI) and vascular damage (detected as hemorrhagic lesions by SWI/SWIM) are important pathologies in mTBI that are associated with patients’ neurocognitive and clinical symptoms in their recovery.

**Study Design:** Adult mTBI patients will be screened and enrolled at the acute stage (within 24 hours after injury) from the emergency department of our local Level-One Trauma Center. Both up-to-60-minute MRI scan and neuropsychological/clinical assessment will be conducted in mTBI patients. In the subacute (1 month) and chronic (6 months) stages after injury, the patients will be brought back to repeat both the MRI scans and neurocognitive evaluations. Age/gender/education-matched healthy controls will be recruited and followed up using the same imaging and neuropsychological protocol of evaluation.

**Specific Aims:** **Specific Aim 1** is to assess whether the advanced MRI data (SWI and DTI) acquired acutely (within 24 hours after injury) are more sensitive than conventional imaging (CT and cMRI) in detecting mTBI. **Specific Aim 2** is to determine at what time point after the injury (i.e., acute, subacute and chronic) these advanced MR techniques can differentiate mTBI patients from healthy controls. **Specific Aim 3** is to use susceptibility weighted imaging and mapping (SWIM), our next generation of SWI technique, to quantify the amount of iron in microbleeds, to monitor any changes (evolution) of the microbleed over time and to monitor oxygen saturation compared to normal volunteers. And **Specific Aim 4** is to determine which MRI indices have statistically significant associations with neurocognitive outcome in mTBI patients over all time points.
**BODY**

*Summary of the Statement of Work for Phase 1:*

**Phase I (Years 1-2):** recruit a cohort of 50 mTBI patients from the emergency setting of our local Level-One trauma center, and 50 non-TBI volunteers to establish and validate an image-based diagnostic approach to brain injury.

a) Screen and enroll mTBI patients; perform the MRI protocol (conventional imaging, DTI and SWI); conduct NP tests and clinical outcome measures.

Due to the late approval of IRB, we started enrollment fairly late (March, 2012). To date, we have successfully recruited two mTBI patients and scanned them at the acute stage (within 24 hours after injury).

b) Screen and enroll healthy volunteers and perform the same procedures as mentioned above.

We have successfully enrolled 7 control subjects in the past month.

c) Follow up mTBI patients and controls at 1-month and 6-months after injury using the same imaging protocol, NP tests and outcome measures.

We have successfully performed 1-month follow up in our two patients and two controls.

d) Analyze the data and establish a baseline imaging database for mTBI patients and normals.

We have established the quantification schemes necessary to analyze this data for DTI and SWIM. We are in the process of creating an internal database from which we can gather all relevant quantitative information such as total lesion load, FA histograms and mean FA.

e) Report preliminary data by presenting it to conferences or publish it in TBI and imaging related journals.

   We have published 2 papers and 2 book chapters. We have also given 9 presentations related to this work during the last year by Prof. Haacke and Prof. Kou. The details are given in the reportable results section.

f) Develop and use SWI and SWIM for use in evaluating abnormal vasculature and microbleeds in mTBI patients.

We are delighted to report that we have made major progress in the evaluation of cerebral microbleeds using a new iterative SWIM algorithm. The reader is referred to the paper by J. Tang et al. “Improving susceptibility mapping using a threshold-based K-space/image domain iterative reconstruction approach.”, MRM, June 26, 2012, epub, ahead of print for a detailed description of this new concept. However, the basic concept is given below.

While we were pending for the IRB approval of our human data collection, we spent considerable time on the methodology itself and have made some dramatic progress in this direction. We have just published a paper on an advanced form of susceptibility mapping (SM) which we refer to as “Iterative SWIM”. The concept is to take the first guess of the SM and keep only the highest components and then do a forward
model. Now we use the ill-defined portions of k-space from this forward data and embed it into the original k-space data and reconstruct. This has a dramatic effect in terms of removing artifacts. An example data simulation is shown below (Figure 1). Note that even after the first iteration there is a dramatic improvement in the image.

![Simulation Image]

**Figure 1**: Simulations showing the comparison of the calculated susceptibility distributions for a cylinder perpendicular to $B_0$, indicated by a white long arrow, at different threshold values ($a$) applied to $g(k)$ as well as the initial $\chi_I(r)$ map. The diameter of the cylinder is 32 pixels with a susceptibility $\Delta \chi$ of 0.45 ppm inside the cylinder. a) The top row of images shows calculations with no added phase noise and the second and the third row shows calculations with added phase noises $\delta = 0.025$ and 0.05 radians, respectively. The first column of images are initial $\chi_I(r)$ maps for reference. b) The variation of the mean calculated susceptibility inside the cylinder with different threshold value, $a$. The mean susceptibility value is independent of the noise level; therefore, only mean value from $\delta = 0$ is provided. The error bar shows the standard deviation (SD) of the calculated susceptibility values. c) The variation of the root mean square error (RMSE) $\Delta \chi$.
mean squared error (RMSE) of the susceptibility values outside the cylinder as a function of the threshold value, \( a \), and the noise level.

\textbf{g) Simultaneous acquisition of both MR angiography and venography data.}

We have developed a dual echo SWI technique that will provide the ability to not only perform SWI and SWIM but also to calculate T2*. This is not the ordinary double echo sequence but a fully flow compensated double echo sequence so no interference from arteries takes place. It can image both the arteries and veins that the same time, which could potentially assess a relative complete picture of vessel damage after brain injury (see Figure 2). Specifically, we have designed a flow rephase/dephase interleaved double-echo GRE sequence which offers fully flow rephased SWI data for venography, and TOF MRA plus flow dephased data for enhancing angiography using a non-linear subtraction (NLS) method. To our knowledge, currently no MR method other than the interleaved double-echo sequence we proposed can provide all the data needed for both MRAV imaging and selective MRA enhancement in a single scan. Three different types of image contrast, i.e., TOF MRA, SWI and flow dephased dark blood images, could be obtained simultaneously with perfect alignment to each other so that no realignment process is necessary. In conjunction with NLS, one can obtain high resolution SWI and enhanced TOF MRA without the need for contrast agent (Figure 2 a-b), and the process can be easily automated without much additional computational power. NLS offers a clean angiography free of venous contamination as if acquired with maximal TOF effects. Most noticeably, NLS seems to even outperform the low dose CE TOF data by its higher artery-tissue contrast (Figure 2 c-e), extra revelation of some small arteries (e.g. at the frontal lobe), uniform background signal and the lack of veins (except for the easily distinguishable superior sagittal sinus). For future works, the acquisition time may be further reduced to provide whole brain coverage using a segmented echo planer imaging (seg-EPI) readout approach or compress sensing (CS) since the subtracted images have highly sparse information.

\end{figure}

\textbf{h) Investigate the early response of the neurovascular system to brain concussion}

In our preliminary study, we investigated the neural vascular response to mild TBI at the acute stage. Specifically, we adopted a combined use of both SWIM and ASL to answer this question.

\textbf{Subject Enrollment:} Twelve mTBI patients were recruited in emergency setting in our Level-1 trauma center. Eighteen aged- and gender-matched healthy controls were also recruited for comparison. All patients met the definition of mTBI by the American Congress of Rehabilitation Medicine (ACRM) with Glasgow Coma Scale (GCS) score of 13-15 at emergency entry. All patients completed a short
neurocognitive test, standard assessment of concussion (SAC), at the acute stage. SAC is a short instrument to measure patients orientation, delayed recall, attention, and executive function.

**SWIM Processing:** All SWI images were processed to produce SWIM data by using our previously developed method in our in-house developed SPIN software [1]. Specifically, the following steps were used: a) High pass filtering of original phase image to get SWI phase image, b) Inverse transform to generate susceptibility maps of the veins, c) Regularization and interpolation of the data in k-space of the phase image to reduce reconstruction artifacts, and d) finally, minimum intensity projection (mIP) of slices over 8 mm thickness.

After SWIM processing, eight major veins and small transmedullar veins were selected by using semi-automated region of interest (ROI) analysis to quantify blood oxygen saturation of each one (see Figure 3). A student t-test was used to compare the control and patient group data.

**ASL Data Processing:** First, the skull-stripped untagged T2 weighted image was used to create a mask to skull-strip the relative CBF (rCBF) images. The skull-stripped untagged T2 weighted images were then normalized to the T1 weighted ICBM template by using SPM8 to generate a transformation matrix. Next, the transformation matrix was applied to the rCBF images. Then, the Wake Forest University (WFU) Pickatlas, which is in the same space as ICBM template, was used to extract the rCBF values from specific predefined structures and lobes. rCBF values from frontal, parietal, occipital and temporal lobes were extracted. In addition, values from thalamus and basal ganglia, including caudate nucleus, putamen and globus pallidus, were also extracted.

![Figure 3: Measurement of susceptibility of major veins. As numbered on the figure, the major veins are 1-Septal Vein (right), 2-Septal Vein (left), 3- Central Septal Vein, 4-Thalamic Striatal Vein (right), 5-Thalamic Striatal Vein (left), 6-Internal Cerebral Vein, 7-Basilar Vein of Rosenthal (right), 8-Basilar Vein of Rosenthal (left), 9-Transmedullar Vein (right), and 10-Transmedullar Vein (left).]
**Results:**

Our data demonstrate that: a) patient group has significant lower susceptibility signal than control group in left thalamus striatal veins (See Figure 4), which implies that patient group has lower deoxygenation in thalamus region than controls; b) Patient group has significant higher CBF levels than control group in left frontal lobe and left striatal region, including caudate, putamen and globus pallidus (See Table 1); c) patient group demonstrated significantly reduced SAC scores than published normative data, especially in delayed recall (See Figure 5); and d) the imaging data is not correlated with SAC data.

Figure 5: Testing scores of Delayed Recall in the Standard Assessment of Concussion (SAC). As indicated by the bar chart, patients at acute stage have significantly lower scores of delayed recall, which suggests of memory problem.

i) **Investigating medullary vein damage**

*A new dimension in imaging technology* is the discovery of vascular damage in the form of extravasated blood, thrombus and reduced levels of oxygenation that may better illuminate our understanding of brain injury, particularly related to trauma. Using the SWI and SWIM technology discussed above, we have recognized that there are major changes in iron content and local oxygen saturation, important for evaluating potential changes in local perfusion or tissue function (similar to what is seen in stroke using SWI). SWIM can also be used to monitor changes in iron content over time which can be used to see if previous iron deposition is being resorbed or if bleeding continues, both important diagnostic pieces of information for the clinician.

In this current project, we have demonstrated that there is a lower impact load, either inertia or direct impact forces, that may damage only veins, and we have shown medullary vein damage that hasn’t been visualized with other techniques (Figure 6). The medullary veins drain the frontal white matter of the brain, so reduced blood flow here could possibly impair the higher level frontal neurocognitive function. Treatments that improve blood flow to the brain, then, might be a promising direction to pursue.
Figure 6: An example mild traumatic brain injury case in the presence of both blast and subsequent traumatic brain injury. The left septal vein and medullary veins draining into it are both show abnormal signal representing either iron deposition or increased levels of deoxyhemoglobin or both. Left image: SWI data. Middle image: SWI filtered phase. Right image: SWIM data showing quantified iron content.

j) Investigating medullary vein structure in three dimensions

Overall results from modeling of major vessels suggests that blood vessels increase the stiffness of the brain and help to resist both rotational and linear impulses and may also increase the threshold of neural injury. However, there is no data that describe the mechanical interaction between the vessels and brain. Medullary vein damage may be due to the presence of internal shear forces (intracerebral stresses). How this occurs likely depends on the stiffness and natural frequency of the structure impacted. For impacts with structures of relatively soft stiffness the brain tends to move with the skull because of the predominantly low frequencies involved in these impacts. These movements result in intracerebral strains (ICS) that can produce lesions in the central parts of the brain. Knowing the tissue properties and the local structures of the vessels and how they are embedded in the surrounding tissue is necessary for proper modeling of the problem. The SWI and MRA data that we have collected makes it possible to create a detailed model of the medullary veins down to 250 microns in size (see Figure 7). Armed with this model and estimates for the tissue properties it may be possible in the future to predict local venous damage. The determination of vessel vulnerability could help engineer safety devices such as helmets to protect the brain from forces that cause venous damage.
Figure 7: Modeling the medullary veins. An SWI projection image is used to find the medullary veins and then they are extracted in 3D. a) An example image from SWI data showing the septal vein and the confluence of several medullary veins. b) A projection of a 3D model of the medullary veins branching off the septal vein. The resolution in the model is 62.5 microns and the vessels range in size from 1mm (the septal vein) to the first branchings (0.5mm) to the second branchings (0.25mm). These veins can be damaged in frontal or side impact.
KEY RESEARCH ACCOMPLISHMENTS

The following accomplishments have been made in the past year:

- Final approval of study protocol by three Institutional Review Boards (IRBs).
- Recruitment and follow up of patients and controls is established and in progress.
- Analysis of preliminary data. Our data demonstrated an increased blood flow as early response of mild TBI patients.
- A new finding of medullary vein damage has been discovered that is present not only in moderate and severe TBI but also in mild TBI.
- Technical development of susceptibility weighted imaging and mapping (SWIM), including:
  - A method of simultaneous acquisition of both MR angiography and venography has been developed.
  - An advanced iterative approach has been developed to improve the post processing of SWIM data.
REPORTABLE OUTCOMES

Papers:

b) DTI paper on mild TBI. We are currently working on a paper related with DTI study of mild TBI by using our DTI analysis approach as mentioned above.

c) A book chapter entitled “The presence of venous damage and microbleeds in traumatic brain injury and the potential future role of angiographic and perfusion magnetic resonance imaging” is in press.

f) A manuscript comparing ASL with SWIM data is in progress.

Presentations:

Our group has given a number of presentations in national and international meetings.

2011

a) The project PI, Dr. E Mark Haacke, was invited by the Human Brain Mapping society to give a presentation on SWIM on June 29th, 2011, Quebec City, Canada.

b) Dr. Haacke also met with members of Senator Harry Reid’s office in Las Vegas regarding his research on August 30th, 2011

c) Dr. Zhifeng Kou gave a plenary presentation on brain trauma in 2011 NABIS meeting on September 15th, 2011, New Orleans, Louisiana.

d) Dr. Haacke organized and held a TBI Workshop on November 18, 2011 from 8:00am – 4:00pm at Wayne State University. There were four topic sessions with five speakers in each section for around twenty short talks. Dr. Haacke spoke about the new venous concepts and Dr. Kou about progress in mild TBI.

2012

f) Henry Ford Hospital. The role of the vasculature in neurodegenerative disease with a focus on TBI and CCSVI. January 5th, 2012.

k) Susceptibility weighted imaging at the 19th Annual Audiology Conference at the VA Hospital in Johnson City, Tennessee, on June 21st, 2012.

Grants, Honors and Awards

- Dr. Zhifeng Kou obtained a Seed Grant from the International Society for Magnetic Resonance in Medicine (ISMRM) in the annual conference in Melbourne, Australia in May 2012.
- Dr. Zhifeng Kou won the prestigious Charles Hayes award from the North American Brain Injury Society (NABIS) in 2011.
CONCLUSION

Our work during this first year has already led to some major breakthroughs in understanding traumatic brain injury. First, we have observed medullary vein damage even in mild TBI. The implications for this are two-fold: we may be able to understand why certain individuals are suffering from frontal white matter neurocognitive problems and we may be able to propose a treatment for these individuals. Second, we have developed a power quantitative susceptibility mapping advance called iterative SWIM which opens the door to mapping bleeding in TBI. This has the importance of monitoring current damage and patient recovery in the sense that one can follow tissue recovery and clearing of iron from the tissue. Third, we have married SWI and MRA to allow for a complete vascular study of TBI. The impact here is that we should be able to better understand the brain's hemodynamics post trauma. In summary, we are on track with our technical development and are now on track to collecting the human data. Although this may take some time, we anticipate being able to complete this data collection by the end of year two. Our future work will continue along the lines proposed in the original statement of work where we will compare the imaging at different time points and look for biomarkers of patient outcomes.
Improving Susceptibility Mapping Using a Threshold-Based K-Space/Image Domain Iterative Reconstruction Approach

To improve susceptibility quantification, a threshold-based k-space/image domain iterative approach that uses geometric information from the susceptibility map itself as a constraint to overcome the ill-posed nature of the inverse filter is introduced. Simulations were used to study the accuracy of the method and its robustness in the presence of noise. In vivo data were processed and analyzed using this method. Both simulations and in vivo results show that most streaking artifacts inside the susceptibility map caused by the ill-defined inverse filter were suppressed by the iterative approach. In simulated data, the bias toward lower mean susceptibility values inside vessels has been shown to decrease from around 10% to 2% when choosing an appropriate threshold value for the proposed iterative method. Typically, three iterations are sufficient for this approach to converge and this process takes less than 30 s to process a 512 x 512 x 256 dataset. This iterative method improves quantification of susceptibility inside vessels and reduces streaking artifacts throughout the brain for data collected from a single-orientation acquisition. This approach has been applied to vessels alone as well as to vessels and other structures with lower susceptibility to generate whole brain susceptibility maps with significantly reduced streaking artifacts. 

Susceptibility weighted imaging (SWI) using phase information has become an important clinical tool. However, the use of phase information itself has stimulated great interest both as a source of contrast and as a source for producing susceptibility maps (SM). The impetus for solving the inverse problem from magnetic field perturbation came from the work described by DeVille et al. (25). This was noted by Marques and Bowtell in 2005 (26). Salomir et al. (27) were the first group to utilize this concept in MRI. Unfortunately, this inverse process is ill-posed and requires a regularization procedure to estimate the SM. There are a variety of approaches to tackle this problem (7-24). One unique method uses a multiple orientation data acquisition to remove the singularities (17). Constrained regularizations have shown good overall results, but they require longer reconstruction times and assumptions about the contrast in or near the object to be detected. 

