AWARD NUMBER: W81XWH-13-1-0211

TITLE: Development of Antidepressants as Novel Agents To Treat Small Cell Lung Cancer

PRINCIPAL INVESTIGATOR: Julien Sage

CONTRACTING ORGANIZATION: Stanford University
                         Stanford, CA 94305

REPORT DATE: August 2014

TYPE OF REPORT: Annual Report

PREPARED FOR: U.S. Army Medical Research and Materiel Command
               Fort Detrick, Maryland 21702-5012

DISTRIBUTION STATEMENT: Approved for Public Release;
                         Distribution Unlimited

The views, opinions and/or findings contained in this report are those of the author(s) and should not be construed as an official Department of the Army position, policy or decision unless so designated by other documentation.
Small cell lung cancer (SCLC) is an aggressive neuroendocrine subtype of lung cancer with high mortality. We used a systematic drug repositioning bioinformatics approach querying a large compendium of gene expression profiles to identify candidate U.S. Food and Drug Administration (FDA)–approved drugs to treat SCLC. We found that tricyclic antidepressants and related molecules potently induce apoptosis in both chemonaïve and chemoresistant SCLC cells. The candidate drugs activate stress pathways and induce cell death in SCLC cells, at least in part by disrupting autocrine survival signals involving neurotransmitters and their G protein-coupled receptors. These experiments identify novel targeted strategies that can be rapidly evaluated in patients with neuroendocrine tumors through the repurposing of approved drugs.

INTRODUCTION

The identification of therapeutic approaches for the treatment of cancer is an arduous, costly, and often inefficient process. Drug repositioning, which is the discovery of new indications for existing drugs that are outside their original indications, is an increasingly attractive mode of therapeutic discovery. In addition to saving time and money, an advantageous aspect of drug repositioning is that existing drugs have already been vetted in terms of safety, dosage, and toxicity. Therefore, repurposed candidate drugs can often enter clinical trials much more rapidly than usual. The primary goal of the research funded by this award is to validate candidate drugs identified through a computational repurposing approach against small cell lung cancer and to uncover the mechanisms of action of these drugs.

KEYWORDS

SCLC, small cell lung cancer, drug repositioning, tri-cyclic antidepressants, GPCR signaling

OVERALL PROJECT SUMMARY

Small cell lung carcinoma (SCLC) is a neuroendocrine form of lung cancer. SCLC patients have a 5-year survival of less than 5%. This dismal survival rate has remained the same for the last 30 years and ~200,000 patients die every year worldwide from SCLC, emphasizing the need for the development of novel therapeutic approaches against this aggressive cancer subtype. The idea behind this proposal is to use a drug repositioning approach to identify and validate FDA-approved drugs that can be repurposed to treat SCLC. A unique aspect of our strategy is that we use a novel bioinformatics-based drug-repositioning pipeline based on the analysis of thousands of gene expression profiles experiments.

We had already conducted a preliminary bioinformatics analysis and identified candidate drugs that are predicted to inhibit the growth of SCLC. Among these candidate drugs are inhibitors of G-protein coupled receptors (GPCRs) including anti-depressant molecules; those are novel candidate inhibitors of SCLC. Our objective was to test the effects of these drug candidates on mouse and human SCLC cells in culture and in vivo and to identify one or two top candidates, as well as to uncover the mechanisms of action of these candidates. In the past year, we found that tricyclic antidepressants (TCAs) and related molecules potently induce apoptosis in both chemonaïve and chemoresistant SCLC cells. The candidate drugs activate stress pathways and induce cell death in SCLC cells, at least in part by disrupting autocrine survival signals involving neurotransmitters and their G protein-coupled receptors.

Specific tasks and timeline (defined in the initial Statement of Work):

- Task 1 (from now to the beginning of the funding period, including the time required for review and approval processes for mouse studies): expansion and maintenance of the mouse colony to continually generate mice with the appropriate genotypes, including NSG immunocompromised mice. This task has been achieved, but we keep the mouse colony active for new experiments.

- Task 2 (first few months): experiments in mouse and human SCLC and control cell lines to test the effects of the four top candidate drugs. This task has been largely achieved.

- Task 3 (months 1-9): while the first cohorts of mice developing are aging, we will perform short-term experiments in allografts and xenografts transplanted under the skin of NSG mice. The effects of the drugs will be quantified using markers of proliferation, apoptosis, and differentiation. This task has been largely achieved.

- Task 4 (months 6-18): 4-6 months after Ad-Cre infection, tumor development will be measured in Rb/p53/p130 mutant mice using the luciferase reporter and mice will be treated with the drugs.
Histopathological analysis will be performed, using markers of proliferation and differentiation. This task has been largely achieved.

- Task 5 (months 18-24): we will complete the experiments in Aim 1 in cell lines and mice. This task has been largely largely achieved.

- Task 6 (months 6-12): once we have identified the best cell lines and the top candidate drugs, we will perform the initial experiments to investigate the mechanisms of action of these drugs. In particular, we will measure cell death, cell proliferation, ROS production. This task has been largely achieved.