MATERIALS AND METHODS

Briefly, the expression for the susceptibility distribution (26,27) derived from the phase data can be written as (for a right handed system (28)):

\[ \chi(r) = \text{FT}^{-1} \left[ \frac{1}{g(k)} \times \text{FT} \left[ \Phi(r) \right] \right] \quad [1] \]

where,

\[ g(k) = \frac{1}{3} - \frac{k_z^2}{k_x^2 + k_y^2 + k_z^2} \quad [2] \]

and \( \Phi(r) \) is the phase distribution, \( T_E \) is the echo time, \( \gamma \) is the gyromagnetic ratio for hydrogen protons, \( B_0 \) is the main field strength, \( k_x, k_y, \) and \( k_z \) are coordinates in k-space, and \( g(k) \) is the Green’s function or filter. Clearly, the analytic inverse filter \( g^{-1}(k) = 1/g(k) \), is ill-posed when \( g(k) \) is equal or close to zero, i.e., points on or near two conical surfaces in k-space at the magic angles of 54.7° and 125.3° from the \( B_0 \) axis. This ill-posedness...
leads to severe artifacts (including severe streaking) in $\chi(k)$ and noise amplification (29). Thus, for a proper pixel-by-pixel reconstruction of $\chi(r)$, recovering the correct values of $\chi(k)$ near the region of singularities is critical.

K-space Iterative Approach

If the shapes of the structures of interest are known, then one can use this information in the SM to create a more accurate k-space of said SM in the conical region. The structure of the vessels is obtained directly from the first pass SM $\chi_{i-0}(r)$. The detailed steps of the iterative method are discussed below and shown in Fig. 1.

- **Step-1**: An initial estimate of the SM, $\chi_{i-0}(r)$, is obtained by applying a regularized version of the threshold-based inverse filter, $g^{-1}_\text{reg}(k)$ (18), in Eq. 1 using the suggested threshold value, $\text{thr} = 0.1$. The subscript “i” denotes the SM after the $i$th iteration (“$i = 0$” denotes the initial step before doing the iterative method and $i = 1$ for the first iteration).

- **Step-2**: The geometry of the structures of interest is extracted from $\chi_{i-0}(r)$ using a binary vessel mask, i.e. outside the veins, the signal in the mask is set to zero, and inside it is set to unity. Since streaking artifacts associated with veins in the SM are usually outside the vessels, after multiplying the $\chi(r)$ map by the mask, little streaking remains in the SM. This leads to $\chi_{\text{vm},i}(r)$ as shown in Fig. 1b. Vessel mask generation will be addressed in the next section.

- **Step-3**: $\chi_{\text{vm},i}(k)$ is obtained by Fourier transformation of $\chi_{\text{vm},i}(r)$ (Fig. 1c).

- **Step-4**: The predefined ill-posed region of k-space in $\chi_{\text{vm},i}(k)$ is extracted (Fig. 1d). These extracted k-space data are denoted by $\chi_{\text{vm,cone},i}(k)$. The size of $\chi_{\text{vm,cone},i}(k)$ is decided by a threshold value, $a$, which is assigned to $g(k)$. For the matrix size $512 \times 512$, the percentages of the cone region in k-space for a given $a$, are 2.4% ($a = 0.01$), 24.1% ($a = 0.1$), 47.1% ($a = 0.2$), and 70.6% ($a = 0.3$), respectively. When $a$ increases, the size of $\chi_{\text{vm,cone},i}(k)$ increases too. If $a$ is increased too much then most of the original information will be lost.

- **Step-5**: Data from $\chi_{\text{vm,cone},i}(k)$ and $\chi_{i-0}(k)$ (Fig. 1e) are merged. This means part of $\chi_{i-0}(k)$ has been replaced by $\chi_{\text{vm,cone},i}(k)$. The merged data are denoted by $\chi_{\text{merged},i}(k)$ (Fig. 1f).

- **Step-6**: Inverse Fourier transformation of $\chi_{\text{merged},i}(k)$ gives the improved SM, $\chi_{i+1}(r)$ (Fig. 1g).

- **Step-7**: $\chi(r)$ in step-1 is replaced by $\chi_{i+1}(r)$ from step-6 and the algorithm is repeated until

$$\sqrt{\sum [(\chi_{i}(r) - \chi_{i+1}(r))^2]} / N < \varepsilon$$

where $N$ is the number of pixels in $\chi(r)$ and $\varepsilon$ is the tolerance value (chosen here to be 0.004 ppm).

Binary Vessel Mask Generation

The binary vessel mask was generated using thresholding from the $\chi(r)$ map itself. The detailed steps are discussed below and shown in Fig. 2.

- **Step-1**: A threshold, $\text{th}_1$, is applied to $\chi_{i-0}(r)$ to create an initial binary vessel mask, $M_0$. The pixels whose susceptibility values are lower than $\text{th}_1$ will be set to zero while those greater than or equal to $\text{th}_1$ will be set to unity. In this study, a relatively low susceptibility of 0.07 ppm is used for $\text{th}_1$ to capture most vessels. However, this choice of threshold inevitably includes other brain structures in $M_0$ that have high susceptibility.

- **Step-2**: A morphological closing operation is performed to fill in holes in $M_0$ to generate an updated mask $M_1$. 

FIG. 1. Illustration of the iterative reconstruction algorithm to obtain artifact free $\chi(r)$ maps.
Step-3: A median filter is applied to remove noise in $M_1$ and create $M_2$.

Step-4: False positive data points from $M_2$ are removed as follows: First, the $\chi(r)$ map is Mipped over five slices centered about the slice of interest to better obtain contiguous vessel information, as seen in $\chi_{\text{MIP}}(r)$. Second, another threshold, $\text{th}_2 = 0.25$ ppm, is performed on $\chi_{\text{MIP}}(r)$ to create a new $\chi_{\text{MIP}, \text{vm}}(r)$ and binary mask $M_P$, which only contains predominantly vessels. Here, 0.25 ppm was chosen to isolate the major vessels in the MIP image. Third, each slice from $M_2$ is compared with $M_P$ on a pixel-by-pixel basis to create $M_3$. If a data point from $M_2$ does not appear on $M_P$, this data point will be treated as a false positive and removed from $M_2$, otherwise this point is retained. This process can be equally well applied to extract other tissues by choosing appropriate values for $\text{th}_1$ and $\text{th}_2$.

2D Cylinder Simulations

Simulation of a two dimensional cylinder and its induced phase was first performed using a $8192 \times 8192$ matrix. A lower resolution complex image was then obtained by taking the Fourier transform of this matrix and applying an inverse Fourier transform of the central $512 \times 512$ matrix in k-space. This procedure is to simulate Gibbs ringing effects caused by finite sampling which we usually see in conventionally required MR data sets. Gibbs ringing comes from discontinuities in both the magnitude and phase images. To avoid Gibbs ringing from magnitude discontinuities, we used a magnitude image with a uniform signal of unity. Cylinders with diameters 32, 64, 128, 256, 512, and 1024 were simulated on $8192 \times 8192$ matrices and their effective diameters were 2, 4, 8, 16, 32, and 64 on $512 \times 512$ matrices. All phase simulations were performed using a forward method (8,26,27,30) with $B_0 = 3$ T, $\Delta \chi = 0.45$ ppm in SI units, $T_E = 5$ ms, and the cylinder perpendicular to the main magnetic field. The susceptibility value of 0.45 ppm represents venous blood when the hematocrit (Hct) = 0.44, $\Delta \chi_{\text{do}} = 4\pi \times 0.27$ ppm (31) and the oxygen saturation level = 70%, where $\Delta \chi_{\text{do}}$ is the susceptibility difference between fully deoxygenated and fully oxygenated blood (32). A relatively short echo time was chosen to avoid phase aliasing that can affect the estimated susceptibility values.

Selection of a TBSO Method to Generate the $\chi_{\text{MIP}}(r)$ Map

TBSO methods (11,15,18,24) use a truncated $g(k)$ to solve the singularity problem in the inverse filter $g^{-1}(k)$ when $g(k)$ is less than a predetermined threshold value, thr. When $g(k) < \text{thr}$, $g^{-1}(k)$ is either set to zero (11,24); or to $1/\text{thr}$ (15); or set to $g^{-1}(k) = 1/\text{thr}$ first and then $g^{-1}(k)$ is brought smoothly to zero as $k$ approaches $k_{\text{zo}}$. This smoothing is accomplished by multiplying $g^{-1}(k)$ by $\alpha^2(k_z) = \alpha(k_z) = (k_z - k_{\text{zo}})/|k_{\text{zo}} - k_{\text{thr}}|$ where $k_z$ is the $z$ component of that particular point in k-space, $k_{\text{zo}}$ is the point at which the function $g^{-1}(k)$ becomes undefined, and $k_{\text{thr}}$ is the $k_z$ coordinate value where $|g(k)| = \text{thr}$ (18).

SMs using the methods in Refs. 11,15,18 were calculated based on Eq. 1 using the 2D cylindrical model. Equation 1 can be used to calculate the SM for the simulated 2D cylinder model perpendicular to the main field since the 2D perpendicular model is a special case of the 3D model with 1 slice [10]. Streaking artifacts are obvious in all three SMs (figures are not shown). The calculated mean susceptibility values inside the cylinder
The effect of high-pass (HP) filtering the phase data on the \( r(r) \) map generated by the iterative method was also studied. Phase images of a cylindrical geometry with diameters of 2, 4, 8, 16, 32, and 64 voxels were simulated. Homodyne HP filters (33) with a 2D hanning filter (full width at half-maximum, FWHM = 4, 8, 16, and 32 pixels) were applied on these phase images in both image and slice directions. SM reconstructions were stopped based on the criteria in step 7 of the iterative process.

Three Dimensional Brain Model Simulations

To address the potential of the iterative technique to improve the SM of general structures such as the basal ganglia, a 3D model of the brain was created including the red nucleus (RN), substantia nigra (SN), crus cerebri (CC), thalamus (TH), caudate nucleus (CN), putamen (PUT), globus pallidus (GP), gray matter (GM), white matter (WM), cerebrospinal fluid (CSF), and the major vessels (34). The structures in the 3D brain model were extracted from two human 3D brain datasets and the accuracy of the estimated susceptibility values in parts per million (ppm) for the structures SN, RN, PUT, and GP, were taken from Ref. 12 and others were from measuring the mean susceptibility value in a particular region from SMs using Ref. 18 from in vivo human data: RN = 0.13, SN = 0.16, CC = −0.03, TH = 0.01, CN = 0.06, PUT = 0.09, GP = 0.18, vessels = 0.45, GM = 0.02, CSF = −0.014, and WM = 0. All structures were set inside a 512 × 512 × 256 matrix of zeros. The phase of the 3D brain model was created by applying the forward method (8,26,27,30) to the 3D brain model with different susceptibility distributions using the imaging parameters: \( T_E = 5 \text{ ms} \) and \( B_0 = 3 \text{ T} \). A comparison between the phase maps from this brain model and a real data set is shown in Fig. 3. To match the imaging parameters of the real data set, \( B_0 = 3 \text{ T} \) and \( T_E = 18 \text{ ms} \) were applied for the results presented in Fig. 3. Except for Fig. 3, all other figures in the paper associated with the 3D brain were simulated by using \( T_E = 5 \text{ ms} \).

In Vivo MR Data Collection and Processing

A standard high-resolution 3D gradient echo SWI sequence was used for data acquisition. A transverse 0.5 mm isotropic resolution brain dataset was collected at 3 T from a 23-year-old healthy volunteer. The sequence parameters were: TR = 26 ms, flip angle = 15°, read...
bandwidth = 121 Hz/pixel, $T_E = 14.3$ ms, 192 slices, and a matrix size of $512 \times 368$. To reconstruct $\chi_{\omega}(r)$ with minimal artifacts, the following steps were carried out:

1. The unwanted background phase variations were removed using either: (a) a homodyne HP filter (FWHM = 16 pixels) (33) or (b) Prelude in FMRIB Software Library (FSL) (35) to unwrap the phase, followed by the process of Sophisticated Harmonic Artifact Reduction for Phase data (SHARP) (36) with a filter radius of 6 pixels. To reduce artifacts in the calculated SMs, regions with the highest phase deviations due to air/tissue interfaces were removed manually from the HP filtered phase images and the phase in those regions were set to zero.

2. A complex threshold approach (37) was used to separate the brain from the skull.

3. The phase image with an original matrix size of $512 \times 368 \times 192$ was zero filled to $512 \times 512 \times 256$ to increase the field-of-view and to avoid streaking artifacts caused by the edge of brain to alias back to the reconstructed SM.

4. The regularized inverse filter, $g^{-1}(k) (18)$ was applied to obtain $\chi_{\omega}(r)$, followed by the iterative process using $a = 0.1$. For in vivo data, the iterative program was terminated at the third iterative step.

RESULTS
Selection of Threshold Level Based on Simulations
To find the optimal threshold value, SMs were reconstructed using $a = 0.01, 0.03, 0.07, 0.1, 0.15, 0.2, 0.25$, and 0.3, respectively, with different noise levels (Fig. 4). The streaking artifacts shown in $\chi_{\omega}(r)$ (the first column in Fig. 4a) have been significantly reduced by the iterative method and fall below the noise level when $a > 0.1$. Also, when $a > 0.1$, the mean susceptibility value

![Image of simulation results](image-url)
inside the cylinder was found to increase to 0.44 ppm when the diameter of the cylinder was larger than 8 pixels (Fig. 4b) and this trend is independent of the object size and the noise in the phase image. The optimal result in terms of obtaining the true susceptibility value was with a threshold of 0.1. Figure 4c shows a plot of RMSE of the susceptibility values from the whole region outside the 32-pixel cylinder using different $a$. The RMSE of the susceptibility values decreases as $a$ increases. Therefore, for vessels, a value of $a = 0.3$ would be the optimal value. However, a large threshold value means replacing more original k-space with the k-space only consisting of vessel information which will reduce the signals from other brain structures and blur these structures. Since the SM using $a = 0.1$ already reveals the optimal susceptibility value for the vessels and an acceptable RMSE, it is appropriate to choose 0.1 for more general applications to study the entire brain.

Figure 4a compares the converged $\chi_{i=0}(r)$ map with the $\chi_{i=0}(r)$ map, where $b$ is the iterative step required to reach convergence. In this data, $b = 2$ when $a = 0.01$ and 0.03, $b = 3$ when $a = 0.07, 0.1$, and 0.15 and $b = 4$ when $a = 0.2, 0.25$, and 0.3 for $\sigma_{\text{phase}} = 0$. When $\sigma_{\text{phase}}$ increases, more iterative steps were required to reach convergence. For instance, the maximum iterative step number is 9 when $\sigma_{\text{phase}} = 0.2$ radians. Using a noise level of 0.025 radian in the phase image as an example, $g_{\text{reg}}^{-1}(k)$ (18) leads to a susceptibility noise of roughly 0.025 ppm in the $\chi_{i=0}(r)$ map. The iterative approach leads to a slight decrease in background noise, 0.021 ppm, in $\chi_{i=0}(r)$ map when $a = 0.1$. The background noise was measured in a region outside the streaking artifact indicated by the black circle in Fig. 4a. The overall decrease in RMSE in the background (Fig. 4c) is a consequence of both a decrease in streaking artifacts and a reduction in thermal noise contribution.

Selection of the Optimal Iterative Step

The inverse process (18) was applied to the dipole field in Fig. 5a to give the $\chi_{i=0}(r)$ map shown in Fig. 5b; prominent streaking artifacts are evident in this image. Streaking artifacts are significantly reduced at each step of the iterative method quickly reaching convergence (Fig. 5c–e). The largest improvement is seen in the first iterative step, which is verified by Fig. 5f, showing the difference between Fig. 5c ($\chi_{i=1}(r)$ map) and Fig. 5b ($\chi_{i=0}(r)$ map). After the second iteration, we can see some minor streaking reductions (Fig. 5g, the difference between the $\chi_{i=1}(r)$ map and $\chi_{i=2}(r)$ map). The mean susceptibility value approaches 0.44 ppm in a single step. Similar results (not shown) are also obtained when the iterative method is run with different aspect ratios between the in-plane resolution and the through plane resolution (such as 1:2 and 1:4). The iterative results always lead to higher final susceptibility values compared to the initial value in $\chi_{i=0}(r)$. Finally, even when an HP filter is applied, up to a 10% increase in the susceptibility is realized (Fig. 5i). The SMs of large vessels benefit from a low order HP filter (FWHM = 4 pixels) and small vessels up to 8 pixels benefit from a HP filter (FWHM = 16 pixels).

Effect of the Iterative Approach on Susceptibility Values in the 3D Brain Model

SM Reconstruction Using a Vessel Mask Only

Figure 6a,d represents $\chi_{i=0}(r)$, without noise and with 0.025 radians of noise in phase images. Figure 6f is the vessel map. Streaking artifacts (delimited by the black arrows) are obvious in Fig. 6a,d and significantly reduced in the $\chi_{i=3}(r)$ maps (Fig. 6b,e) using $a = 0.1$. Figure 6c is the $\chi_{i=3}(r)$ map using $a = 0.2$. As can be seen, when $a$ increases, the iterative method still works for vessels, but brain tissues become more blurred. Figure 7a plots the mean susceptibility values inside the vessel (vein of Galen), GP, SN, RN, PUT, and CN from $\chi_{i=3}(r)$ maps generated by using $a = 0.1, 0.15, 0.2, 0.25$, and 0.3, respectively. The susceptibility value in the brain model and $\chi_{i=0}(r)$ map are also provided in the plot as references. Generally, the susceptibility values of brain tissues except vessels decrease as $a$ increases while, for vessels, the susceptibility value is 0.41 ppm in the $\chi_{i=0}(r)$ map and is increased to 0.45 ppm in the $\chi_{i=3}(r)$ maps.

SM Reconstruction Using a Mask Including Vessels and Brain Structures

The iterative method is not limited to improving SM from just vessels; it can also be applied to the entire brain. Figure 6g shows a coronal view of the $\chi_{i=0}(r)$ map for the brain model. The $\chi_{i=3}(r)$ map using a mask keeping all major structures (GP, SN, RN, PUT, CN) and vessels is shown in Fig. 6h. In practice, this is equivalent to setting thresholds in the $\chi_{i=0}(r)$ map to be greater than 0.09 ppm to extract all these high susceptibility structures from the $\chi_{i=0}(r)$ map to create the mask. Figure 6h reveals that streaking artifacts associated with veins as well as all major structures have been reduced. Figure 6i shows the difference between Fig. 6g, h. In addition, streaking artifacts sometimes cause the appearance of “false” structures. For instance, there is no internal capsule (IC) included in the model (Fig. 6i), yet we see an IC-like structure in the $\chi_{i=0}(r)$ map (Fig. 6j) (indicated by a dashed white arrow in Fig. 6j). The iterative method removes the streaking artifacts and the “false” IC (Fig. 6k). Figure 7b shows susceptibility values in each structure in the brain model for $\chi_{i=0}(r)$ and $\chi_{i=3}(r)$ when the mask includes vessels and all major structures. The underestimated susceptibility values of all major structures and vessels in the $\chi_{i=0}(r)$ map have been recovered by the iterative method in the $\chi_{i=3}(r)$ map.