- Task 7 (months 6-18): we will perform all the experiments for the second part of Aim 2, investigating the role of various GPCRs in promoting survival in SCLC cells. This task has been largely achieved.

- Task 8 (months 18-24): we will use that time to apply for additional funding and to initiate a novel series of experiments (including gene expression profiles, and the analysis of signaling pathways). This task is still in progress.

Please find the data supporting these statements in the manuscript attached (Cancer Discovery) ¹.

As noted by Sheila Rowe, the Science Officer who reviewed the first version of our annual report, we have been more efficient than planned in our timeline and performed a large number of the experiments proposed in the original application just before the grant was awarded. Please note, however, that the grant was awarded August 1st, 2013, and the manuscript was resubmitted 2 weeks later and accepted another week after that, so there is some overlap between the funding time and the final acceptance of the paper, and we have used some of the funds from this award to complete the experiments.

**KEY RESEARCH ACCOMPLISHMENTS**

- We validated tricyclic antidepressants such as Imipramine as inducers of cell death in SCLC (Aim 1 of the research proposal)
- We determined that TCA treatment inhibit PKA signaling in SCLC cells and leads to increased stress signals eventually resulting in cell death (Aim 2 of the research proposal)

More recent work in the past year (related to the initial Statement of Work):  
A number of the initial tasks (presented above) have been largely achieved, but we have been performing a number of related experiments, which are presented below:

1) As discussed in the initial proposal, we have been on the lookout for novel drugs to test. We tested a number of other drugs from the initial drug

**Figure 1:** Computational drug repositioning – top candidate drugs from the second iteration.
repositioning but none of these drugs showed promising results (data not shown). In collaboration with our previous collaborators (Drs. Atul Butte and Purvesh Khatri), we then performed a second drug repositioning analysis in silico, using novel gene expression datasets for human SCLC in the literature and improved computational methods. This analysis generated a second list of candidate drugs to test (these candidates are now coined “perturbagens”) (see Figure 1 for the top candidates).

Interestingly, we found drugs interacting with signaling pathways that we previously identified as critical in SCLC cells in our Cancer Discovery study \(^1\) (e.g. JNK). It is also well known that PI3K \(^2\) and Bcl-2 \(^3\) are playing a role in SCLC cells. We have just begun to validate some of these new compounds and for example wee intrigued by Selamectin, an activator of glutamate-gated chloride channels, which is normally used in pets to kill parasites. Our preliminary observations indicate that this chemical indeed potently induces cell death in SCLC cells in culture (Figure 2).

2) At the same time as we are exploring novel candidate drugs, we have continued our analysis of the mechanisms by which TCAs may induce cell death in SCLC cells. In collaboration with the laboratory of Jan Carette at Stanford, we have performed a whole-genome screen \(^4\) to identify genes whose loss-of-function would prevent the induction of cell death by Imipramine; in this screen, every gene in the genome has been disrupted by several retroviral integrations and top candidates are genes for which many independent integrations are shown. The results of this screen are shown in Figure 3. Notably, among the top candidates, a number of regulator of cell death were found (e.g. BCL2L1, also known as BCLXL, or BAX, or PMAIP1 also known as NOXA). Very interestingly, PMAIP1 was initially identified as “Phorbol-12-Myristate-13-Acetate-Induced-Protein-1”, which means it is induced by the phorbol ester PMA, itself identified in the new drug repositioning experiment (top hits in Figure 1). We are still trying to understand what these observations are telling us and have begun preliminary experiments to validate these findings.

Another interesting candidate from this experiment is SLC3A2, which is also known as CD98; it is a solute carrier that can transport amino acids in cells, such as phenylalanine, tyrosine, leucine, arginine and tryptophan. It has been found in a gene fusion event in lung cancer \(^5\) and could play a role in SCLC progression \(^6\); it may also play a role in metastasis \(^7\). However, its role in the survival of SCLC cells is completely unknown and we have begun to generate reagents to study its function in SCLC; one...

![Figure 2: Selamectin induces cell death in mouse SCLC cells in culture (MTT assays) (representative experiments).](image1)

![Figure 3: Genome-wide haploid genetic screen to identify mediators of cell death by Imipramine in cancer cells. Genes are indicated on the left: red indicates genes that were found in previous creens from the Carette lab and are probably not specific; orange indicates that while the p-value is low, the number of insertions raises some concerns regarding the hit; green indicates the best candidates.](image2)
interesting observation is that SLC3A2 interacts with the glucose transporter GLUT1, which raises the possibility that its loss-of-function may affect tumor metabolism.

3) In parallel to these new mechanistic efforts, we have explored the possibility that an alternative mechanism for how TCAs kill neuroendocrine cancer cells: a possible lysosomotropic mechanism in which the drugs may accumulate in lysosomes, blocking their function, thereby leading to cell death. The best known lysosomotropic agent is chloroquine (because its deprotonated form is more membrane-permeable than its protonated form, it is trapped in lysosomes). Our experiments to test this possibility indicate that there may be indeed some induction of cell death in culture in SCLC cells through this mechanism (Figure 4), but this is only seen at high doses of the drug (around 20 hours after treatment) and we do not know yet if similar mechanisms may be at play in tumors in vivo.