Effect of Errors in the Vessel Map

Accurately extracting vessels from $\chi_{i=0}(r)$ is critical for the iterative method. Figure 8b–d and the corresponding enlarged views (Fig. 8f–h) from the rectangular region indicated in Fig. 8a show the $\chi_{i=0}(r)$ maps using an accurate (Fig. 8j), a dilated (Fig. 8k), and an eroded (Fig. 8l) vessel map to show the effect of errors in the vessel mask on the $\chi_{i=3}(r)$ map. The dilated and eroded vessel maps were generated using Matlab functions based on a 3-by-3 square structuring element object. The susceptibility values measured from a vein indicated by the white arrow in Fig. 8e are 0.40 ± 0.03 ppm (Fig. 8e),
The iterative method still works if the vessel is slightly enlarged but does little to change the original $x_i = 0(r)$ map if the vessels are too small or absent in the mask. As we just discussed, streaking artifacts produced "false" vessels indicated by the dashed black arrow in Fig. 8e since these vessels are not in the model (Fig. 8i). These false vessels disappeared in Fig. 8f.

Results from the In Vivo Dataset

In the in vivo example, we compare the differences between SHARP (Fig. 9a–d) and a homodyne HP filter (FWHM = 16 pixels) (Fig. 9e–h). Compared to the transverse view, streaking artifacts are more obvious in the sagittal or coronal view. Figure 9a shows the $x_i = 0(r)$ map with severe streaking artifacts. The streaking artifacts were significantly reduced in the $x_i = 3(r)$ map (Fig. 9b) using $a = 0.1$. The streaking artifacts associated with the superior sagittal sinus vein (indicated by two black arrows in Fig. 9a) were significantly decreased in Fig. 9b,d. The subtracted image (Fig. 9c), Fig. 9a minus Fig. 9b, reveals the removed streaking artifacts. These streaking artifacts are one of the reasons why the $x_i = 0(r)$ maps appear noisy. In the $x_i = 3(r)$ map, the reduction in streaking artifacts from individual veins leads to a decrease of noise therefore an increased SNR of veins. If veins are the only interest, even a threshold of 0.2 can work reasonably well (Fig. 9d). Two relatively big veins, V1 and V2, indicated by the white dashed and white solid arrows, respectively, in Fig. 9b, were chosen to measure the susceptibility values. Results are provided in Table 1. The susceptibility values of these two veins have been improved by roughly 16% by the iterative method. The standard deviation of the susceptibility values measured

0.45 ± 0.03 ppm (Fig. 8f), 0.45 ± 0.03 ppm (Fig. 8g), and 0.40 ± 0.07 ppm (Fig. 8h), respectively. The iterative method still works if the vessel is slightly enlarged but does little to change the original $x_i = 0(r)$ map if the vessels are too small or absent in the mask. As we just discussed, streaking artifacts produced "false" vessels indicated by the dashed black arrow in Fig. 8e since these vessels are not in the model (Fig. 8i). These false vessels disappeared in Fig. 8f.

Results from the In Vivo Dataset

In the in vivo example, we compare the differences between SHARP (Fig. 9a–d) and a homodyne HP filter (FWHM = 16 pixels) (Fig. 9e–h). Compared to the transverse view, streaking artifacts are more obvious in the sagittal or coronal view. Figure 9a shows the $x_i = 0(r)$ map with severe streaking artifacts. The streaking artifacts were significantly reduced in the $x_i = 3(r)$ map (Fig. 9b) using $a = 0.1$. The streaking artifacts associated with the superior sagittal sinus vein (indicated by two black arrows in Fig. 9a) were significantly decreased in Fig. 9b,d. The subtracted image (Fig. 9c), Fig. 9a minus Fig. 9b, reveals the removed streaking artifacts. These streaking artifacts are one of the reasons why the $x_i = 0(r)$ maps appear noisy. In the $x_i = 3(r)$ map, the reduction in streaking artifacts from individual veins leads to a decrease of noise therefore an increased SNR of veins. If veins are the only interest, even a threshold of 0.2 can work reasonably well (Fig. 9d). Two relatively big veins, V1 and V2, indicated by the white dashed and white solid arrows, respectively, in Fig. 9b, were chosen to measure the susceptibility values. Results are provided in Table 1. The susceptibility values of these two veins have been improved by roughly 16% by the iterative method. The standard deviation of the susceptibility values measured

0.45 ± 0.03 ppm (Fig. 8f), 0.45 ± 0.03 ppm (Fig. 8g), and
0.40 ± 0.07 ppm (Fig. 8h), respectively. The iterative method still works if the vessel is slightly enlarged but does little to change the original $x_i = 0(r)$ map if the vessels are too small or absent in the mask. As we just discussed, streaking artifacts produced “false” vessels indicated by the dashed black arrow in Fig. 8e since these vessels are not in the model (Fig. 8i). These false vessels disappeared in Fig. 8f.

Results from the In Vivo Dataset

In the in vivo example, we compare the differences between SHARP (Fig. 9a–d) and a homodyne HP filter (FWHM = 16 pixels) (Fig. 9e–h). Compared to the transverse view, streaking artifacts are more obvious in the sagittal or coronal view. Figure 9a shows the $x_i = 0(r)$ map with severe streaking artifacts. The streaking artifacts were significantly reduced in the $x_i = 3(r)$ map (Fig. 9b) using $a = 0.1$. The streaking artifacts associated with the superior sagittal sinus vein (indicated by two black arrows in Fig. 9a) were significantly decreased in Fig. 9b,d. The subtracted image (Fig. 9c), Fig. 9a minus Fig. 9b, reveals the removed streaking artifacts. These streaking artifacts are one of the reasons why the $x_i = 0(r)$ maps appear noisy. In the $x_i = 3(r)$ map, the reduction in streaking artifacts from individual veins leads to a decrease of noise therefore an increased SNR of veins. If veins are the only interest, even a threshold of 0.2 can work reasonably well (Fig. 9d). Two relatively big veins, V1 and V2, indicated by the white dashed and white solid arrows, respectively, in Fig. 9b, were chosen to measure the susceptibility values. Results are provided in Table 1. The susceptibility values of these two veins have been improved by roughly 16% by the iterative method. The standard deviation of the susceptibility values measured

FIG. 5. a: Phase images from a cylinder with a diameter of 32 pixels are simulated with: $\Delta x = 0.45$ ppm, $B_0 = 3$ T, and $T_E = 5$ ms. The cylinder is perpendicular to the main field. No thermal noise was added in these images. b: The initial $x_i = 0(r)$ map. c: The SM from the first iteration, $x_i = 1(r)$ map. d: $x_i = 2(r)$ map and e: $x_i = 3(r)$ map using threshold value $a = 0.1$. The SM has converged at $x_i = 3(r)$ map. The streaking artifacts are reduced as the number of iterative steps increases. f: The difference image of (c) subtracted from (b) illustrates that the streaking artifacts were reduced by the iterative procedure and the largest improvement happens in this first iterative step. g: The difference image of the $x_i = 1(r)$ map subtracted from the $x_i = 2(r)$ map indicates that the streaking artifacts were further reduced by the second iterative step. h: The difference image of $x_i = 2(r)$ map subtracted from $x_i = 0(r)$ map shows much less improvement at the third iterative step. Thus it indicates a convergence of the iterative procedure. All images were set to the same window level setting for direct comparisons and for enhancing the presence of the streaking and the remnant error. i: The effect of the iterative approach on the changes in susceptibility values from HP filtered phase images. Differences between the values in iterative and non-iterative susceptibility map reconstruction (i.e., $x_{\text{converged}}(r) - x_0(r)$) from HP filtered phase images are plotted for different filter sizes. Results for four filter sizes (FWHM = 4, 8, 16, and 32 pixels) are shown here. Applying an HP filter leads to an underestimation of $\Delta x$ (18). The iterative approach helps to improve the accuracy of the estimated susceptibility values. The range of the gray-scale bars is chosen to highlight the artifacts in the images. It does not reflect the quantified higher susceptibility values inside cylinders.

Susceptibility Mapping Using Iterative Approach
from a uniform region inside the WM decreased from 0.042 ppm in $\chi_{i=0}(r)$ map to 0.035 ppm and 0.023 ppm in the $\chi_{i=3}(r)$ map with $a = 0.1$ and 0.2, respectively. The baseline susceptibilities of the major structures are higher with SHARP than with the HP filter. The iterative method works for brain structures too when the structure is included in the mask. For instance, the mean susceptibility values of the GP and SN have been increased from $0.155 \pm 0.058$ ppm and $0.162 \pm 0.067$ ppm in the $\chi_{i=0}(r)$ map to $0.163 \pm 0.070$ ppm and $0.186 \pm 0.083$ ppm in the $\chi_{i=3}(r)$ map, from the dataset processed using SHARP. The result after HP filtering (Fig. 9e) shows more edge artifacts indicated by the left arrow in Fig. 9e. Much of this error was reduced by the iterative method (Fig. 9f). It seems that the iterative method compensated for the worse first guess (Fig. 9e) and ended up with almost the same result (Fig. 9f,h) as having started with SHARP (Fig. 9b,d) from the image perspective. Since a
small sized HP filter cannot remove rapid phase wrapping at air-tissue interfaces; we had to cut out the region near the sinuses in the phase images.

DISCUSSION

In this article, a threshold-based k-space/image domain iterative approach has been presented. Simulations and in vivo results show that the ill-posed problems of streaking artifacts and biases in the estimates of susceptibilities can be significantly reduced. The replacement of the \( \chi(k) \) values near the singularities by \( \chi_{vm}(k) \), which is obtained from the geometric information from the \( \chi(r) \) map itself, obviates many of the current problems seen in the TBSO methods. Since \( \chi_{vm}(r) \) contains little streaking artifacts itself, the values used inside the thresholded regions in \( \chi(k) \) now contain no artifact either. In this sense, we obtain an almost perfect k-space without bad data points in the region of singularities. This explains why this method converges quickly and the major improvement is in the first iterative step (Fig. 5).

The proposed iterative approach is different from the other threshold-based methods (11,15,18,19,24) which fill a predefined conical region using a constant, zero or 1/thr threshold (11,15,24) or the first-order derivative of \( g^{-1}(k) \) (19). The iterative method uses full geometry information from the SM (vessels or predefined structures and not edge information) to iteratively change k-space values in the conical region using the forward model. This is also quite different than other currently proposed solutions (9,12,20,22). Even though spatial priors such as gradients of the magnitude are used (9,12,20,22), in those methods, the meaningful values of the singularity regions in k-space are obtained through solving the complex cost function problem. However, the iterative method uses priors not from the magnitude image but from the SM. The missing data in the singularity regions are obtained through iterating back and forth between

FIG. 7. The plots of mean susceptibility values inside the vessel (vein of Galen), GP, SN, RN, PUT, and CN from \( \chi_{vm}(r) \) maps. The first two data points of each curve is the value inside each structure from the brain model and the \( \chi_{i=0}(r) \) map, respectively. a: \( \chi_{i=3}(r) \) maps generated by applying a region of interest map which consists only vessels using \( a = 0.1, 0.15, 0.2, 0.25, \) and 0.3, respectively. b: \( \chi_{i=3}(r) \) maps generated by applying a region of interest map which consists of the GP, SN, RN, PUT, CN, and vessels using \( a = 0.1 \).

FIG. 8. Comparison of the reconstructed \( \chi_{i=3}(r) \) maps using (j) accurate, (k) dilated, and (l) eroded vessel maps. Their corresponding vessel maps and the enlarged views from the rectangular regions are provided in (b)–(d) and (f)–(h). (a) and (e) The initial \( \chi_{i=0}(r) \) maps and (i) the original brain model as references. The circle in the midbrain in the \( \chi(r) \) maps represents the RN and is indicated by a black arrow in (i). Other hyper-intense regions in SMs are vessels.
the SMs and their k-space. The advantage of cost function approaches is that they do not need to predefine the singularity region in k-space which is solved by the optimization process automatically (although the optimization process itself is usually quite time-consuming). On the other hand, the iterative method is the most time-efficient. It is fast enough to reconstruct SMs for a $512 \times 512 \times 256$ data set using an Intel Core i7 CPU 3.4 GHz processor in less than 30 s, since in practice usually three iterations are good enough to generate decent results.

The threshold value also plays a key role. A threshold value of 0.1 is a reasonable choice since a lower threshold value leads to an increase in noise and a higher threshold value leads to a blurring of the object (Figs. 6c, 9d, h).

It is known that the ill-posedness of the inverse filter will increase the noise level from the phase to the SM. Based on both simulations and real data, we find that there is a factor of 4 increase in noise in the SM relative to the original phase data. This result and the fact that $B_0 = 3$ T, $T_K = 5$ ms, and $\sigma_{\chi_{i-0}} = 0.025$ ppm make it possible to write the total noise in the background region in $\chi_{i-0}(r)$ as $0.025 \cdot 4 \cdot (3B_0)/(5T_K)$ in ppm. The noise in $\chi_{i-3}(r)$ will be less than this value since the iterative method will reduce streaking artifact in SM.

The iterative method can be used to remove streaking artifacts associated with not only vessels but also other

Mean and standard deviation for the susceptibility values (in ppm) of two veins processed using SHARP and a HP filter (FWHM = 16 pixels), respectively, were chosen from the 0.5 mm isotropic resolution data. V1 and V2 are shown in Fig. 9. The susceptibility values of these two veins have been increased by the iterative method. There is not much variation of the susceptibility value with different threshold values.

In conclusion, both simulations and human studies have demonstrated that the proposed iterative approach can dramatically reduce streaking artifacts and improve the accuracy of susceptibility quantification inside the structures of interest such as veins or other brain tissues. Given its relatively fast processing time, it should be possible to expand its use into more daily clinical practice. With the improved accuracy of the susceptibility values inside veins, this method could be used potentially to improve quantification of venous oxygen saturation (18).

The development of functional brain magnetic resonance imaging (fMRI) has been a boon for neuroscientists and radiologists alike. It provides for fundamental information on brain function and better diagnostic tools to study disease. In this paper, we will review some of the early concepts in high resolution gradient echo imaging with a particular emphasis on susceptibility weighted imaging (SWI) and MR angiography (MRA). We begin with the history of our own experience in this area, followed by a discussion of the role of high resolution in studying the vasculature of the brain and how this relates to the BOLD (blood oxygenation level dependent) signal. We introduce the role of SWI and susceptibility mapping (SWIM) in fMRI and close with recommendations for future high resolution experiments.

Introduction

In the early 1990s, our research interests were in developing and understanding 3D gradient echo imaging methods to study neurological diseases. It would be no surprise to the reader that we were delighted to see the early work from Seiji Ogawa at Bell Labs (Ogawa et al., 1993) and Jack Belliveau and colleagues at MGH (Belliveau et al., 1991) regarding the use of magnetic resonance imaging (MRI) for functional MRI (fMRI) of the brain. The news came to our attention quickly, as we were then focusing on the effects of changes in local fields in gradient echo imaging at Case Western Reserve University (CWRU) more as artifacts than as a useful tool. At that time, we had interests in O17 imaging (Hopkins et al., 1988; Kwong et al., 1991) using gradient echo imaging for brain function and Amos Hopkins, the major instigator in this direction, became interested immediately in collaborating with people at MGH on the concept of fMRI with O17 imaging. Some of the experiments done in this area showed that we could see major changes in the pial veins between activation and resting state (Frahm et al., 1993; Haacke et al., 1994; Lai et al., 1993), and that the early explanation of diffusion as the source of signal change in fMRI was likely not correct. This began what was then known as the brain/vein debate.

It took some years later and a number of key papers to show that the intravascular and extravascular effects, at least at 1.5 T, were the major sources of signal change in fMRI. To demonstrate this, researchers applied strong dephasing gradients and/or saturation pulses to basically remove the arterial signal from the images and then evaluated the fMRI response (Duong et al., 2003). After suppressing blood flow, there was little fMRI response remaining, implicating a major intravascular source. An example of the effect of saturation pulses applied outside the slices of interest for a 3 T fMRI experiment
in the visual cortex is shown in Fig. 1. Clearly, there is a decrease in the signal even for the gradient echo EPI sequence. It should be noted that for the long TR experiments used for whole brain multi-slice EPI, there is a strong inflow of fresh blood, which is referred to as “inflow BOLD enhancement" (Duong et al., 2003; Duyn et al., 1994). By suppressing the signal from blood, the inflow BOLD enhancement effects are also suppressed, leaving only the extravascular effects. During the last 20 years, many papers have been written studying the role of intravascular and extravascular BOLD effects, even up to today, especially since higher and higher field strengths have become available and more and more signal is generated from extravascular effects (Baudendistel et al., 1998; Boxerman et al., 1995; Casciaro et al., 2008; Song et al., 2007; Ugurbil et al., 2000).

The role of high resolution

One of our goals has been to look for methods to increase resolution and yet keep imaging time reasonable. One early example of this was partial Fourier imaging (Haacke et al., 1999; Xu and Haacke, 2001). This approach allowed us (and still does) to take an asymmetric echo, keep flow compensation for short echoes, and collect many points after the echo to maintain high resolution in the read direction. We also focused on segmented EPI to improve speed for high resolution imaging (Haacke et al., 1986; Xu and Haacke, 2008). We believed that new information awaited us structurally and functionally if we could push resolution down to 100 μm. Today, high-field and parallel imaging are re-opening the door to that goal. The group in Minnesota pioneered this direction in the visual cortex by studying ocular dominance columns with high resolution fMRI (Menon et al., 1997; Yacoub et al., 2008). Of course, the most interesting approach would be to create high resolution functional imaging with anatomical qualities, whether it be vascular, metabolic, or brain function. No doubt researchers in this field will continue to fine tune the MR microscope to push these limits further and further in the future thanks to the continued technical developments that lead to higher signal-to-noise, faster imaging and better resolution.

Why high resolution? Evidently the workhorse for fMRI today remains a low resolution scan with roughly 3 mm resolution in each direction. The argument for this is that the signal-to-noise (SNR) has to be high enough that one can detect changes in signal as small as 1%. However, it depends on whether or not there is a scale invariant

---

**Fig. 1.** GE- (a, b) and SE-EPI (c, d) t-maps obtained without (a, c) and with (b, d) blood saturation, showing a reduced BOLD response when blood signal is saturated. TE of GE- and SE-EPI was 24 ms and 96 ms respectively. The blood saturation was done by placing two saturation bands above and below the imaging slab, and the visual stimulation was 8 Hz flashing checkerboard with 30 s/30 s on/off block design.

**Fig. 2.** Activations in the primary motor cortex using a block design finger tapping paradigm. (a) Filtered 3D GRE images of single subtraction between activation and resting state, with voxel size of $1.75 \times 1.75 \times 2$ mm$^3$; (b) phase image from the same slice showing the motor cortex; (c) t-value map calculated from the GE-EPI data acquired using 3.5 mm isotropic voxels and a TE of 30 ms; (d) same as in (c) but with modified window level settings; (e) sagittal reformat of the 3D GE subtraction; and (f) sagittal MP-RAGE image. Imaging parameters for the 3D GRE sequence were: TR/TE = 30/20 ms, flip angle = 15°, BW = 80 Hz/pixel, 2 × GRAPPA, resolution = $0.875 \times 0.875 \times 2$ mm$^3$, N$_z$ = 64, acquisition time for each block was 96 s. The average signal change in GE-EPI activation (d) is about 0.8% with maximum of 3.5%, and the signal change in the 3D GRE data (e) is about 14%.
response. For capillary structures, resolution is probably not important. But what are we really seeing in current low resolution EPI fMRI results? In 1999, Hoogenraad et al. (1999) showed that a very high resolution gradient echo scan could be used to collect fMRI data (albeit much more slowly than EPI) and then collapsed back to the same low resolution as EPI and that the results were basically the same. This suggests that the signal from the major veins still plays a key role in the fMRI response even for low resolution imaging (see Fig. 2).

As mentioned earlier, the only way to really remove the intravascular effects is by saturation or dephasing or both, and in this way one can be sure that the response being imaged is predominantly extravascular. But saturation alone may not explain the fact that there remains some signal from what appears to be the same location as before in Fig. 1 but just reduced in amplitude. Consider the high resolution angiogram in Fig. 3. The role of saturation can be appreciated in this figure and its effect is demonstrated by subtraction of the saturated data from the unsaturated data (Fig. 3c). The second image (Fig. 3b) shows that the signal from the arteries and veins is almost isointense to the surrounding tissue but certainly not completely nulled either due to $T_1$ recovery. To remove any remnant effects from the venous blood, one could then apply dephasing gradients. This should null any remaining intravascular contribution to the signal (see also (Song et al., 1996) and Fig. 4). This was indeed the argument in the early brain/vein debate.

The results in Fig. 2 however are very suggestive. They are identical in nature to the earlier results from Frahm et al. (1993), Haacke et al. (1994), Lai et al. (1993), only acquired faster at 3 T. The unfiltered EPI acquired with lower resolution show pretty much the same areas of activation. The filtered EPI activation t-maps have lost the ability for good spatial localization and show activation badly blurred over that portion of the brain. Perhaps one of the best clinical applications for these high resolution fMRI methods would be in the study of eloquent cortex when the neurosurgeon must operate on a tumor (Baudelet et al., 2006; Hou et al., 2006; Sherman et al., 2011). Given the results seen in the 3D data with complete visualization of the brain, one wonders why this method has not been used more in the last 20 years. Can we use high resolution gradient echo methods practically? To understand when this is possible, we need to first address the role of vessel size.

The work by Cheng and Haacke (2001) tried to address this question of scale variance more carefully, showing that the expected fMRI response is scale invariant when the voxels are larger than the largest veins, hence making EPI the method of choice after that point ($2 \times 2 \times 2$ mm$^3$ is probably large enough to meet that limit and would provide far better spatial delineation than what people are using today which is often just a broadly spread out inflow enhanced vascular response). However, Haacke et al. (1994) and Cheng and Haacke (2001) also showed that when the scale becomes on the order of the vessel size and smaller, there will be a dramatic increase

![Fig. 3](image-url)

(a) MaxIP images of a normal TOF; (b) TOF with a fixed arterial saturation pulse; and (c) their subtraction image. The imaging parameters were: $0.5 \times 0.5 \times 0.5$ mm$^3$ isotropic voxels, TR/TE = 20/11 ms, flip angle = 15°, and fully flow compensated. All MaxIP was done over 16 slices. Although most major vessels are suppressed, one can see some remnant arterial/venous signal even with saturation. The reduced signal from the veins in this case actually leads to a poorer signal cancellation in the usual SWI data (not shown here) which relies on having a strong intravascular component.

![Fig. 4](image-url)

(a) MRA MaxIP images acquired without dephasing gradients, and (b) MinIP images acquired with dephasing gradients, with a VENC value of 0.94 cm/s. Both arteries and even medullary veins are well suppressed. (c) is the result of subtracting (b) from (a), removing most of the background tissues while accentuating the vessels. All MaxIP was done over 16 slices of 0.5 mm thickness. In this subtraction both arteries and veins are evident although the venous structures are not as bright as the arteries structures in part because the signal from the veins is already suppressed because of their low $T_2^*$ value.

in signal response. In fact, in Lai et al. (1993), the authors showed an image from Duvernoy et al. (1981) showing the pial vein, venules and capillaries, and commented that as resolution improves so will the ability to localize the fMRI signal once the resolution is on the order of the size of the vessel (vein) of interest. The general argument against this has been that there is not enough SNR or temporal resolution to collect the data at such high resolution (and Cheng and Haacke's paper even suggests this to a point). However, this has all changed with the advent of high fields such as 3 T and even more so with 7 T, where very high SNR and very high resolution fMRI has become viable. It is a testament to the progress made in MRI that the picture from Duvernoy showing the pial veins, venules and capillaries has basically been replicated now with SWI filtered phase (Haacke et al., 1995; Haacke and Reichenbach, 2011) and gradient echo images at 7 T (Ge et al., 2008; Lee et al., 2010) and is beginning to be seen at 3 T (Haacke and Reichenbach, 2011).

In the early days, much work went into suppressing the signal from the veins (Duong et al., 2003; Glover et al., 1996). But now it is possible to do what was alluded to in the work of Haacke et al. (1994), image the small draining veins adjacent to the activated tissue, especially if the goal is to do the neuroscience to understand the sources of the local neural activity involved in activation. With these high SNR, high resolution, rapid scanning methods, it should be possible to begin to see local changes in venous oxygen saturation (which is the underlying mechanism of BOLD effect) at the level of medullary veins (several hundred microns) to perhaps even local changes in venules (50 μm). It turns out that the optimal resolution according to Cheng and Haacke is about four times larger than the vessel volume. So a vein that is 250 μm could be seen and imaged with a resolution of 500 μm (as it is now with SWI for example (Belliveau et al., 1992; Haacke et al., 1997, 2004, 2009; Mittal et al., 2009) or a vessel that is 50 μm could be seen with a resolution of 100 μm. Practically, the results are better than Cheng and Haacke had anticipated. The 7 T data of today can already reveal venules with a resolution of 0.2 × 0.2 × 1 mm³ (Ge et al., 2008; Lee et al., 2010). We can expect to see many more publications in the future on high resolution functional MRI using 3D gradient echo imaging techniques.

There are some practical issues that need to be dealt with to make imaging with high resolution more attractive. One of these is scanning time and the other is SNR. To cover the entire brain at 3 T with 64 2 mm thick slices and an in-plane resolution of 0.5 mm × 0.5 mm will take about 5 min. Keeping a single activation task running for 5 min is not easy and then of course another 5 min to obtain the resting state images. However, with the marriage of parallel imaging and segmented echo-planar imaging, we anticipate this time being reduced to one and a half minutes. Reducing the resolution slightly to 1 mm × 1 mm × 2 mm would further reduce the time by about 30 s. Now this allows for a more conventional block design of 30 s activation and 30 s resting for five cycles, allowing the entire 3D scan to take place in just 5 min. This is similar to current imaging times in most fMRI experiments.

High resolution MR angiography: the role of saturation and dephasing

Before we address the practical issue of high resolution fMRI with 3D gradient echo imaging and SWI, it is important to understand what is possible on the MR angiography side from the perspective of collecting high resolution data, enhancing contrast, and nulling signal from blood. In fMRI with EPI, one gets excellent intravascular signal contributions thanks to the inflow enhancement from the arterial side and hence venous signal. But with gradient echo imaging, blood signal will be suppressed with respect to gray matter due to blood’s longer T₁. One can do MRA both with and without contrast agent to best enhance the vascular signal and more importantly, the contrast between vessels and surrounding tissue. Recall that if the vascular signal is too low, the enhancement from the intravascular BOLD effect will be minimized. Fig. 3 and particularly Fig. 4 show the capability of high resolution imaging in mapping out not just the major arteries but also, most importantly, smaller branches that are the basic source of blood supply to the tissue.

These images can be further improved by using a magnetization transfer contrast (MTC) pulse, using a saturation band, dephasing the signal from the moving spins, or other means to suppress the background. Consider the use of MTC as a first approach. The problem with MTC is that it lengthens the scan time and increases the specific absorption rate (SAR) making it less desirable to use at high magnetic fields. A second approach is to perform two scans: one with high vessel signal and the other with low signal and subtract them. One can use saturation bands to suppress the arterial signal or venous signal by saturating the inflowing blood, or use a strong set of bipolar gradients to dephase moving spins in both arteries and veins. The advantage of the bipolar gradients over saturation bands is that it suppresses fast flowing blood, requires no SAR increases and can be acquired in an interleaved TR manner (i.e., one TR with dephasing and the next TR without) without interfering with equilibrium of the magnetization and without suffering from misregistration artifacts. The VENC concept in flow quantification methods (Haacke et al., 1999) can be used to describe the dephasing effects, that flowing blood with a velocity higher than the VENC value will be dephased. Setting the VENC values to about 1 cm/s or less should do a reasonably good job dephasing laminar flow even for small vessels (250 to 500 μm sized arteries and veins). The disadvantage is that it still requires twice the time (except in some special double or triple echo sequence designs (Kimura et al., 2009)), and both arteries and veins will be shown in the subtracted images. Fig. 4a shows an example of the usual arterial inflow effects, Fig. 4b a MiniIP image showing that most vessels are dephased, and Fig. 4c the subtraction of Fig. 4b from 4a. As a side note, those in the fMRI field often quote a b-value rather than the VENC value. However, the bipolar gradients are not being used as diffusion gradients, nor is the diffusion effect the underlying mechanism for signal suppression here. Therefore, we have used the more conventional nomenclature from MR angiography of VENC value above which aliasing occurs. With a pair of bipolar rectangular gradients, for simplicity, one can relate the VENC value to the b-value via VENC = n/(6b¹/²) (since VENC = n/(2γG²τ)), where τ is the duration of one gradient lobe. So, for example, if the applied gradient is 25 mT/m with 5 ms duration, then b = 3.73 s/mm² and VENC = 0.94 cm/s. Since the peak flows in pial veins is on the order of 1–4 cm/s, one can expect their signal to be fully suppressed with a VENC of 0.94 cm/s.

As a fourth approach, a contrast agent can be used to enhance vessel signal throughout the brain without being concerned about saturation effects even for slower flowing blood in small vessels. The challenge in imaging the vessels in vivo is to strive to mimic the example of the arteries from Salamon (1971) as shown in Fig. 5a. In this sagittal view, one can see the radial branching of the arteries into the brain. Many of the major arteries that are a few millimeters in size bifurcate into arteries that are perhaps only 100 to 200 μm in size. These in turn branch into vessels only a few dozen microns in size and these finally to the capillaries. Using the high resolution MRA approach with contrast agent injection yields the comparative results shown in Fig. 5b. Although no dephasing example has been used to subtract away the remaining background tissue, there is still clear evidence of small arteries in these images that are approaching 100 to 200 μm in size. A key component in understanding the role of the vasculature in BOLD imaging is to be able to map out the arteries and veins separately. Further, since a major component of the BOLD signal comes from intravascular effects, the use of a T₁ reducing contrast agent to increase the venous signal should in principle lead to an improvement in the BOLD response.

The thrust for high resolution MR angiographic approaches is not just to better understand the vascular structure and source of vascular...
Susceptibility weighted imaging (SWI)

Throughout this early period our interest was to understand BOLD imaging by studying the veins. This focus eventually led to pushing the resolution limits until, in 1997 (Reichenbach et al., 1997), we came up with the concept of susceptibility weighted imaging (SWI). One of the key participants in this work was Jurgen Reichenbach, then a post-doctoral fellow in St. Louis, Missouri at the Mallinckrodt Institute of Radiology (he is now a full Professor running his own imaging laboratory at the Friedrich-Schiller Univeristat in Jena, Germany). Other researchers who were involved at this time included Song Lai (Lai et al., 1993) and Frank Hoogenraad (Hoogenraad et al., 1999). Although the precursor to this had been a paper in 1995 studying the susceptibility effects that could be visualized with phase (Haacke et al., 1995), the potential clinical applications started first with SWI. During the next ten years, we saw SWI show its value in a wide-ranging set of conditions such as aging, multiple sclerosis, stroke, trauma and tumors (Mittal et al., 2009; Obata et al., 2004). The usual TE, TR and flip angle values at 3 T are 20 ms, 30 ms and 15°. Bandwidth is kept low at around 100 Hz/pixel to keep signal-to-noise high. With parallel imaging, whole brain coverage for the lower resolution of 0.5 × 1.0 × 2 mm³ takes only 3 to 4 min. An example of a processed MRA/SWI data set at 3 T is shown in Fig. 6. Until recently, only one echo was used with SWI scans, but there are now a number of papers extolling the virtues of multiple echo SWI with the idea that the first echo can be used for MRA (Barnes and Haacke, 2009b; Deistung et al., 2009; Du and Jin, 2008; Haacke and Reichenbach, 2011), the second for SWI and the combination for T₂*. Here the small medullary veins are clearly seen in the MinIP images for SWI. With sufficient resolution, phase can be measured in the small veins and is, of course, proportional to the susceptibility, which, in turn, is proportional to the deoxyhemoglobin content. Phase itself has been used to measure changes in flow indirectly through changes in oxygen saturation in traumatic brain injury studies (Shen et al., 2007) and more recently in stroke (Li et al., 2011b). But because phase is non-local and depends on the geometry of the source and the location of the object relative to the main field, a direct measure of the venous susceptibility would be more appropriate. Hence, our closing section will be about the use of susceptibility mapping to measure oxygen saturation (Barnes and Haacke, 2009a; Li et al., 2011a; Reichenbach et al., 1997).

Susceptibility weighted imaging and mapping (SWIM) and oxygen saturation maps

The ability to map oxygen saturation may help develop the potential of high resolution SWI as a means to detect local BOLD changes, especially in 2004 (Haacke et al., 2004), we published again with an effort to push the SWI filtered phase as a useful tool in itself. We have also used the phase as a means to map the primary motor cortex as the iron content in the gray matter is quite high in this region and the phase images give excellent gray matter/white matter contrast there (Ogg et al., 1999). More recently, there has been increased interest and attention paid to phase in fMRI (Rowe and Haacke, 2009; Rowe and Logan, 2004). The final thrust in this direction is an interesting return to quantifying oxygen saturation using susceptibility mapping (de Rochefort et al., 2008; Haacke et al., 2010) or it has also been called susceptometry (Fernandez-Seara et al., 2006). Perhaps one day direct measurements of changes in oxygen saturation at the level of the smallest veins will be a viable means to study local neural responses.

Practically, SWI has been used to create exquisite images of the veins without contrast agent. The standard clinical approaches use a resolution of 0.5 × 1.0 × 2 mm³ or when there is time 0.5 × 0.5 × 2 mm³. The usual TE, TR and flip angle values at 3 T are 20 ms, 30 ms and 15°. Bandwidth is kept low at around 100 Hz/pixel to keep signal-to-noise high. With parallel imaging, whole brain coverage for the lower resolution of 0.5 × 1.0 × 2 mm³ takes only 3 to 4 min. An example of a processed MRA/SWI data set at 3 T is shown in Fig. 6. Until recently, only one echo was used with SWI scans, but there are now a number of papers extolling the virtues of multiple echo SWI with the idea that the first echo can be used for MRA (Barnes and Haacke, 2009b; Deistung et al., 2009; Du and Jin, 2008; Haacke and Reichenbach, 2011), the second for SWI and the combination for T₂*. Here the small medullary veins are clearly seen in the MinIP images for SWI. With sufficient resolution, phase can be measured in the small veins and is, of course, proportional to the susceptibility, which, in turn, is proportional to the deoxyhemoglobin content. Phase itself has been used to measure changes in flow indirectly through changes in oxygen saturation in traumatic brain injury studies (Shen et al., 2007) and more recently in stroke (Li et al., 2011b). But because phase is non-local and depends on the geometry of the source and the location of the object relative to the main field, a direct measure of the venous susceptibility would be more appropriate. Hence, our closing section will be about the use of susceptibility mapping to measure oxygen saturation (Barnes and Haacke, 2009a; Li et al., 2011a; Reichenbach et al., 1997).

Susceptibility weighted imaging and mapping (SWIM) and oxygen saturation maps

The ability to map oxygen saturation may help develop the potential of high resolution SWI as a means to detect local BOLD changes, especially
at high fields. The presence of local changes in susceptibility causes a local change in magnetic field inside the object and a non-local change outside the object of interest. The phase inside the object is a constant while the change outside decays as $1/r^2$ for a cylinder and $1/r^2$ for a sphere. These non-local phases are generally unwelcomed. SWI usually emphasizes phase of one sign and uses this to enhance the magnitude image (Reichenbach et al., 1997; Xu and Haacke, 2006).

As alluded to earlier, the phase itself is of great interest. It has been used for contrast between white matter and gray matter (Haacke et al., 1995, 1999; Ogg et al., 1999; Shmueli et al., 2009) and today for contrast between a variety of structures in the brain and throughout the body. It offers the potential to study everything from vessel wall to even imaging nerves (Haacke et al., 1999). The problem with phase is that it is a non-local manifestation of the magnetic field. However, this very non-local behavior contains everything we need to predict the inherent local susceptibility source (Deville et al., 1979; Haacke et al., 2010; Salomir et al., 2003). This has garnered great interest in the last few years to create a quantitative susceptibility map (QSM) of the tissue (de Rochefort et al., 2008; Liu et al., 2009; Marques and Bowtell, 2008; Salomir et al., 2003) for the study of brain iron and oxygen saturation. The latter is possible because the resulting field inside the veins is directly related to the hematocrit and the local oxygen saturation. Therefore, a QSM (or as we refer to it, SWIM) analysis can provide, in practice, a relative oxygen saturation map of the major veins in the body. When the hematocrit is known, the absolute oxygen saturation can be found (Barnes and Haacke, 2009b; Haacke and Reichenbach, 2011). With such a map, one could, in principle, open a new means to study fMRI by directly monitoring changes in oxygen saturation.