Figure 4: A possible lysosomotropic effect of TCAs in SCLC cells. Kp1 mouse SCLC cells (A) and H69 human SCLC cells (B) were treated with varying doses of Imipramine at 30 µM (I30), 50 µM (I50), and 75 µM (I75) under different conditions: acidic pH (6.5), alkaline pH (9), with 0.5 µM or 1 µM of bafilomycin (Baf0.5 or Baf1), and 0.5 µM or 1 µM of oligomycin (Oligo0.5 or Oligo1). Representative FACS histograms of Kp1 (C) and H69 (D) cells treated with and without 50uM of Imipramine for 20 hours and stained with Lysotracker green. Black arrows depict an increase in Lysotracker signal.

3) Finally, we have been pursuing our analysis of the possible role of PKA downstream of TCAs in SCLC cells: PKA was identified as a key enzyme downstream of TCAs in our previous analysis since PKA activators completely blocked the inhibitory effects of TCAs. This part of the project has been slowed by the long time it has taken to obtain mice in which a point mutation in PKA allows for its specific inactivation using a small molecule inhibitor and at the same time may allow to identify its targets (technology developed by the Shokat lab). However, to first confirm that PKA is indeed active in SCLC cells, we have used methods developed in the Shokat lab to identify active kinases in cells (“inhibitor bead” approach).

Using this platform, we have performed preliminary experiments that have successfully mapped groups of activated kinases in a number of human and mouse SCLC xenografts (Fig. 6). Importantly, among the top candidates identified in these pilot experiment is PKA (Figure 5). These experiments solidify our interest in PKA in neuroendocrine tumors.
CONCLUSION

These experiments identify novel targeted strategies that can be rapidly evaluated in patients with neuroendocrine tumors through the repurposing of approved drugs. The goal of the Lung Cancer Research Program is to eradicate deaths from lung cancer to better the health and welfare of the military and the American public. One area of focus for the LCRP is the cure and the control of lung cancer. Our proposal directly addresses this long-term goal because we identified novel FDA-approved drugs that can be used to treat patients with SCLC, the most aggressive subtype of lung cancer. Importantly, the smoking rate in the military is still higher than in the rest of the populations (~32% versus ~21%) and SCLC development strongly correlate with cigarette smoking; thus, while the general population may benefit from our work, military personnel may benefit even more from our studies.

Beyond the publication that has resulted from this work, we have also performed an investigator-driven clinical trial at Stanford (phase 2a, led by Dr. Joel Neal) – this was funded by other funds from the Stanford Cancer Institute. While only a few patients were enrolled, this clinical trial, which is now closed (https://clinicaltrials.gov/ct2/show/NCT01719861?term=NCT01719861&rank=1), was very instructive and will help us initiate a larger trial soon hopefully.

Future/ongoing plans: as discussed above, we have performed a number of “screens” in the past year to refine our drug repositioning analysis but also to better understand the mechanisms underlying our past observations. We will follow up on these screens and top candidates and we will publish the results of the clinical trial. We are also applying for additional sources of funding to pursue this work.

A Drug Repositioning Approach Identifies Tricyclic Antidepressants as Inhibitors of Small Cell Lung Cancer and Other Neuroendocrine Tumors

INTRODUCTION

The identification of therapeutic approaches for the treatment of cancer is an arduous, costly, and often inefficient process. Drug repositioning, which is the discovery of new indications for existing drugs that are outside their original indications, is an increasingly attractive mode of therapeutic discovery. In addition to saving time and money, an advantage of drug repurposing strategies is the fact that existing drugs have already been vetted in terms of safety, dosage, and toxicity. Therefore, repurposed candidate drugs can often enter clinical trials much more rapidly than newly developed drugs (1). Recent advancements in computing, concomitant with the dramatic expansion of available high-throughput datasets, have enabled the development of *in silico* approaches to drug discovery, including the incorporation of genomics-, network-, systems-, and signature-based approaches. Although these computational approaches are still in their infancy, emerging evidence suggests that they enable the discovery of novel treatment options for a wide range of human diseases (2–6).

Lung cancer is the number-one cause of cancer-related deaths in the world, with more than 1.3 million deaths annually. Lung cancer is divided into two major histopathologic groups: non–small cell lung cancer (NSCLC; ∼80%–85% of cases) and small cell lung cancer (SCLC; ∼15%–20% of cases; refs. 7, 8). SCLC is a very deadly subtype of lung cancer characterized by the rapid expansion and metastasis of small cells with neuroendocrine features. Patients are most commonly diagnosed with metastatic (extensive stage) disease. Without treatment, they may survive only a few weeks to months after the initial diagnosis, but systemic chemotherapy improves the median survival to approach a year. Still, there is no cure with currently used therapies, and there is no approved targeted therapy for SCLC despite numerous attempts and clinical trials (9). In recent years, a substantial effort from many groups has been made to identify novel treatment options for SCLC. For instance, a proteomic profiling approach has recently identified PARPi as a potential therapeutic target in SCLC (10). However, it is essential to identify additional therapeutic strategies to block the growth of SCLC tumors.