As a means to demonstrate a systemic BOLD effect, we scanned a subject with and without caffeine. The patient ingested a 200 mg NoDoz pill and then was scanned over a 30 min period. The SWI MinIP images are shown in Figs. 7a and b, and the SWIM MaxIP images are shown in Figs. 7c and d, both before and after caffeine intake. Although the SWI projections are qualitatively exquisite images, the QSM or SWIM projections are quantitative in nature. Despite the fact that the hematocrit is not known, a measurement of the venous signal changes normalized to the pre-coffee data provides an accurate measure of the percent change in oxygen saturation and is independent of the hematocrit. It is very difficult to measure BOLD changes in the parenchyma since the blood volume fraction is so small and the BOLD changes are small, but this is not a problem in the major veins (Sedlack et al., 2008). Even changes in the medullary veins are visible in Figs. 7c and d. Perhaps this new approach will open the door to using the veins as the major source of functional activity in the future rather than trying to discard the venous information.

### Summary and conclusions

With the advent of high fields, it is now possible to image the vasculature of the brain with high resolution rapidly. Having the ability to do so provide a means to understand better the flow and function of the vasculature system and to model the vascular system for any individual. In return, modeling the system can predict what we expect to see from an activated to resting state (Marques and Bowtell, 2008). This will surely lead to a better understanding of why different individuals respond differently to specific stimuli, and certainly to separating out structural effects from real functional effects. Along these lines, we would recommend that all fMRI experiments that collect T1 weighted images for anatomical information also collect a high resolution SWI scan to monitor the venous vasculature in the activated regions of interest.

Further, imaging with high resolution may herald the day when complicated statistical analysis will no longer be needed as rapid 3D scanning during a single activated and resting state may allow for simple subtractions to be used to monitor changes in the vascular system. When resolution becomes so high that individual local veins draining the activated region can be discerned, the percent change in fMRI experiments can jump to as high as 30% (Cheng and Haacke, 2001; Haacke et al., 1994; Lai et al., 1993).

</table>
Axonal injury (TAI). The vascular network is ubiquitous and is an integral part of the tissue structure. In this chapter, we focus on angiographic and venographic-related imaging methods and their role in assessing mild, moderate, and severe TBI. We begin with an introduction to susceptibility weighted imaging (SWI) and magnetic resonance angiography (MRA) and then provide evidence of different types of vascular damage. Examples of TBI-induced microbleeds are presented along with the concept of low-impact medullary vein damage (MVD). This MVD has been seen even for so-called mild TBI cases. Vascular damage can also manifest as a reduction in local perfusion even when no clear macroscopic vessel damage is seen. To further understand the role of vascular abnormalities, we then introduce the different perfusion weighted imaging (PWI) techniques available and their application in TBI. The combination of SWI and PWI should make it possible to differentiate the role of local thrombus versus changes in oxygen saturation in MVD, for example. Since MRA and SWI are able to provide a full description of the brain’s vasculature in 3D, we briefly discuss the presence of finite element modeling in understanding vascular injury. We conclude with recommendations related to the use of perfusion with MRA, SWI, and oxygen saturation measurements to obtain a complete picture of the hemodynamics of the brain.
Chapter 4
The Presence of Venous Damage and Microbleeds in Traumatic Brain Injury and the Potential Future Role of Angiographic and Perfusion Magnetic Resonance Imaging

E.M. Haacke, Waqar Raza, Wu Bo, and Zhifeng Kou

4.1 Introduction

Imaging is playing a more and more important role in the diagnosis and longitudinal follow up of traumatic brain injury (TBI). It has been suggested that for both anatomical and functional purposes magnetic resonance imaging (MRI) offers one of the best means to investigate the status of brain function and hemodynamics (Duhaime et al. 2010; Haacke et al. 2010a). Among injury pathologies, vascular injury is an important part of the spectrum. It is associated with diffuse axonal injury (DAI) and traumatic axonal injury (TAI). This bleeding has become a symbolic sign of brain tissue damage from DAI or TAI in diagnostic radiology (Grossman 1996). The vascular network is ubiquitous and is present at all levels in terms of size from the 5 μm capillaries, to the 50 μm arterioles and venules, to the several 100 μm large vessels, and finally those vessels on the order of a millimeter. Presumably, disruption of these vessels leads to a disturbance of local blood perfusion.

Vascular damage can manifest in a number of ways. Recently, Kou et al. gave a summary of the different patterns of vascular bleeding (Kou et al. 2008, 2010). Although more dated, chapter by Grossman et al. gives a classical description of the different types of hemorrhages (Grossman 1996). Anatomically, at a macroscopic level, both hemorrhages and non-hemorrhagic shearing lesions are found in major white matter (WM) tracts, including frontal white matter, corpus callosum, internal capsule, the upper part of the brain stem, the gray matter (GM)/(WM) boundaries and the cerebellar region. Morphologically, there are several types of bleeding. Extra axially, there are epidural and subdural hematomas, which could be caused by direct impact; subarachnoid hemorrhage, which can be seen reasonably well visualized with computed tomography (CT) and now with MRI as well (Wu et al. 2010).
and periventricular hemorrhage, which is due to the vascular damage along the
ventricle walls or associated with damage in the splenium of the corpus callosum.
For parenchymal hemorrhage, examples include (a) petechial microbleeds, where
blood is seen to build up at isolated points after TBI; (b) DAI, where multi-focal
bleeding is seen in the major white matter tracts; and (c) focal contusions, including
coup and contra-coup contusions, which are often seen in direct impact or falls.
If the focal contusion reaches a certain size, it may need immediate surgical inter-
vention to alleviate the rise of intracranial pressure (ICP).

Of course any impact may have microvascular repercussions and, as such, damage
could easily occur at both axonal and microvascular levels simultaneously since
axons and neurons are completely intertwined with the vasculature (although each
has its own unique mechanical properties). From a biomechanical point of view, the
neural vasculature provides physical and structural support of neuronal and glial
cells. From a physiological point of view, the blood flow provides nutritional sup-
port for neuronal and glial cells. By the time of axonal injury, it is hard to imagine
that there is pure axonal injury without any vascular damage or functional distur-
bance. The impairment of the neurovascular blood supply further jeopardizes the
nutritional support and the physiological hemostasis environment for neuronal cells
to survive the recovery battle. This impairment may be manifest as a reduction in
perfusion to the tissue. An immediate perfusion reduction is seen when using the
weight drop impact model in rats using the Marmarou model even without any evi-
dent tissue damage (Shen et al. 2007). Perfusion usually recovers to normal levels
within 72 h in rats. Depending on the injury severity, the vascular damage could
present as macroscopic damage or bleeding or severe reductions in deoxyhemoglo-
bin without any direct evidence of tissue damage. Damage to the vessel could lead
to an impaired neural vascular tone, either sympathetic or parasympathetic vasocon-
striction, and further result in the loss of control of blood flow or to reduced perfu-
sion (Bouma and Muizelaar 1995). Or it may even be an autoimmune response
through which the brain protects itself in case there is major bleeding after impact.
We just do not yet understand the mechanisms behind these immediate responses to
mechanical impact.

Furthermore, arteries and veins are different in many aspects. Anatomically,
major veins are located on the surface of the brain with branches collecting returning
blood from the inside of the brain, while major arteries are located inside the
brain and tend to branch out. From Ommaya’s Centripetal Theory or Gennarelli’s
Depth of Lesion model, with the increase of the injury severity, the injured locations
tend to penetrate from the surface deeper into the brain. That means the brain sur-
fce is always the most vulnerable location of injury, which makes veins exposed to
this trauma more vulnerable. Biomechanically, arteries are smaller but much stron-
ger than veins since they must withstand the systolic blood pressure during the
pumping of blood. Weaker venous walls makes veins more vulnerable than arteries
for the same force of impact. As a result, the veins on the cortical surface tend to be
the most vulnerable part of the vascular structure. Damage here may also lead to
deeper damage to the veins draining into these surface veins. Originally developed
as a venography technique, susceptibility weighted imaging (SWI) has the unique
capacity to visualize both venous structures and hemorrhagic bleeds. This allows researchers to visualize the spatial relationship between bleeding and vascular structures. Therefore, it is possibly to identify the possible bleeding of veins and/or the changes in local oxygen saturation of the tissue feeding these veins.

Modern imaging technologies now make it possible to image the vasculature, perfusion, and oxygen saturation all in one sitting with MRI methods. Although the former can also be done with CT angiography (CTA) using a contrast agent, CT is based on the use of ionizing radiation in the form of x-rays. On the other hand, MR angiography (MRA) and SWI can be used to image the arteries and the veins, respectively, down to 250 μm without a contrast agent. Perfusion imaging can also be done with CT with the help of a contrast agent. MRI also requires a contrast agent for dynamic contrast enhanced (DSC) perfusion weighted imaging (PWI). However a contrast agent is not required for arterial spin labeling (ASL) or for an average cerebral blood flow measurement using flow quantification in the neck (Haacke 2012). Although oxygen saturation can be measured using positron emission tomography, it is much more accessible and patient friendly to use when extracted from MRI measures such as T2 (Lu and Ge 2008; Ge et al. 2012), T2* (Li et al. 1998), or susceptibility mapping (Haacke et al. 2010b).

In this chapter, we will focus on these angiographic- and venographic-related imaging methods and their role in assessing mild, moderate, and severe TBI. We will begin with an introduction to SWI and MRA and then provide evidence of different types of vascular damage at different levels of impact. We will show that for mild TBI, even when other damage is not visible with most clinical techniques, there is potential venous damage. We will then introduce the different perfusion techniques available and their application in TBI. After that, we will discuss the role of finite element modeling in understanding the vascular injury, and, finally we will conclude with recommendations related to the use of perfusion with MRA, SWI, and oxygen saturation measurements. Taken together, these MRI techniques offer different aspects of neural vascular injury and tend to complement each other to depict a clear panorama of this phenomenon.

### 4.2 Susceptibility Weighted Imaging (SWI) and Mapping (SWIM)

SWI exploits the susceptibility differences between tissues. It uses phase images to detect these differences and subsequently a phase mask to enhance the presence of veins, blood products, and iron-containing tissues. Due to its sensitivity to deoxyhemoglobin in venous blood and hemosiderin in hemorrhage, SWI is commonly used in TBI studies (Haacke et al. 2010b; Tong et al. 2008). Compared with the traditional invasive manner of clinical monitoring of cerebral vascular damage and reductions in blood flow, this method offers a novel, safe, and noninvasive approach to quantify changes in oxygen saturation and cerebral blood flow (Shen et al. 2007; Fujima et al. 2011) and to visualize structural changes in the brain’s vasculature.
after TBI. These three pieces of information can be used to improve the diagnosis of the state of health of brain tissue both pre- and post-TBI. The detection of micro-hemorrhages and shearing lesions in TAI/DAI in trauma patients is often difficult as the injuries tend to be relatively small and can be easily missed by low-resolution scans. SWI is usually run at relatively high resolution (1 mm$^3$ or better) and is extremely sensitive to bleeding in the GM/WM boundaries making it possible to see very small lesions and increasing the ability to detect more subtle injuries.

The phase information collected in SWI represents the magnetic field distribution created from the different sources such as veins, microbleeds, ferritin, and hemosiderin. It is possible to use this phase information to find the local source of the field changes. Using a rather simple dipole approximation, it is possible to develop an inverse reconstruction approach that uses the phase information to create a source or susceptibility map (Haacke et al. 2010b; Zaitsev et al. 2011). We refer to this quantitative susceptibility mapping as SWIM. The problem with phase is that a simple spherical dipole source will create a non-local phase behavior that will make it very difficult to do a good job with SWI by itself. By creating SWIM data, that phase disappears and is replaced by the source itself, the local sphere. This new approach should make it possible to map out iron content in microbleeds and to map oxygen saturation in the major veins in the brain (Haacke et al. 2010b, 2011).

### 4.2.1 Visible Vascular Injury in TBI and the Presence of Damaged or Compromised Medullary Veins

In this section, we will review what can be seen in TBI using SWI and discuss a new finding, the presence of damaged or compromised medullary veins. Whenever there is damage to the vascular system that leaves behind extravasated blood, there is a good chance that it will be seen with SWI. Depending on the scope of the damage, one may see local damage as focal lesions or one may see widespread damage in the form of DAI. This damage may or may not produce an alteration in brain function. Successfully visualizing the damaged veins by itself is an important biomarker of TBI but, to be sure if there is or is not a perfusion deficit, one also needs to measure perfusion. Even if there is a perfusion loss in the putatively damaged tissue, one needs to measure oxygen saturation to see if the tissue function is intact. With all four components, the anatomy of the vasculature, the presence of vascular damage, the state of perfusion, and the level of oxygen saturation, it should be possible to obtain a relatively complete picture of the hemodynamics of the brain.

As a demonstration of the types of venous damage we are now seeing with SWI, we show several cases of medullary vein damage (MVD) from frontal and side impacts. Figure 4.1 shows two separate cases of mild TBI with clear damage to the medullary veins. In reviewing more than 100 TBI cases, including mild, moderate, and severe, we have seen 35 cases with MVD. Of the 100 cases, 15 of these were mild and of these 15 only 3 showed MVD. However, in these three cases, no other technique showed the presence of tissue damage (Figs. 4.1, 4.2, and 4.3).
4 Imaging Blood Flow in TBI

4.3 MR Angiography

Depending on the impact strength, the vasculature can be severely damaged in TBI. It behooves us to study the small vessel damage and eventually compare this to any perfusion deficit. The SWI data above already suggest that veins are more sensitive to abnormal stress/strain changes than arteries because they have weaker vessel walls. However, one would expect that would also be true for smaller arteries. In any case, to really do a complete job studying TBI, imaging both the small

---

Fig. 4.1 Medullary vein damage in the frontal lobes shown with SWI. Resolution is $0.5 \text{ mm} \times 0.5 \text{ mm} \times 2 \text{ mm}$. (a) MVD emanating from the septal vein in the left frontal lobe (*upper arrows*). This image also shows blood in the ventricles (*lower arrows*). (b) MVD in both the left and right frontal lobes. The damaged medullary veins are depicted by arrows.

---

Fig. 4.2 Lateral medullary vein damage shown with SWI. Resolution is $0.5 \text{ mm} \times 0.5 \text{ mm} \times 2 \text{ mm}$. (a) Lateral MVD in the frontal lobes. (b) Lateral MVD in the left temporal lobe. This patient also shows damage in the right anterior cerebral artery territory. (c) Lateral MVD in the left frontal lobe emanating from the septal vein. The damaged medullary veins are depicted by arrows.
arteries and small veins would seem to be the right way to go. Up to recently, the major focus in imaging vessels has been at the M1/M2/M3 levels but not beyond. Now the capability exists to see much smaller arteries, on the order of 100–250 \( \mu \)m. The methods that make this possible are the usual time-of-flight (TOF) MRA methods, TOF with background suppression such as magnetization transfer contrast (MTC) or preferably, at high field, using a rephasing/dephasing method, and finally the use of a contrast agent to enhance the signal from the vessels far above the background tissue. In principle, the latter two can also be combined for potential further improvement in vessel–tissue contrast. An example of a conventional MR angiogram and the same individual post-contrast is shown in Fig. 4.4a. The data are collected with 0.5 mm isotropic resolution which means that even some 250 \( \mu \)m-sized vessels may be visualized if their signal is high enough. (Pushing this to 250 \( \mu \)m in plane resolution makes it possible to see even 100 \( \mu \)m-sized arteries but takes too long practically at the moment.) (Haacke et al. 2011). The advantage of the conventional approach is that there are no veins visible in the images. When a contrast agent is used, both arteries and veins get bright, although the larger veins tend to be not as bright at 3 T as they have a much lower T2*. Despite the veins causing some difficulty in visualizing the arteries, with high-resolution 3D imaging, arteries and veins can be separated by image processing. Figure 4.4b shows that there are indeed smaller arteries now visible that could not be seen without the use of a contrast agent (Fig. 4.4).
Damage to vessels may cause a change in the brain’s microcirculation that leads to a persistent state of hypoperfusion and improper delivery of vital metabolites to the brain parenchyma. The toxic contents may also leak through damaged blood brain barrier (BBB) into the already vulnerable neurons. This is not dissimilar to what we see with stroke patients, and it would behoove us to collect the same type of information for TBI patients. Early impairment of cerebral blood flow (CBF) in patients with severe injury correlates with poor brain tissue oxygenation (Zwienenberg and Muizelaar 2001). Some researchers have suggested that it would be important to normalize cerebral perfusion and blood flow after TBI for better outcome (Gennarelli 1987). In clinical studies, a global reduction in CBF has been found in the first few hours following TBI using 133Xe (Zwienenberg and Muizelaar 2001; Gennarelli 1987; Gennarelli and Graham 1998; Kelly and Martin 1997). This is similar to what is found in animal studies as well (DeWitt et al. 1992). Patients who have a global CBF below the threshold for infarction (approximately 18 mL/100 g/min) (Bouma et al. 1991) have a worse clinical outcome. However, Zhao et al. reported a threshold for ischemia as 30 mL/100 g/min in his study (Zhao and Nowak 2006). Kelly et al. showed that outcome for patients with CBF less than this were poor (Kelly and Martin 1997). CBF and brain tissue oxygenation are proving to be crucial parameters to monitor in intensive care units along with others. Moreover, measurement of absolute regional blood flow at rest allows a clear estimation of the magnitude of blood flow changes that occur with drug treatment or other interventions. There are
several perfusion-imaging techniques available today for measuring cerebral
perfusion in brain tissue and for visualizing the healthy and damaged vessels in the
brain. We give a brief overview of these as they are related to applications in TBI.

4.4.1 Computer Tomography

Since the prohibition of the use of Xenon by the FDA, contrast enhanced perfusion
has become the method of choice in CT. Computed tomography perfusion (CTP) is
initiated by injecting iodinated contrast media (iodixanol) into a peripheral vein.
Only a few studies have been performed on TBI using this technique but the results
show that there were significant perfusion changes. One study reported a significant
decrease of blood flow after trauma in a group comparison (Metting et al. 2010).
However, unlike conventional CT, which can show bleeding or mass effect on indi-
vidual basis, perfusion changes on CTP would rely on quantitative measurement to
show group differences. Wintermark et al. suggested that intermittent perfusion-CT
measurements will complement the information acquired by continuous cerebral
perfusion pressure (CPP) alone. Perfusion-CT gives exclusive information about
the regional heterogeneity of brain perfusion. This information will be very useful
in differentiating patients with preserved auto-regulation and impaired autoregula-
tion and could therefore steer interpretation of CPP measurements and therapy
(Wintermark et al. 2004).