In this study, we sought to use a systematic drug-repositioning bioinformatics approach to identify novel U.S. Food and Drug Administration (FDA)–approved candidate drugs to treat SCLC. Using this strategy, we identified tricyclic antidepressants (TCA) and related inhibitors of G protein–coupled receptors (GPCR) as potent inducers of cell death in SCLC cells and other neuroendocrine tumors.

RESULTS

To identify novel therapeutic strategies for patients with SCLC, we used a bioinformatics approach that evaluates
Figure 1. A bioinformatics-based drug-repositioning approach identifies candidate drugs to inhibit SCLC. A, schematic representation of the bioinformatics workflow for the repositioning approach used to identify potential candidate drugs for the treatment of SCLC. B, representative MTT survival assays of cells cultured in 0.5% serum (n ≥ 3 independent experiments). A549 are NSCLC cells, H82, H69, and H187 are human SCLC cell lines, and Kp1, Kp2, and Kp3 are mouse SCLC cell lines. Cells were treated for 48 hours with 20 μmol/L clomipramine, 50 μmol/L imipramine, 30 μmol/L promethazine, 100 μmol/L tranylcypromine, 100 μmol/L pargyline, and 10 μmol/L bepridil. C, MTT survival assays of NSCLC (A549 and LKR13) and SCLC cells (H82, H69, H187, Kp1, Kp2, and Kp3) cultured in 2% serum (n > 3 independent experiments) for 48 hours with 50 μmol/L imipramine, 30 μmol/L promethazine, and 10 μmol/L bepridil. Similar results were obtained in cells growing in dialyzed serum (data not shown). The black bars represent the vehicle-treated cells normalized to 100%. *, P < 0.05; **, P < 0.01; ***, P < 0.001.

Note: The unique set of canonical targets associated with the top-scoring SCLC-repositioning hits was evaluated for biologic enrichment in KEGG pathways using DAVID. The enrichment statistic P values were adjusted for multiple testing using the Benjamini-Hochberg method, and pathways with adjusted $P < 0.05$ are reported as being enriched for targets of top-scoring SCLC-repositioning hits.

therapeutic potential of FDA-approved drugs for a given disease by comparing gene expression profiles in response to these drugs in multiple cell types across multiple diseases (ref. 4; Fig. 1A). From this drug-repositioning approach, we computed a list of candidate drugs with predicted efficacy against SCLC (Supplementary Table S1). This list contained a wide variety of drugs, including some chemotherapeutic agents previously tested with some success in patients with SCLC (e.g., doxorubicin and irinotecan; ref. 7), suggesting that these agents used in the clinic may affect the SCLC gene expression signature. Rather than screen a large number of candidate drugs in cells, we first annotated the known targets of the top-scoring candidates, as well as the pathways enriched in these drug targets (Table 1). This analysis led us to focus on drugs targeting molecules in the “Neuroactive ligand receptor interaction” and “Calcium signaling” pathways, the top two most significant pathways. Notably, SCLC cells are known to express molecules in these pathways, including neurohormonal ligands, channels, and receptors (11–13).

We selected an initial group of six drugs for experimental validation from these two groups. In the “Neuroactive ligand receptor interaction” module, imipramine and clomipramine are two first-generation TCAs with moderate to strong serotonin and epinephrine reuptake inhibition activity, which also display strong anticholinergic, antihistaminic, and antiadrenergic effects. Promethazine is a first-generation histamine H1 receptor antagonist that also possesses anticholinergic and antiadrenergic activities. Tranylcypromine and pargyline are receptor antagonist that also possesses anticholinergic and antiadrenergic effects. Promethazine is a first-generation histamine H1 receptor antagonist that also possesses anticholinergic and antihistaminic effects. Bepridil is an entry in the list of drugs that blocks both voltage- and receptor-operated calcium channels.

We first conducted cell viability assays after exposure to the drugs in culture. As a negative control, we used the lung adenocarcinoma (NSCLC) cell lines A549 (human) and LKR13 (mouse), which are not expected to respond to the same candidate drugs (5). We tested three established human SCLC lines (H82, H69, and H187) and three primary tumor cell lines from a genetically defined mouse model of SCLC (Kp1, Kp2, and Kp3; ref. 14). The doses and concentrations used were optimized for each drug and ranged from 1 to 20 μM/L for bepridil and 10 to 100 μM/L for clomipramine, promethazine, imipramine, tranylcypromine, and pargyline; all of these doses have been well documented in multiple cellular contexts. We confirmed that the IC50 of these drugs in the human and mouse SCLC cells used was in the same range as was previously reported (Supplementary Fig. S1A; data not shown). Next, we used the IC50 of the selected drugs to determine the survival of each cell line compared with its vehicle-treated control. Treatment of SCLC cells with imipramine, clomipramine, promethazine, and bepridil, but not tranylcypromine or pargyline, significantly inhibited the growth of mouse and human SCLC cells but not NSCLC cells when cultured in 0.5% or 2% serum (Fig. 1B and C). Cells were also responsive to the drugs in higher serum conditions (5% and 10%; data not shown). Phase contrast images of control and treated SCLC cells suggested that imipramine, promethazine, and bepridil were inducing cell death rather than having cytostatic effects (Supplementary Fig. S1B). Of note, the least responsive SCLC cell line in this initial analysis, H82, is often classified as a variant SCLC cell line with decreased neuroendocrine features.

On the basis of these experiments in culture, we selected one drug in each of the three main categories to carry out experiments in vivo (imipramine, promethazine, and bepridil). Once measurable tumors had formed after subcutaneous injection of SCLC cells in immunocompromised NOD-SCID, Gamma (NSG) mice, we treated the transplanted mice for 2 weeks daily with each drug (Fig. 2A). All three drugs inhibited the growth of transplanted mouse Kp1 and Kp3 SCLC cells and human H187 SCLC cells as single agents, although the effects of bepridil were not as significant on the human cell line (Fig. 2B and C and data not shown); promethazine inhibited the growth of human H82 SCLC xenografts significantly, whereas imipramine had a less profound effect (data not shown). We next treated a human primary SCLC tumor growing under the skin of NSG mice with imipramine or promethazine (Fig. 2D) and found that the two drugs had a long-term cytostatic effect on tumor growth (Fig. 2D and E).

These results led us to further investigate the effects and mechanisms of action of the two best candidate drugs, the TCA imipramine and the antihistamine and antiemet promethazine. To determine the efficacy of the candidate drugs on primary tumors in vivo, we examined how endogenous SCLC tumors developing in the lungs of Rb/p53/p130-mutant mice (15) responded to drug treatment. Five months after intratracheal instillation of Ad-Cre to delete the three tumor suppressor genes and initiate
tumor development, at a time when these mutant mice have developed advanced lesions, daily intraperitoneal injections of imipramine, promethazine, or saline were carried out on groups of mutant mice. After 30 days of treatment (Fig. 3A), the analysis of whole lungs and hematoxylin and eosin (H&E)–stained sections indicated that imipramine- and promethazine-treated mice had fewer and smaller SCLC tumors than control mice (Fig. 3B). Drug treatment significantly reduced tumor burden as measured by the total tumor area occupying the lungs and the size of the tumors (Fig. 3C and D). Three of 10 control mice developed large metastases in their livers, as described before (15), whereas no large lesions were found in the six promethazine-treated and nine imipramine-treated mice analyzed.

Patients with SCLC are typically treated with a combination of a platinum-based agent and etoposide. Patients often respond well initially but almost invariably relapse with disease that is often resistant to their primary therapy and other agents (9). We observed strong toxicity in tumor-bearing mice simultaneously treated with both cisplatin and etoposide (data not shown), limiting our ability to assess the long-term response of endogenous tumors to both drugs. Consequently, to determine the effects of the candidate drugs on chemoresistant tumors, we treated Rb/p53/p130;Rosa26LSL-Luciferase− mutant mice bearing SCLC tumors with saline or cisplatin only, using luciferase expression to monitor tumor burden in vivo (Fig. 3E). Tumors that had survived chemotherapy...
Figure 3. Imipramine and promethazine inhibit the growth of SCLC tumors in a preclinical mouse model. A, strategy used for the treatment of Rb/p130/p53–mutant mice developing endogenous SCLC tumors. B, representative photographs of whole lungs and corresponding H&E-stained sections from mutant mice 6 months after Ad-Cre infection, 1 month after the beginning of treatment with saline, imipramine (25 mg/kg), or promethazine (25 mg/kg). C, quantification of the tumor surface area (pixel area units quantified by ImageJ) of mutant mice treated with saline (n = 10), imipramine (n = 9), and promethazine (n = 6; from five independent experiments). An unpaired t test was used to calculate the P values of imipramine-treated (P = 0.0017) and promethazine-treated (P = 0.0008) mice compared with control triple knockout mice. D, bar graph showing the percentage size distribution of the tumors from mutant mice injected with saline (n = 10), imipramine (n = 9), and promethazine (n = 5). Values are shown as the mean ± SEM. *, P < 0.05; **, P < 0.01; ****, P < 0.001; ns, not significant. E, strategy used for the treatment of Rb/p130/p53;Rosa26Lox-Stop-lox-Luciferase mice developing endogenous SCLC tumors and treated with saline and cisplatin weekly to generate chemonaïve and chemoresistant tumors. Deletion of the lox-Stop-lox cassette by Cre allows expression of the reporter and measurement of tumor volume. F, fold change of the tumor volume measured by luciferase activity in saline- and cisplatin-treated mice. G, NSG mice were subcutaneously implanted with the saline-treated and cisplatin-treated mouse SCLC cells shown in F and the fold change of the tumor volume was measured at the times indicated of daily intraperitoneal injections with vehicle control (saline; n = 4) and imipramine (25 mg/kg; n = 4). Values are shown as the mean ± SEM. An unpaired t test was used to calculate the P values of imipramine-treated versus saline-treated chemonaïve and chemoresistant tumors at different days of treatment. *, P < 0.05; **, P < 0.01; and ***, P < 0.001. Values that are not significant are not indicated. H, representative images of cisplatin- and saline-treated SCLC allografts collected 17 days after daily treatment.
and control chemonaive tumors (Fig. 3F) were then grown in culture or transplanted into immunocompromised recipient mice (Fig. 3E). We found that chemoresistant mouse tumors were inhibited by imipramine treatment similar to chemo-naive tumors both ex vivo (data not shown) and in primary allografts (Fig. 3G and H). Thus, tumor cells emerging from long-term treatment with a chemotherapeutic agent are still inhibited by this candidate drug.