4.4.2 Positron Emission Computer Tomography

Positron emission tomography (PET) is a nuclear medicine test in which tissue
function can be imaged. In a PET scan, the tracer stays in the blood stream rather
than being absorbed by surrounding tissues, thereby limiting the images to areas
where blood flows. Damaged tissues have reduced metabolic activity; therefore,
gamma radiation from these areas is reduced or absent (Alexander 1995). Indeed,
some PET data suggest discordance between blood flow and metabolism following
TBI (Obrist et al. 1984); (Abu-Judeh et al. 1998; Mintun et al. 2001). The results of
the Mintum study indicate that the metabolic state of the traumatically injured brain
should be defined differentially in terms of glucose and oxygen metabolism. The
use of FDG-PET demonstrates that hyperglycolysis occurs both locally and glob-
ally following severe head injury in humans cellular pathophysiology characteristic
of head injury (Bergsneider et al. 1997). TBI studies in animals have shown a well-
deefined triphasic pattern of the cerebral metabolic rate of glucose (CMRglc)
(Bergsneider et al. 2001). The initial brief response of hyperglycolysis is followed
by a second relatively prolonged period of metabolic depression. The second period,
characterized by metabolic depression, typically lasts several hours and is associ-
ated with persistent neurological deficits as long as the metabolic depression is
present. The third period is characterized by a recovery behavioral function that parallels that of the recovery of metabolic function. No such pattern was seen in human data (Bergsneider et al. 2001).

Soustiel et al. compared the respective effects of established measures used for management of TBI patients on CBF and cerebral metabolic rates of oxygen (CMRO2), glucose (CMRGlc), and lactate (CMRLct) and found out that moderate hyperventilation could aggravate pre-existing impairment of CBF and metabolism (Soustiel et al. 2006). Therefore, TBI patients should be carefully monitored. Some suggest the use of mannitol for ICP control.

It is now well established that PET is somewhat superior to SPECT in terms of spatial resolution and permits a better visualization of subtle abnormalities. With the advent and implementation of novel tracers as well as improvement in instrumentation, molecular brain imaging using PET may be able to illustrate TBI pathophysiology and point to novel treatment strategies. However, despite these advantages PET requires the use of radiation.

### 4.4.3 Single-Photon Emission Computed Tomography (SPECT)

SPECT is a nuclear medicine tomography imaging technique that uses gamma rays to probe the tissue, specifically to show blood flow to tissues and organs. A SPECT scan integrates two technologies to view the body namely, CT and a radioactive material (tracer). The tracer makes it possible to see how blood flows to tissues and organs. Before the SPECT scan, a gamma-emitting radio-labeled chemical is injected into the blood stream that can then be detected by the scanner. The computer collects the information emitted by the gamma rays and translates them into two-dimensional cross-sections. These cross-sections can be merged to create a 3D image of the brain. A SPECT scan is primarily used to view blood flow through both arteries and veins in the brain. Tests have shown that it might be more sensitive to brain injury than either MRI or CT scanning because it can detect reduced blood flow to injured sites (Lewine et al. 2007; Abdel-Dayem et al. 1998). These qualifications aside, SPECT offers promise with regard to meeting the criteria of sensitivity, incremental validity, and clinical correlates. SPECT scans are cheaper and more readily available than the higher resolution PET scans, but they also still involve the use of radiation and radioactive agents. Another reason for SPECT not gaining so much popularity is that it requires co-registration with MRI.

### 4.4.4 Laser Doppler Flow

Laser Doppler is an inexpensive, noninvasive method of measuring the continuous circulation of blood flow on a microscopic level. The beam from a low-power laser (usually a laser diode) penetrates the skin sufficiently to be scattered with a
Doppler shift by the red blood cells and returns to be concentrated on a detector. These measurements are useful to monitor the effect of exercise, drug treatments, environmental, or physical manipulations on targeted micro-sized vascular areas. It is reported by Rafols et al. using Laser Doppler Flow (LDF) that the hypoperfusion following TBI is a result of the loss of autoregulatory response of reacting vessels of the brain. This loss of autoregulation causes the improper delivery of oxygen and metabolites to the brain tissue and results in secondary injury and poor cognitive outcome (Rafols et al. 2007). In this study, he used the Marmarou model to induce TBI to avoid focal brain contusions and tissue necrosis. This study revealed a 37% reduction in cortical blood flow. Ultrastructural alterations in the lumen and wall of sensorimotor cortical microvessels, including endothelial cell distortion and luminal collapse, were seen between 1 and 48 h after trauma. Smooth muscle in the wall of reacting microvessels showed evidence of increased contractility that coincided temporally with the decreased perfusion of cortical CBF.

Thomale et al. showed that the acute hypoperfusion after TBI is due to vasoconstriction (Thomale et al. 2002). This study also found hyperemia occurring between 24 and 48 h after TBI in the controlled cortical impact model using LDF. Muir et al. studied the continuous pattern of CBF following TBI in a lateral percussion fluid model (Muir et al. 1992). The results showed that seconds after injury, blood flow in the left parietal cortex increased about 200% followed falling to about 80% of control after 5 min, and to 56% at the 1 h time point. Dewitt et al. reported that L-arginine administered after TBI prevents post-traumatic hypoperfusion and that pre-treatment with superoxide dismutase will restore CBF after a brief period of hypoperfusion (DeWitt et al. 1992). Lam et al. performed a study to monitor autoregulation using LDF in patients with head injury. It was concluded from the study that maintenance of CPP is important in preventing cerebral ischemia (Lam et al. 1997). Zweifel et al. showed that changes in CBF detected by LDF matched well with flow measurements performed with Transcranial Doppler Sonography (Christian et al. 2010).

The clinical application of LDF is limited by a number of problems. It can only access a small volume of brain tissue and thus can only monitor a focal area and LDF does not provide absolute values for blood flow. Further, since LDF is operator dependent especially in making contact on the skull for cases of subdural hematoma or prominent subarachnoid space, inaccurate measurements may follow (Lam et al. 1997).

### 4.4.5 Transcranial Doppler Sonography

Transcranial Doppler Ultrasound (TCD) is a noninvasive method for the measurement of flow in the major vessels in the head such as the middle cerebral artery (MCA), petrosal sinuses, and ophthalmic vessels. It is commonly used in the standard care of TBI patients. TCD is particularly accurate in detection of episodes of hypoperfusion induced by low CPP (Brandi et al. 2010), (Schmidt et al. 2000) and ICP (Homburg et al. 1993). This is a relatively quick and inexpensive test and is growing in popularity in the USA. The equipment is portable, making it possible to use not only in the...
hospital but also in a doctor’s office, nursing home, or patient’s home. There are two methods used for recording the data. The first method uses “B-mode” imaging, which displays a two-dimensional image as seen by the ultrasound probe. Once the desired blood vessel is found, blood flow velocities can be measured with a pulsed Doppler probe to plot velocity over time. Together, these make a duplex test. The second method of recording uses only the second probe function, relying instead on the training and experience of the clinician in finding the correct vessels.

A number of observational studies have suggested that vasospasm develops in some patients following TBI (Oertel et al. 2005). Lee et al. confirmed that hemodynamically significant vasospasm with low CBF was a significant predictor of poor outcome (Lee et al. 1997). These studies have almost exclusively used TCD to identify vasospasm criteria similar to those used in subarachnoid hemorrhage. The limitation of transcranial Doppler is penetrating the bone. There are several “windows” through the temporal area that allow the visualization of the petrosal sinuses and the ophthalmic vein. TCD can also be used to measure flow in the middle, anterior, and posterior cerebral arteries.

Cerebral perfusion should be estimated as soon as possible after severe TBI to deaccelerate secondary brain injury. TCD is a simple and noninvasive method for cerebral perfusion assessment and is particularly accurate to detect hypoperfusion. Catherine et al. confirmed that early TCD makes it possible to identify high-risk patients with impaired cerebral perfusion and poor outcome. Moreover, this study (Catherine et al. 2007) has also discovered that TCD goal-directed therapy has the potential to improve cerebral perfusion before invasive cerebral monitoring is available, thereby limiting secondary brain injuries. Although study suggested the need for further studies to define optimal treatment TCD threshold values for the initial management of TBI, and its effect on outcome (Catherine et al. 2007).

### 4.4.6 Magnetic Resonance Imaging

MRI is perhaps the most used imaging modality for studying the anatomy and function of the brain today. The findings in standard MRI studies of TBI are similar to CT, but MRI is more sensitive than CT for small lesion detection such as TAI and DAI as seen with SWI (see above). MRI also offers a variety of different measures to study TBI such as Diffusion Tensor Imaging (DTI), Magnetic Resonance Spectroscopy Imaging (MRSI), and functional magnetic resonance imaging (fMRI) (Haacke et al. 2011) which are not part of the focus of this chapter. There are three major methods that are used at the moment to study either local or global perfusion to the brain.

#### 4.4.6.1 DSC Perfusion Weighted Imaging (PWI)

PWI is sensitive to microscopic blood flow. The method is based on monitoring a non-diffusible contrast material gadolinium DTPA (dimeglumine pentaacetic acid or diethylenetriamine pentaacetic acid) passing through brain tissue. The signal
intensity decreases as the contrast bolus passes through the tissue and returns to normal over time. Recording this time-varying signal, and extracting the concentration as a function of time, it is possible to derive the following measures of blood flow, cerebral blood volume (CBV); CBF; mean transit time (MTT) and time to peak (TTP), as well as a variety of other hemodynamic parameters. To date, there are few studies describing the use of MR perfusion in TBI evaluation or predicting outcomes after TBI. One small study (Garnett et al. 2001) showed in patients with focal injuries visible in T2 images that reductions of rCBV were found in focal lesions and significant increases of rCBV were found in pericontusional areas. This finding is also consistent with the concept of traumatic penumbra (Menon 2003). Furthermore, a subset of these patients also showed reduced rCBV in normal appearing white matter, and these patients had significantly poorer outcomes (Garnett et al. 2001). Secondary damage in TBI is usually a result of altered hemodynamics and cerebrovascular factors. Hayward et al. investigated hemodynamic coupling between CBF and CBV. In this work, surprising results were found that CBV was the same for patients and controls in all regions considered. A significant decrease in CBF was found at 48 h after TBI but the CBV remained unchanged (Hayward Nick Mark 2011). Our own work in this direction has just begun. However, we have one example with deep MVD and PWI that appears to show several regions of reduced mean transit time (Fig. 4.5). If this pattern is found to be replicated in other cases, it would demonstrate that the damaged area is also associated with reduced perfusion (Fig. 4.5).

### 4.4.6.2 Arterial Spin Labeling

ASL is an arterial spin tagging technique that relies on the detection of magnetically labeled blood. Once the magnetization of the inflowing arterial blood has been modified (generally inverted) upstream, it induces a small MR signal change downstream (a few percent of the tissue magnetization). Meanwhile, the magnetization of the perfusion tracer (i.e., the labeled water) is rapidly relaxing. Return of the longitudinal magnetization toward its equilibrium values takes a few seconds. Although ASL techniques have not entered widespread clinical usage, their utility has been demonstrated for a variety of acute and chronic cerebrovascular diseases such as stroke and epilepsy. (Wintermark et al. 2005). One significant advantage of ASL is the ability to perform multiple repeated measurements without the use of a contrast agent. This might be necessary before and after treating the patient with a cerebrovascular dilator (acetazolamide) or vasoconstrictor inhibitor (clazosentan), for example. Kim et al. used ASL to measure the resting state CBF in 28 moderate to severe TBI patients in the chronic stage and found that (a) there was a global decrease of CBF compared to controls and (b) prominent regional hypoperfusion was present in the posterior cingulate cortices, the thalami, and multiple locations in the frontal cortices (Kim et al. 2010). However, in the population of mTBI, how cerebral perfusion is being affected in patients and their association with patients’ neurocognitive status is still not understood. Given the milder severity in mTBI
patients, perfusion imaging at the acute stage could be meaningful both for clinical decision-making and patients’ outcome prediction. Ge et al. also employed ASL to study 21 mTBI patients at the chronic stage and demonstrated reduced CBF in both sides of the thalamus, which is correlated with the patients’ speed of information processing, memory, verbal, and executive function (Ge et al. 2009). ASL has also been used in conjunction with functional brain imaging studies and with animal studies, but these directions are outside the scope of the material presented in this chapter. However, some of the fMRI/ASL research does suggest that there are reductions in CBF that may be related to diffuse pathology.
4.4.6.3 Blood Flow Measurements in the Neck and the Poor Man’s Bulk Perfusion Measure

Phase-contrast MR images are used for blood flow measurement in the neck and brain. Flow can be obtained for all major vessels in the neck thereby allowing a measure of the cardiovascular input and output to the brain. By measuring flow at C1/C2, one can focus on just the internal carotid artery and vertebral artery. By normalizing this arterial inflow to brain volume, it is possible to obtain the average flow in units of mL/100 g tissue/min. CSF flow can also be measured at this level. Similarly, by measuring flow at C7/T1, the total venous outflow can be determined. Flow is actually measured throughout the cardiac cycle (on the order of 20–40 points per cardiac cycle). A number of flow measures can be then determined including, flow velocity (average, peak positive, and peak negative), volume flow rate (average, positive, and negative), and total flow volume per cardiac cycle. The following arteries and veins of left and right sides are measured: common carotid arteries, internal/external carotid arteries, vertebral arteries, internal/external jugular veins, vertebral veins, deep cervical veins, anterior jugular vein, and any other major veins that are apparent.

4.5 Measuring Oxygen Saturation Changes with SWIM

Blood oxygen saturation imaging provides a means to monitor changes in oxygen saturation indirectly. SWI can be used to not only visualize small veins and microbleeds but also provide phase information for major veins. Such changes can occur when there is a change in blood flow. When the local field changes because of deoxyhemoglobin changes, the phase changes in and around the major veins. In Fig. 4.6 below, we show the effect of a systemic reduction in blood flow to the brain after ingestion of 200 mg of caffeine (the subject ingested a 200 mg NoDoz pill). Measuring changes in phase is tantamount to measuring changes in oxygen saturation (Shen et al. 2007). Similarly, reductions in perfusion or local bleeding can lead to the apparent enlargement of a local medullary vein (see Figs. 4.1 and 4.2) caused by either this blood oxygenation level dependent (BOLD) effect or by local bleeding in and around the vessel.

Applying susceptibility mapping to the phase yields a SWIM image (Fig. 4.7b) that looks similar to the SWI data of the venous system (Fig. 4.7a). Although the latter is important in detecting vascular abnormalities, it is not quantitative. With high-enough resolution and improved SWIM algorithms, it is expected that major veins (roughly 2 mm or greater in diameter) will yield reasonably accurate values for the oxygen saturation in those veins (Figs. 4.6 and 4.7).
Fig. 4.6  SWI projection images showing the same individual (a) pre-caffeine and (b) post-caffeine. The patient had ingested one No-Doze pill containing 200 mg of caffeine. Note the increased contrast of the smaller veins. This is caused by the increased levels of deoxyhemoglobin after caffeine. Since caffeine is a vasoconstrictive agent, the blood flow slows to the brain. However, since the cerebral metabolic rate of oxygen utilization (CMRO2) does not change, the amount of deoxyhemoglobin increases.

Fig. 4.7  SWI versus SWIM. (a) SWI projection image from Fig. 4.6b showing the major veins in the brain. (b) SWIM image (of a different individual) showing a quantitative map of oxygen saturation in the brain.
4.6 Role of Finite element Modeling in Understanding TBI

Finite element (FE) models of brain injury are essential to study brain injury mechanisms. A number of studies have been conducted to investigate the contribution of the vasculature on the dynamic response of the brain in traumatic injury (Zhang et al. 2002). The hypothesis is that the vascular tree contributes to the strength of the neural tissues of the brain when it is subjected to applied loads. Data on mechanical properties of vascular tissues (Monson et al. 2000; Arbogast and Margulies 1997) suggest that cerebral vessels are much stiffer than brain tissue. Two-dimensional FE models of the brain with and without the simulation of major cerebral arteries were evaluated to test the hypothesis that the structural stiffness of the human brain is influenced by the pressure of these vessels. Overall results from this study suggest that explicit modeling of blood vessels increases the stiffness of the brain to resist both rotational and linear impulses and increases the threshold of neural injury. Zhang et al. assumed in her study that the blood vessel walls were directly connected to the surrounding brain tissues (Zhang et al. 2002). However, there is no data that describe the mechanical interaction between the vessels and brain.

Medullary vein damage may be due to the presence of internal shear forces (intracerebral stresses). How this occurs likely depends on the stiffness and natural frequency of the structure impacted. For impacts with structures of relatively low stiffness, the brain tends to move with the skull because of the predominantly low frequencies involved in these impacts. These movements result in intracerebral strains (ICS) that can produce lesions in the central parts of the brain. These ICS usually occur when the natural frequency of the impact is less than about 250 Hz, with the result that the outer parts of the brain move with the skull causing shear strains in the cerebral tissue as the inner parts of the brain lag behind the outer due to initial effect. A theoretical model suggests that the natural frequencies of the head and the structure are the characteristics with most importance in determining the distribution of injury in the brain for a particular location of impact on the head (Willinger et al. 1994). Clearly, knowing the tissue properties and the local structures of the vessels and how they are embedded in the surrounding tissue is necessary for proper modeling of the brain injury due to a given loading condition. The SWI and MRA data we have collected makes it possible to create an anatomically detailed FE model of the medullary veins down to 250 μm in size (see Fig. 4.8). Armed with this detailed local model embedded in the whole brain model and estimates for the tissue properties, it may be possible in the future to predict local venous damage and surrounding neural tissue injury. Some early attempts to model the vasculature from MRA data were presented by Parnaik et al. (2004) (Fig. 4.8).
4.7 Conclusions and Future Directions

SWI has proven to be one of the methods of choice along with DTI and T2 weighted FLAIR (Fluid Attenuation Inversion Recovery) when imaging TBI. SWI detects abnormalities caused by focal lesions and DAI, many of which may be missed in conventional MRI and CT scans. Currently, there is a paucity of information about perfusion in human TBI studies. It is likely that perfusion could play a major role in understanding patient outcomes. Perfusion combined with oxygen saturation measurements using SWIM may also open the door for a better understanding of the type of damage done in TBI. However, there is still one missing piece to the puzzle that is a critical precursor to understanding flow changes in TBI and that is the arterial system. Despite our focus on measuring blood products, veins, oxygen saturation, and perfusion, it is critical to gain an understanding of damage to the arterial system as well. Practically, the ideal protocol would be to start with an MR angiogram (MRA) and venogram (SWI) at the beginning of the scanning for TBI patients. Recently, we have implemented a double echo sequence that can be used to create both MRA and SWI data for such an analysis (Haacke et al. 2012). This should then be followed by a perfusion scan and any other key sequences such as FLAIR and DTI. We anticipate that it may then be possible to better diagnose many more mild TBI patients than is otherwise possible today.
Acknowledgments  We would like to thank Sagar Bush for Fig. 4.8, Tang Jin for Fig. 4.7, Meng Li for Fig. 4.5, and Yongquan Ye for Fig. 4.4, and to Yongquan Ye for reviewing the chapter and Liying Zhang for reviewing the section on finite element methods for studying brain trauma.