Together, these experiments indicate that the expansion of SCLC cells is potently inhibited by imipramine and promethazine and suggest that both chemoresistant tumors and disseminated tumors may respond to treatment in patients with advanced disease.

The visual appearance of SCLC cells treated with imipramine and promethazine in culture suggested that these drugs inhibit SCLC growth by inducing cell death (Supplementary Fig. S1B). Indeed, we found that drug treatment led to apoptotic cell death in culture (data from two representative cell lines, mouse Kp1 cells and human H82 cells), in transplanted tumors, and in endogenous mouse tumors (Fig. 4A–C and Supplementary Fig. S2A and S2B). A concomi-tant decrease in proliferation was also observed in tumor sections in vivo (Supplementary Fig. S2C). Importantly, treatment with the pan-caspase inhibitor zVAD-FMK rescued the cell death induced by imipramine after 24 hours in a dose-dependent manner (Fig. 4D and E), further indicating that apoptotic cell death is a major mechanism by which the candidate drugs inhibit SCLC growth. No induction of cell death was observed in human A549 and mouse LKR13 NSCLC cells in culture at the drug concentrations used (Fig. 1C; Supplementary Fig. S1B, and data not shown) or in the lung epithelium of mice treated daily for 1 month with the candidate drugs, including lung neuroendocrine cells (Supplementary Fig. S2D).

We also noted large areas of necrosis in treated tumors (Supplementary Fig. S2B) and found that treatment of SCLC cells with an inhibitor of necrosis also partly rescued the cell death induced by the candidate drugs in culture (Supplementary Fig. S2E). Thus, the candidate drugs induce a rapid cell death specifically in neuroendocrine tumor cells.

Washing out the drugs up to 6 hours after addition to the cells was enough to prevent the appearance of cell death and the decrease in viability observed 24 hours after treatment, whereas exposure of the cells to imipramine for 8 hours or more was sufficient to induce an irreversible cell death in SCLC cells (Supplementary Fig. S3A). This observation allowed us to begin to explore the signaling mechanisms downstream of imipramine treatment in SCLC cells (16, 17). Because the calcium channel blocker bepridil also had some inhibitory effect on SCLC cells (Fig. 1 and Supplementary Fig. S1), we examined changes in calcium levels in response to imipramine and promethazine. We observed a rapid decrease in intracellular calcium levels in SCLC cells after treatment with both drugs (Fig. 4F and Supplementary Fig. S3B and S3C). We also observed increased levels of reactive oxygen species (ROS) after drug treatment (Supplementary Fig. S3D). Increased ROS and oscillations in calcium levels have been directly linked to activation of caspases and apoptotic cell death in certain contexts, including via activation of stress mitogen-activated protein kinase (MAPK) pathways (18). Accordingly, we found changes in the c-jun-NH2-kinase (JNK)/c-Jun path-way upon treatment of SCLC cells with imipramine starting at 1 hour after treatment (Fig. 4G). This rapid activation of the stress MAPK pathway was detected only in SCLC cells and not in mouse or human NSCLC cells (Fig. 4H). Combined treatment of SCLC cells with imipramine and the selective JNK inhibitor SP600125 resulted in a sig-nificant rescue of the cell death induced by imipramine (Fig. 4I). Together, these experiments indicate that treatment of SCLC cells with the candidate drugs triggers cellular stresses culminating in apoptotic and necrotic cell death.

The variety of responses triggered by imipramine and promethazine and their known binding to multiple receptors at the surface of cells makes it very likely that one reason they are so effective at inducing death in SCLC is their action on multiple targets. This broad range of action of the candidate drugs may be a positive aspect clinically. Nevertheless, we sought to identify at least some of the molecules targeted by these drugs in SCLC. On the basis of previous pharmacologic studies (19, 20), the dose of imipramine that we used in mice is in the same range as the dose to treat depression in patients, suggesting that the candidate drugs act at least in part through the targets for which they have the highest affinity, including the histamine H1 receptor (H1R), the muscarinic acetylcholine receptor (mAChR; including the CHRM3 isoform), the 5-HT2 serotonin receptor (HTR2; and in particular HTR2a), and the α1-adrenergic receptor (ADRA1a and ADRA1b; refs. 21–26). Our analysis of microarray experiments from human (27–29) and mouse (15) SCLC, binding assays, and previous reports (30–32) indicated that these GPCRs are expressed in SCLC cells (Supplementary Fig. S4A and S4B). These observations led us to treat SCLC cells with related mol-ecules and selective inhibitors of these GPCRs; we also ectopi-cally added purified ligands. Treatment with amitriptyline and desipramine, two first-generation TCAs with high bind-ing affinity to H1R, HTR2, ADRA1, and mAChR; doxazosin mesylate (a selective ADRA1 antagonist); azelastine (H1R); 4-DAMP (CHRM3); and ritanserin (HTR2) in all cases led to a significant reduction in cell survival specifically in SCLC cells and not in NSCLC cells (Fig. 5A and Supplementary Fig. S5A–S5E). Furthermore, the addition of purified epine-phrine and of a selective agonist of the H1R to the culture medium was sufficient to increase survival and partially res-cued the cell death phenotype induced by promethazine and imipramine (Fig. 5B and Supplementary Fig. S5F). Acetylcholine and serotonin also partially rescued the cell death induced by promethazine, which possesses fewer targets than imipramine (Supplementary Fig. S5G and S5H). Importantly, SCLC cells express the enzymes required for the biosynthesis of the ligands that normally activate the main GPCRs inhibited by this drug (Supplementary Fig. S6A). We also detected the rapid production of serotonin and epinephrine in the supernatant of SCLC cells by mass spectrometry (Supplemen-tary Fig. S5B and S5C). Of note, competition by these endo-genous ligands may explain the relatively high concentrations of drugs required to induce cell death in SCLC cells.

Different GPCRs often activate similar downstream sig-naling pathways, including the Gx, adenylyl cyclase/cAMP/ protein kinase A (PKA) module and the Gx, phospholipase C β (PLCβ)/protein kinase C (PKC) module (24, 33). Our analysis of microarray experiments indicated that most of
Tricyclic Antidepressants Inhibit SCLC

**Figure 4.** Imipramine and promethazine induce the apoptotic cell death of SCLC cells through activation of caspase-3. **A,** representative immunoblotting of cleaved caspase-3 (CC3) in mSCLC (Kp1) and hSCLC (H82) cells treated with 50 μmol/L imipramine for 12 hours. Karyopherin was used as a loading control. **B,** representative immunostaining of CC3 in tumor sections (white dashed lines) from Rb/p53/p130-mutant mice treated daily with saline, imipramine, and promethazine for 30 consecutive days. **C,** quantification of the percentage of CC3-positive cells per tumor area of saline- (n = 142 tumors from 10 mice), imipramine- (n = 153 tumors from 9 mice; P < 0.0001), and promethazine- (n = 103 from 6 mice; P < 0.0001) treated tumors. **D** and **E,** effects of the combined treatment of imipramine (50 μmol/L) and the pan-caspase inhibitor Z-VAD-FMK on the survival of mSCLC (D) and hSCLC (E) after 24 hours of treatment, as measured by the MTT viability assay. Values from three independent experiments are shown as the mean ± SEM. The paired t test was used to calculate the P values of imipramine-treated cells versus control dimethyl sulfoxide (DMSO)-treated cells and of imipramine-treated cells versus Z-VAD-FMK-treated cells combined with imipramine. The black bars represent the vehicle-treated cells normalized to 100%. *, P < 0.05; **, P < 0.01; ***, P < 0.001; ns, not significant. **F,** quantification of the percentage of mSCLC cells (Kp1 and Kp3) with low Ca2+ levels by FACS analysis of control untreated cells (Ctrl) and imipramine-treated cells at the times indicated. Values from three independent experiments for each cell line are shown as the mean ± SEM. An unpaired t test was used to calculate the P values of imipramine-treated cells versus the untreated control cells at the times indicated. *, P < 0.05; **, P < 0.01; ***, P < 0.001; ns, not significant. **G,** representative immunoblotting of p-c-Jun, total c-Jun, p-JNK, and total JNK in mSCLC cells (Kp1) treated with 50 μmol/L imipramine for the indicated times. Tubulin was used as a loading control. **H,** representative immunoblotting of p-c-Jun, total c-Jun, p-JNK, and total JNK in mSCLC cells (Kp1 and H82) and NSCLC cells (LKR13 and A549) treated with 50 μmol/L imipramine for 1 hour. Tubulin was used as a loading control. **I,** effects of the combined treatment of 50 μmol/L imipramine and 500 nmol/L of the JNK inhibitor SP600125 on mSCLC cells (Kp1) after 24 hours of treatment, as measured by the MTT viability assay. Values from three independent experiments are shown as the mean ± SEM. An unpaired t test was used to calculate the P values of imipramine-treated cells versus control DMSO-treated cells and of imipramine-treated cells versus SP600125-treated cells combined with imipramine. *, P < 0.05 and ***, P < 0.001. DAPI, 4′,6-diamidino-2-phenylindole.