CHAPTER 2

Magnetic Resonance Imaging

Biomarkers of Mild Traumatic Brain Injury

Z. KOU,*a R. R. BENSONb AND E. M. HAACKEa

2.1 Introduction

Traumatic brain injury (TBI) affects 1.5 million Americans each year,1,2 the majority of which are mild TBI (mTBI).3 Today, more people who might have had more severe TBI or died in motor vehicle accidents suffer milder head injury, thanks to the advancements in motor vehicle safety. mTBI affects over 1 million Americans annually. It is a major public healthcare burden, yet has been overlooked for decades.1,2 Despite its name, the impact of mTBI on the patients and their family are not mild at all.3 mTBI patients typically develop a variable constellation of physical, cognitive, and emotional symptoms, collectively known as post-concussive syndrome (PCS), that significantly impact their quality of life. The direct cost of mTBI in the U.S. is approximately $16.7 billion annually and this does not include the indirect costs to society and families.3–5

Up to 50% of patients with mTBI have persistent neurocognitive symptoms at three months and 5% to 15% at 1 year.6,7 Meanwhile, among the 1.8 million troops who have served in Iraq and Afghanistan, it is estimated that at least 20%
of returning troops have suffered at least one, and some multiple, concussions. This means up to 360,000 veterans may have brain injuries after discharge.\textsuperscript{8} However, most symptomatic mTBI patients have normal CT and conventional MRI scans,\textsuperscript{9,10} even with the greater sensitivity of MRI to TBI.\textsuperscript{11} In addition to neuroimaging, clinical indices of severity, such as the Glasgow Coma Scale (GCS) and duration of post-traumatic amnesia (PTA) are lacking in sensitivity in mTBI and are not helpful in predicting outcome.\textsuperscript{12} In summary, using currently available clinical instruments, it is difficult to determine which mTBI patients will have prolonged or even permanent neurocognitive symptoms.

With greater appreciation of incidence and impact of “civilian,” sports, and military mTBI, there is an increasing need to identify a minimally invasive biomarker (or biomarkers) of mTBI. A clinically useful biomarker or biomarkers should ideally be very sensitive to TBI (including mild cases) but should have reasonable specificity. That TBI pathology is not singular but involves multiple functional and structural changes affords greater opportunity for detection and characterization of injury with sensitive instruments. Similarly, biomarkers meeting these criteria should improve clinical trial efficiency since patients with similar types and grades of pathology could be grouped together in order to reduce the chances of a negative result due to prohibitive pathologic heterogeneity.

With both hardware and pulse sequence design advances, newer MRI methods have demonstrated the ability to detect and localize with high resolution several of the pathologic and pathophysiologic consequences of mTBI. These advanced MR technologies include susceptibility weighted imaging (SWI) for hemorrhage detection,\textsuperscript{13} MR spectroscopy (MRS) for metabolite measurement,\textsuperscript{14} diffusion weighted and diffusion tensor imaging (DWI/DTI) for edema quantification\textsuperscript{15} and axonal injury detection,\textsuperscript{16} perfusion weighted imaging (PWI) and arterial spin labeling (ASL) to measure blood flow to brain tissue,\textsuperscript{17} and functional MRI (fMRI), which measures changes in blood oxygen level locally in response to neuronal activity.\textsuperscript{18} Having a number of imaging biomarkers, all of which are obtained in a single scanning session (or multiple for longitudinal study) and are sensitive to different consequence of traumatic injury affords great advantages: 1) enhanced sensitivity; 2) ability to study interrelationships among these biomarkers and between the biomarkers and clinical/ neurocognitive deficits; 3) improved clinical management resulting from more precise characterization of injuries; and 4) enhanced power of clinical interventional studies (see above). Furthermore, the information comes “cheaply” since MRI is non-invasive and is widely available.

### 2.2 Search Criteria and Results

The purpose of this chapter is to review the current status and clinical impact of MR imaging findings in mTBI. BeLanger \textit{et al.}\textsuperscript{19} provided an informative review on this topic in 2007. Since then many original works have been published.

The following inclusion criteria were used to identify potential papers: a) must be cited in Medline database; b) must use MRI as a major component of the study; c) only clinical (human) studies of mTBI patients; d) published in the
past five years (i.e. 2006 and later); and e) published in peer-reviewed English language journals. Readers interested in moderate to severe TBI imaging are encouraged to refer to another recent review paper, which covers SWI, DTI, and MRS.19

The authors conducted a Medline search at www.pubmed.com in September 2011 by using the search phrases “mild traumatic brain injury” and “magnetic resonance imaging.” There were a total 356 publications, of which 46 were reviews and 310 were original studies. After excluding articles that did not fit our criteria, we found a total 62 articles; 11 reviews and 51 original studies. Of original studies, 32 used structural imaging, DTI, MRS, and perfusion imaging and 19 articles used fMRI, including both resting state fMRI and task-oriented fMRI. This review focuses on clinical MRI, DTI, MRS, and perfusion imaging. The following was categorized according to the technical approaches being used. The literature is listed in Table 2.1.

### 2.3 Clinical CT and MRI

Although CT is still the first step in the search for large hemorrhages that may require surgical intervention, it is insensitive to small hemorrhages, whether from early contusion or from diffuse axonal injury. Most patients with mTBI have normal CT and conventional MRI findings. Indeed, they usually do not get clinical MRI scans in the emergency department, which sees the majority of patients with mTBI. Any intracranial abnormality would classify the patients as complicated mTBI,20 which could have long-term sequelae similar to moderate TBI. A clinical radiological sequence protocol typically includes T1-weighted imaging for structural damage and brain atrophy, T2-weighted FLAIR for edema and acute stage subarachnoid hemorrhage, and T2* gradient recalled echo (GRE) for hemorrhages.

It would be of clinical value to know: “How many patients with mTBI have positive MRI findings?" and “How these findings may account for their neurocognitive or functional symptoms?” Regarding the prevalence of positive MRI findings in mTBI, different groups reported different findings. After reviewing 182 adolescent patients, Fay et al.21 reported 18% had positive MRI findings. Topal et al.22 reported that of 40 patients with mTBI, 12.5% had positive MRI. In contrast, Lee and colleagues23 reported 50% with positive CT and 75% with positive MRI in 36 mTBI patients with both loss of consciousness and post-traumatic amnesia. The discrepancy among the figures could be due to the different study populations and different patient inclusion criteria.

Regarding the relationship between MRI findings and patient outcome, Muller et al.24 reported that GCS <14, CT/MRI positive, and S100B > 0.14, together, predicted impaired cognitive performance both at baseline and after 6 months. Kurca et al.25 reported that patients with mTBI with true traumatic MRI lesions are different neuropsychologically from those of mTBI with non-specific MR lesions, and neurocognitive and symptom signs have organic bases that can be detected by MRI. Fay et al.21 reported that ratings of PCS in

adolescents were moderated by both cognitive ability and injury severity. Children with lower cognitive ability with complicated mTBI were prone to PCS. Comparatively, Lee et al.\textsuperscript{23} reported that CT and MRI findings were not associated with a patient’s neurocognitive impairment. Clearly, the seemingly conflicting findings on the predictive role of structural MRI need further investigation.

2.3.1 Susceptibility Weighted Imaging (SWI) of Hemorrhagic Lesions

In diagnostic radiology, intracranial hemorrhage has been sought as a biomarker of TBI. Some investigators have suggested that the presence of hemorrhage in DAI is predictive of poor outcome in moderate to severe TBI. SWI was developed by Haacke et al.\textsuperscript{27} as a high resolution venography method. It has been used to evaluate moderate to severe TBI patients since 2003 by Tong et al.,\textsuperscript{13} who have shown that SWI is 3 to 6 times more sensitive than conventional T2* gradient echo imaging (GRE) for detecting suspected DAI lesions in children.\textsuperscript{13,28} SWI has been shown to detect tiny hemorrhages that may be the only abnormal finding that can confirm the presence of brain injury, and change management of the patient. In addition, lesion number and volume identified by SWI are negatively associated with patient outcome\textsuperscript{28} and neuropsychological functions\textsuperscript{29} in patients with moderate to severe injury.

After brain injury, the hemorrhagic bleed may undergo a temporal transformation from oxyhemoglobin and then deoxyhemoglobin in the acute stage; intra- and then extracellular methemoglobin in the subacute stage; and finally, hemosiderin in the chronic stage.\textsuperscript{30–32} SWI is sensitive to deoxyhemoglobin in the acute stage and extracellular methemoglobin in the subacute stage and hemosiderin in the chronic stage.\textsuperscript{30} Therefore, positive results with SWI should provide a biomarker for hemorrhagic brain injury at any stage. However, very few data have been reported regarding the possible role of SWI in an improved detection of microhemorrhages and its predictive value of patient outcome in mTBI. Unlike DTI, which requires complex post-processing and comparison with proper controls, SWI hemorrhage is readily available for radiological reading immediately after MRI scans. This makes SWI more likely to have a direct impact on the radiological diagnosis. Furthermore, with quantitative susceptibility mapping, the hemorrhagic lesion load could be more acutely mapped through next generation SWI analysis and potentially improve the prediction of a patient’s outcome. Figure 2.1 demonstrates an exemplary case to show the SWI detection of brain hemorrhages in mTBI in the acute stage in comparison with the usual clinical T2* GRE.

In summary, there is still a need to evaluate a large number of patients with mTBI by using structural imaging, particularly SWI, to see the clinical value of intracranial hemorrhage detected by MRI. This should be done along with other clinical measures, e.g. GCS, as well as other biological markers, such as serum biomarkers.
2.4 Diffusion Tensor Imaging (DTI) of Axonal Injury

Diffusion imaging sequences are sensitive to traumatic axonal injury (TAI) secondary to stretch and shear forces. DTI measures the bulk motion of water molecular diffusion in biological tissues. It is most useful when tissues are anisotropic, i.e. when diffusion is not equivalent in all directions, such as in skeletal muscle or axons in white matter of the central nervous system. Histological correlates have validated DTI’s sensitivity to brain injury for both focal\(^3\) and diffuse axonal injury\(^4\) models. The apparent diffusion coefficient (ADC) and fractional anisotropy (FA)\(^5,6\) are two parameters derived from DTI that have been extensively studied in TBI. ADC is an estimate of the average magnitude of water movement in a voxel (regardless of direction), while FA is an index of the directional non-uniformity, or anisotropy, of water diffusion within a voxel.

FA has been used to detect alterations in directional diffusion resulting from tissue damage. FA in white matter is highest when fibers are long (relative to voxel dimension) and oriented uniformly (collinear) within a voxel and lowest when fibers are not collinear (e.g. “crossing fibers”) or have been damaged. When axons are injured, as in acceleration/deceleration injuries (such as MVCs), diffusion anisotropy typically decreases. Loss of diffusion anisotropy is the result of a number of axonal changes after injury including: 1) increased permeability of the axonal membrane; 2) swelling of axons; 3) decreased diffusion in the axial (long axis) direction; 4) degeneration and loss of axons in the chronic stage. In general, any pathological alteration of white matter fibers will result in FA decrease, since one or more of these axonal changes occurs in disorders of white matter. Not surprisingly, most clinical studies of moderate and severe TBI have shown FA to be more sensitive than ADC to traumatic injury. On the other

![Figure 2.1](image.png)
hand, ADC, FA, and directionally selective diffusivities (principal, intermediate, and minor components of diffusion) can help to better characterize brain injury pathologies. Trace and mean diffusivity are two other measurements similar to ADC and vary similarly. Changes in FA in association with ADC changes can differentiate the type of edema. For example, in the acute stage, decreased FA in association with increased ADC suggests vasogenic edema, while increased FA in association with decreased ADC suggests cytotoxic edema. Decreased FA in association with decreased ADC and decreased longitudinal (parallel to the long axis of the axons) water diffusivity suggests axonal transport failure as occurs in degenerative neurological diseases such as in ALS.

Regarding the location of brain lesions detected by DTI, Niogi et al. summarized that the frontal association pathways, including anterior corona radiata, uncinate fasciculus, superior longitudinal fasciculus, and genu of corpus callosum (CC), were the mostly frequently injured WM structures in this cohort of mTBI patients. Single subject results were not reported but it can be assumed that significant inter-individual variability for location and extent of WM injury exists due to varying injury mechanisms (and forces) and biological (neural and non-neural) differences across patients.

2.4.1 Imaging at Different Pathological Stages

Interestingly, despite the higher incidence of milder TBI compared with more severe TBI in Western countries, there are many fewer mTBI imaging studies reported in the literature. One reason is the fact that recruitment of patients with mTBI is more difficult, since they are typically outpatients. Another reason is the common conception that mTBI is a transient problem from which virtually all who are afflicted will recover fully. Therefore, some question the clinical importance of studying mTBI. Certainly, insurance reimbursement for MRI scanning of mTBI is rare and even rarer in the acute setting, so that “adding on
research sequences” is not possible. With these limitations in mind, a growing literature on DTI in TBI has begun to address the DTI findings at different stages.

2.4.1.1 Acute Stage

There are conflicting findings for FA and ADC in mTBI. Chu et al.,38 Wu et al.,39 and Wilde et al.40 from Baylor College of Medicine scanned 10 to 12 adolescents with mTBI within 6 days of injury and reported increased FA, reduced ADC and reduced radial (short axis) diffusivity in WM regions and left thalamus. Similarly, Bazarian et al.41 studied six mTBI patients within 72 hours and reported increased FA in the posterior CC and reduced ADC in the anterior limb of the internal capsule (IC). Similar to Chu et al.,38 and Wilde et al.,39 Mayer et al.42 studied 22 patients with mTBI within 12 days of injury and reported FA increase and reduced radial diffusivity in the CC and left hemisphere tracts.

Inglese et al.,43 in contradiction to Chu et al.,38 Wilde et al.,39,40 Bazarian et al.,41 and Mayer et al.,42 found reduced FA in the splenium of CC and posterior limb of IC in 20 patients with mTBI imaged up to 10 days after injury (mean = 4 days). Manually drawn regions of interest were used to assay the genu and splenium of the CC, the centrum semiovale, and the posterior limb IC bilaterally. In the same line as Inglese et al., Arfanakis and colleagues44 studied a handful of patients with mTBI at the acute stage and reported FA decrease in major WM tracts.

2.4.1.2 Subacute Stage

All studies reported reduced FA and/or increased diffusivity; i.e. ADC, trace or mean diffusivity (MD), at this stage. Messe et al.45 studied 23 mTBI at the subacute stage and found significantly increased MD in mTBI patients with poor outcome.45 The authors did not find significant changes of FA values. Lipton et al.46 scanned 20 mTBI patients in the subacute stage and demonstrated reduced FA and increased MD in frontal subcortical WM. Miles et al.47 studied 17 acute and subacute mTBI patients and found reduced FA and increased MD. All of these studies at the subacute stage reported a similar profile of DTI measures except for different locations of injury.

2.4.1.3 Chronic Stage

Three studies report either reduced FA or increased diffusivity or both. Cubon et al.48 studied 10 collegiate athletes with concussion at the chronic stage and found MD increase in left WM tracts, internal capsule, and thalamic acoustic radiations. Lo et al. studied 10 mTBI patients and reported reduced FA and increased ADC in the left genu of the CC and increased FA in internal capsule bilaterally.49 Niogi et al.50 studied 43 patients with chronic mTBI and reported reduced FA in a large number of WM tracts.

All DTI studies of moderate to severe TBI patients16,51–53 and subacute/chronic mTBI patients43,50,54–56 report FA decreases, which are correlated with clinical or neuropsychological measures. However, there are seemingly
contradictory findings in mTBI in the acute stage (within 1 week after injury) in the literature: Inglese\textsuperscript{43} and Arfanakis\textsuperscript{44} both reported FA decreases, while Wilde\textsuperscript{40} and Bazarian\textsuperscript{41} reported FA increases and decreased radial diffusivity. It has been suggested that increased FA acutely may reflect cytotoxic edema,\textsuperscript{40} which would shunt extracellular fluid into swollen cells. This could have the effect of reducing inter-axonal free water and therefore increasing anisotropy.

2.4.1.4 Longitudinal Studies

Only a few investigators have followed FA over time in the same patients. Sidaros \textit{et al.}\textsuperscript{57} studied 23 patients with severe TBI at 8 weeks and again at 12 months and found that partial recovery of initially depressed FA values in the internal capsule and centrum semiovale predicted a favorable outcome. Kumar \textit{et al.}\textsuperscript{58} studied 16 patients with moderate to severe TBI at 2 weeks or less, 6 months, and 2 years and found persistently reduced FA except in the genu of the corpus callosum, where there was partial normalization by 2 years. Recently, two studies by Mayer \textit{et al.}\textsuperscript{42} and Rutgers \textit{et al.}\textsuperscript{55} reported that FA may partially normalize, reflecting recovery. This evidence suggests that a systematic investigation of a large number of patients with mTBI at acute, subacute, and chronic stages is warranted to reveal the evolution of pathophysiology in mTBI.

2.4.2 Correlation Between DTI-Derived WM Injury Topography and Neuropsychological Deficits

Patients with mTBI often develop a constellation of physical, cognitive, and emotional symptoms that are collectively known as post-concussion syndrome (PCS). In terms of neurocognitive symptoms, there are four key domains implicated in chronic neuropsychological impairment after mTBI. These domains include: 1) higher-order attention, 2) executive function, 3) episodic memory, and 4) speed of information processing. To date, several studies have demonstrated typical mTBI cognitive profiles and association with DTI findings. Niogi \textit{et al.} summarized the topographic and neurocognitive deficits.\textsuperscript{37}

Damage to the frontal WM has been reported to be associated with impaired executive function. Lipton \textit{et al.}\textsuperscript{46} studied 20 acute to subacute patients and reported that reduced FA in WM of dorsolateral prefrontal cortex (DLPRC) is correlated with worse executive function. Frontal WM injury is also associated with attention deficit. Niogi \textit{et al.}\textsuperscript{50} reported that reduced FA in the left anterior corona radiata is correlated with attention control in chronic mTBI patients.

Injury at the temporal WM tracts or cingulum bundle may cause memory problems. Niogi \textit{et al.} reported that reduced FA in uncinate fasciculus correlated with memory performance.\textsuperscript{59} Wu \textit{et al.}\textsuperscript{39} reported that FA measure of left cingulum bundle correlated with delayed recall.

Injury of the callosal fibers has been reported to be associated with PCS scores. Wilde \textit{et al.}\textsuperscript{40} studied 10 adolescent patients with mTBI in the acute stage and reported that increased FA and decreased ADC and MD in corpus callosum is correlated with patient PCS score. Bazarian \textit{et al.}\textsuperscript{41} studied 6
patients with mTBI in the acute stage and reported a lower mean trace in the left anterior IC and a higher FA in the posterior CC. FA values correlated with patient’s 72 hours PCS score and visual motor speed and impulse control.

The overall burden or extent of WM injury is associated with both speed of information processing and overall functional outcome. Niogi et al.\textsuperscript{50} studied 34 subacute to chronic mTBI patients and reported that FA decreased in several WM regions, including anterior corona radiata, uncinate fasciculus, CC genu, and cingulum bundle. They demonstrated that the number of damaged WM regions is correlated with patient’s reaction time. Miles et al.\textsuperscript{47} studied 17 mTBI patients at the acute stage and followed them up to 6 months after injury. They reported that, at the acute stage, the increased mean diffusivity (MD) in centra semiovale, the genu and splenium of CC, and the posterior limb of IC tended to correlate with patient response speed at 6 months after injury. Regarding the overall outcome, Messe et al.\textsuperscript{45} divided patients with mTBI into two outcome groups, poor outcome versus good outcome. Poor outcome patients showed significantly higher mean diffusivity (MD) values than both controls and good outcome patients in the corpus callosum, the right anterior thalamic radiations and the superior longitudinal fasciculus, the inferior longitudinal fasciculus and the fronto-occipital fasciculus bilaterally.

Interestingly, injury or reduced blood supply in the thalamus, which is the relay station of neuronal pathways, may cause a constellation of symptoms in speed of information processing, memory, verbal, and executive function. Grossman et al. studied 22 patients with subacute to chronic mTBI by using diffusion kurtosis imaging, which is a more advanced form of diffusion analysis, and demonstrated that overall cognitive impairment is associated with the diffusion measurement in the thalamus and internal capsule.\textsuperscript{60} This work is along the same line of a perfusion study by the same group, which demonstrated that reduced blood flow in the thalamus correlated with patient’s overall neurocognitive function.\textsuperscript{61}

In summary, significant progress has been made by researchers in recent years regarding the prognostic value of DTI in the form of FA for neurocognitive outcome in patients with mTBI. There is still a need to evaluate the neural basis of a patient’s recovery process, which requires longitudinal studies over a large number of patients.

### 2.4.3 Pros and Cons of Different Analytical Approaches

One challenge of DTI is post-processing and interpretation of the images. There are several approaches available, including whole brain histogram analysis, region of interest analysis, voxel-based analysis, and tract-based spatial statistics, to name a few. Each approach has pros and cons. There is no standardized procedure for DTI analysis; it is a moving target. The choice of analytical approach depends on the hypothesis and goal of the study. Table 2.2 lists the pros and cons of each approach.

A whole brain histogram analysis is used to segment out the whole brain WM and plot the FA frequency distribution.\textsuperscript{16} Two studies have demonstrated
that moderate to severe TBI patients had their FA histograms shifted toward zero, and the TBI group had larger variations than controls. In a mTBI study, Inglese et al.\textsuperscript{43} did a whole brain histogram analysis by combining both grey and white matter, and did not find a group difference between mTBI patients and controls. Instead of combining both GM and WM, Lipton et al.\textsuperscript{62} segmented out WM and demonstrated the mTBI patient group’s FA histogram of WM only shifted to lower end. However, as their data demonstrated, it is not as sensitive as that of the voxel-based analysis. The advantage of the histogram analysis is that it is relatively easy to implement. The disadvantage is the lack of regional injury information and lack of sensitivity to subtle changes of the WM, particularly for mild cases. Unless the subject has widespread multifocal injury on WM tracts, a small fraction of WM injury may not demonstrate a shift in the histogram or change its kurtosis.

To test a hypothesis of injury at specific WM tract(s) in association with specific domain of neurocognitive or neural behavioral symptoms, researchers used region of interest (ROI) analysis by either manually drawing or segmenting out the regions in a prior defined template in an automated or semi-automated way. This could also provide needed lesion localization information, which should improve biomechanical models of TBI. Manually drawn ROI is relatively easy and convenient to do. One could use a color-encoded FA diffusion map as a guide to define the boundary of a target region. It works on the native space of the subject’s brain without worrying about the distortion caused by the warping algorithm. However, it is time consuming and error prone. It requires the rater’s prior knowledge of which specific tracts or locations to define the region. It also has a potential inter-rater and intra-rater variability problem.

An automated ROI analysis approach would need initially to transform the images into a standard reference space; for example, International Consortium

Table 2.2 Comparison of different DTI analytical approaches.
of Brain Mapping (ICBM) atlas, by using SPM8, FSL, or other software, in order to derive statistical maps computed from comparing “cases” and non-TBI controls, and then further divide the WM into standardized regions that are already defined on the atlas. Then each regional FA, ADC, or Eigen values could be computed. In this category, several studies reported significant FA differences between mTBI patients and controls.\textsuperscript{42,64} This method overcomes the subjective issue in manually drawn ROIs by using a computer algorithm to warp each subject to a standard space. The result is objective and consistent. However, the use of a computer algorithm for image warping and registration will introduce new problems. Due to individual variations, the warping of one image to a standard space could change the DTI indices’ values from the native space. Furthermore, in a relatively large region like the splenium of corpus callosum, a small fraction of voxels with abnormal FA value could be averaged out by the surrounding voxels in the same region, rendering this method insensitive to small lesions.

Voxel-based analysis (VBA) overcomes the sensitivity issue of the ROI approach by comparing patient and control DTI images voxel by voxel to determine the abnormal voxels between groups. This approach is fully automated, data-driven, and reproducible. Several studies reported different clusters of WM tracts with abnormal FA values by using this method.\textsuperscript{38,41,46,62,65,66} However, it suffers from the same warping and misregistration problems as that of the automated ROI approach. Particularly at the edge of WM or GM/WM junction area, any misregistration will result in comparing WM of one group with GM of another group and result in abnormal values of DTI indices.

To overcome the misregistration problem, a relatively new approach, called tract-based spatial statistics (TBSS), has been introduced.\textsuperscript{67} First, it averages both patient and control brains to form a template brain. Second, it defines a template skeleton of the WM tracts from the center lines of WM of the template

![Figure 2.3](image)

**Figure 2.3** A mTBI patient scanned on the day of injury (5.5 hours after injury) and 6 weeks later. A 31-year-old male fell 10 feet (3.0 m) off a ladder, striking the back of his head with brief loss of consciousness and confusion. The patient developed persistent mild cognitive symptoms 6 weeks after injury. Note the same location of reduced FA in left corona radiata. Similar finding in splenium of CC (not shown). Global WM FA mean was within normal.
brain. Third, all of the subjects’ WM skeletons are non-linearly registered onto the template skeleton. As such, the WM skeletons of all subjects will be aligned at the same space. Abnormal DTI indices could be defined along the skeletons by using a group comparison on a voxel-based analysis. Two groups reported the use of this method in the detection of mTBI\textsuperscript{45,48} in association with patient outcome. This method is automated and reproducible and suitable for data-driven analysis. It has the least problem of misregistration. However, it only looks at the center lines of WM tracts. In thick WM bundles, like corpus callosum, it might miss lesions located off the center lines of WM.

2.4.4 DTI Caveat

In addition to the post-processing concerns mentioned above, another caveat of DTI is that it is experiment dependent. Different magnet field strength and image acquisition parameters, among others, will result in different DTI measures\textsuperscript{19}. Furthermore, to date, most publications are performed with group comparisons between patients and controls instead of an individual-based analysis. However, radiological diagnosis is case-based. A radiologist or a clinician needs to make a decision for each individual subject instead of group comparison. The low sensitivity of DTI to individual case hinders its further implementation as a routine clinical sequence. A relatively standardized protocol is needed to test a large number of controls to determine the normal variations before deciding which specific case has brain injury.

Figure 2.4 A demonstration of TBSS analysis to detect WM injury at the splenium of corpus callosum. A young man involved in a motor vehicle accident with negative structural MR images. TBSS analysis demonstrated significantly lower FA values at the splenium of corpus callosum, as demonstrated in the highlighted area. As shown on the image, it focuses on the skeleton (center lines) of WM.
2.5  *In Vivo* $^1$H MR Spectroscopic Imaging

Cellular changes to neurons and glia following TBI are complex and dynamic. Proton ($^1$H) MRSI has the advantage of measuring brain metabolism *in vivo*, and is able to detect various biochemical processes of brain injury such as the loss (or dysfunction) of neuronal cells. TBI is known to induce changes in N-acetylaspartate (NAA) (a neuronal marker), choline (Cho) (a marker for membrane disruption, synthesis, or repair), and lactate (Lac) (a measure of anaerobic glycolysis). Many studies of metabolic changes after TBI have proven MRS to be a sensitive tool to predict neurologic, cognitive, and functional outcome. Significant decreases of NAA and increases of Cho have been observed in “normal appearing” WM or GM following moderate to severe TBI. Elevated Cho may be detected in WM as a breakdown product after shearing of myelin and the presence of lactate in the brain suggests hypoxic/ischemic injury. Researchers from Loma Linda University Medical Center found that increased frontal white matter (FWM) Cho/creatine and decreased FWM NAA/Cho at acute stage are useful for predicting functional outcome in patients with moderate to severe TBI. In addition, they also found that elevated Glx and Cho in the acute stage are sensitive indicators of injury and predictors of poor outcome in *normal appearing brain* of severe TBI patients. They also found that the decrease of NAA at subacute stage is more predictive of patient outcome.

In mTBI studies, there are relatively less data reported in comparison with moderate to severe TBI studies. For a chronic mTBI study, Kirov et al. scanned 20 mTBI patients and 17 age- and gender-matched controls and reported that the mTBI group had more variations in NAA, Cre, and Cho than the control group. Cohen et al. investigated 20 patients with mTBI from 9 days to years after injury and found that whole brain NAA decreased by 12% along with significant global and grey matter atrophy, in comparison with 19 controls. This further demonstrates NAA as a biomarker of neuronal injury or cellular loss. Regarding the investigations of mTBI in the subacute or semi-acute stages, a few studies reported an NAA/Cr decrease, which is suggestive of neuronal loss.

A recent study on 10 patients with mTBI in the semi-acute stage showed creatine increases in white matter and Glx (glutamate and glutamine) decreases in grey matter. The creatine (Cre) increases in white matter were correlated with patient’s executive function. The same research group also studied a relatively larger group of patients with longitudinal follow-up. In their study of 30 mTBI patients at the first visit within 3 weeks after injury, they reported Cre and Glx increases in WM and Glx decreases in GM. Among the patients, 17 returned for follow-up at the chronic stage; their GM Glx demonstrated normalization and their WM Cre and Glx demonstrated a trend of normalization. Of particular note is that, at the first visit, the mTBI group did not have any difference from the controls in neuropsychological assessment except for more somatic, cognitive, and emotional symptoms. This demonstrates that MRS may be sensitive to subtle changes of the brain, which may not yet be manifesting significant neural cognitive deficits.
As with other MRI techniques, MR spectroscopy has also undergone tremendous advancements in the past two decades, evolving from single voxel MR spectroscopy to 2D spectroscopy imaging and 3D whole brain spectroscopy imaging. Single voxel spectroscopy (SVS) allows acquisition of a single spectrum from one volume element (voxel) typically 8 cm$^3$ or more, whereas 2D or 3D magnetic resonance spectroscopic imaging (2D-MRSI/3D-MRSI), also called chemical shift imaging (CSI), allows for the simultaneous acquisition of multiple spectra from smaller adjacent voxels through multiple sections of the brain. MRSI has an inherent advantage over SVS because it is better able to evaluate regional distributions of neurochemical alterations.

Instead of hypothesizing a certain region or certain slice of the brain to have abnormal metabolite signals; 3D MRSI allows investigators to search the whole brain to identify any area that might have abnormal metabolites. This could be useful in mTBI due to the fact that choosing an arbitrary region to study would be like searching for a needle in a haystack. Govind et al.\textsuperscript{91} used a 3D-MRSI sequence to scan 20 mild and 9 moderate TBI patients and found a widespread decrease of NAA and NAA/Cre, and increases of Cho and Cho/NAA, within all lobes of the TBI subject group, and with the largest differences seen in WM. Examination of the association between all of the metabolite measures and the neuropsychological test scores found the strongest negative correlations to occur in the frontal lobe and for Cho/NAA.

One caveat of the previous MRS work on TBI is that Cre has been used as an internal reference with the assumption that Cre levels will remain constant after injury.\textsuperscript{9} However, this might not be true in an injured brain, which could have Cre disturbance after TBI. As demonstrated by Gasparovic et al.,\textsuperscript{89,90} the Cre increase in mTBI patients at the semi-acute stage might give a false impression of decreased NAA/Cre level. It is therefore important to quantitate metabolite concentrations carefully, particularly after mTBI, to determine possible small changes in all metabolites. Comparing metabolite ratios may mask important metabolite changes.

### 2.6 Perfusion Imaging

After the primary brain damage occurs, even more devastating secondary brain injuries can occur.\textsuperscript{92} This usually includes, but is not limited to, ischemic and hypoxic damage, cerebral swelling, rise of intracranial pressure, hydrocephalus, and infection\textsuperscript{93} in moderate to severe TBI patients at the acute stage. The injury to the brain can result in disturbance of cerebral blood flow (CBF), which correlates with poor brain tissue oxygenation,\textsuperscript{94} and unfavorable neurological outcome,\textsuperscript{95} which is implicated in rendering the brain vulnerable to secondary damage.\textsuperscript{95} It has been recognized that the failure of brain perfusion is the most common type of hypoxic-ischemic brain damage, but is difficult to identify even in histological studies.\textsuperscript{93} Cerebral ischemia (CBF $\leq$ 18 mL/100 g/min) is present in approximately 90% of patients who die with head injury.\textsuperscript{92,96,97} Furthermore, after TBI, the uncoupling between CBF and brain metabolic demand
occurs, whereby local cerebral glucose demand increases and local CBF is disturbed due to damage to the vascular muscle tone and arterioles. The early hyper-glycolysis is thought to be due to the cellular efforts to reestablish ionic gradients. Different aspects of ischemia and/or edema after injury can be quantified using perfusion imaging, including perfusion weighted imaging (PWI) and arterial spin labeling (ASL), and DWI/DTI. Kim et al. used ASL to measure the resting state CBF in 28 moderate to severe TBI at chronic stage and found a) a global decrease of CBF in TBI patients than that in controls, and b) prominent regional hypoperfusion in the posterior cingulate cortices, the thalami, and multiple locations in the frontal cortices.

However, in the population of mTBI, how cerebral perfusion is being affected in patients and their association with patients’ neurocognitive status is still less understood. Given the milder severity in mTBI patients, perfusion imaging at the acute stage could be meaningful both for clinical decision-making and patients’ outcome prediction. Ge et al. also employed ASL to study 21 mTBI patients at the chronic stage and demonstrated reduced CBF in both sides of the thalamus, which is correlated with the patients’ speed of information processing, memory, verbal, and executive function.

In summary, our knowledge is very limited in the understanding of cerebral blood flow and its impact to mTBI patients. Perfusion imaging of mTBI, particularly at the acute stage, might shed new light in our understanding of this disease.

2.7 Delivering Improved Care to Patients with mTBI

Despite the fact that the ED sees the majority of patients with mTBI, most stay only a few hours and then are discharged home. After that, most patients fail to be followed up. The acute stage, within 24 hours after injury, is the critical time point for imaging to deliver a real impact to medicine. Either improved detection or outcome prediction will greatly help emergency physicians develop a better referral pattern or management plan for the patient or notify the patient’s family members to arrange necessary resources in advance. However, most of the patients with mTBI at the acute stage do not get an MRI scan due to the high cost for medical insurance and the lack of accessibility to an MRI magnet. To date, very few studies are designed to target this critical time point. There is an urgent need for a comprehensive use of advanced MRI techniques to evaluate the patients from the acute setting (within 24 hours) to the chronic stage after injury to identify the association between injury pathology and outcome. In the future, with the availability of MR magnets in the ED and reduced costs for an MRI scan, routinely scanning mTBI patients at the acute stage will be possible. However, to determine who will get MRI scan in ED will be another issue, due to cost. In conjunction with other biochemical markers, a policy on clinical decision making would be expected to define a subgroup of patients for MRI scan.
2.8 Conclusions

MRI has demonstrated superior capabilities over CT in the detection of subtle changes of the brain after mTBI. As an advanced MRI technique, DTI can detect white matter abnormalities that are unseen in structural MRI and further map it with a patient’s specific domain of neuropsychological symptoms. Other advanced MRI techniques also demonstrate the potential to detect other types of brain pathologies, including SWI for microhemorrhage detection, MRS for measuring abnormal cerebral metabolites, and perfusion imaging for detecting cerebral blood flow disturbances. In the future, these advanced MRI techniques should be used in a comprehensive way in a large cohort of patients to provide a panorama view of brain pathologies. The MRI investigations at the acute stage, within 24 hours after injury, will most likely impact emergency medicine, which is at the forefront of mTBI care. Furthermore, conjunctival use of imaging with other biological markers, such as serum biomarkers, will likely help screen patients who really need MRI in the acute setting.