The different Gα subunits are usually thought to be Gαq-coupled receptors (26, 34–36), which led us to first test whether blocking PKC signaling may reduce the survival of SCLC cells. However, treatment with the PKC inhibitor GF109203X had no significant inhibitory effect on the survival of mouse and human SCLC cells (Fig. 5C). In addition, treatment with the PKC activator phorbol 12-myristate 13-acetate (PMA) did not rescue the cell death induced by imipramine (Fig. 5D). Accordingly, we did not observe any decrease in phospho-PKC levels (an indicator of PKC activation) at different time points after imipramine treatment in SCLC cells (Fig. 5E and data not shown).
The candidate drugs inhibit the expansion of SCLC cells via several GPCRs. A and B, MTT viability assays of cells cultured at 2% serum (n = 3 independent experiments) and treated with the ADRA1 antagonist doxazosin mesylate in comparison with treatment with imipramine (Imip) for 48 hours (A) and with increasing doses of epinephrine (Epi) in the absence or presence of 50 μmol/L imipramine or 30 μmol/L promethazine (Prom). B. The paired t test was used to calculate the P values of epinephrine-, imipramine-, and promethazine-treated cells versus control cells and of imipramine- and promethazine-treated cells versus epinephrine-treated cells combined with imipramine or promethazine. *, P < 0.05; **, P < 0.01; ns, not significant. C, MTT viability assay for mSCLC (Kp1) and mNSCLC (LKR13) cells following 48 hours of treatment with increasing doses of the PKC inhibitor GF109203X. Values from three independent experiments are shown as the mean ± SEM. An unpaired t test was used to calculate the P values of the drug-treated cells versus control DMSO-treated cells. *, P < 0.05; **, P < 0.01; ns, not significant. D, MTT viability assay for mSCLC (Kp1) cells following 24 hours of treatment with 50 μmol/L imipramine alone and with increasing doses of PMA in the absence or presence of 50 μmol/L imipramine. An unpaired t test was used to calculate the P values of dimethyl sulfoxide (DMSO)–treated cells versus PMA-treated cells and of imipramine-treated cells versus PMA-treated cells combined with imipramine. ns, not significant. E, representative immunoblotting of p-PKC, total PKC, p-CREB, and total CREB in mSCLC cells (Kp1) untreated and treated with 50 μmol/L imipramine for 30 minutes. Tubulin was used as a loading control. F and G, MTT viability assay for mSCLC (Kp1) and mNSCLC (LKR13) cells following 48 hours of treatment with increasing doses of the adenyl cyclase inhibitor KH7 (F) and the PKA inhibitor H89 dihydrochloride (G). Values from three independent experiments are shown as the mean ± SEM. An unpaired t test was used to calculate the P values of the drug-treated cells versus control DMSO-treated cells. *, P < 0.05; **, P < 0.01; ns, not significant. H, MTT viability assay for mSCLC (Kp1) and hSCLC (H187) cells following 24 hours of treatment with 50 μmol/L forskolin (FSK), 100 μmol/L IBMX, or both drugs combined. An unpaired t test was used to calculate the P values of the drug-treated cells versus control DMSO-treated cells. ns, not significant. I, effects of the combined treatment of 50 μmol/L imipramine and 50 μmol/L FSK alone, 100 μmol/L IBMX alone, or FSK and IBMX together, as measured by the MTT viability assay. Values from at least three independent experiments are shown as the mean ± SEM. An unpaired t test was used to calculate the P values of imipramine-treated cells versus control DMSO-treated cells and of imipramine-treated cells versus FSK-, IBMX-, and FSK + IBMX–treated cells combined with imipramine. J, representative immunoblotting of p-c-Jun and total c-Jun in mSCLC cells (Kp1) untreated, treated with 50 μmol/L imipramine for 30 minutes in the absence or presence of 50 μmol/L forskolin (FSK) and 100 μmol/L IBMX, and treated with DMSO. Tubulin was used as a loading control. The black bars in all the MTT assays represent the vehicle-treated cells normalized to 100%. IBMX, 3-isobutyl-1-methylxanthine.

Figure 5.
Some reports suggest that, in certain contexts, the GPCRs targeted by the candidate drugs can also signal through Goα, signaling, leading to an increase in adenylyl cyclase activity, cAMP levels, PKA activity, and ultimately cAMP-responsive element binding protein (CREB; refs. 37–41). Thus, we next tested the alternative possibility that imipramine and promethazine may induce cell death in SCLC cells by interfering with Goα signaling. Indeed, we observed a decrease in the phosphorylation of the PKA substrates CREB and activating transcription factor 1 (ATF1) starting at 30 minutes after imipramine treatment in SCLC cells (Fig. 5E and data not shown). To determine the involvement of the Goα signaling pathway in the survival of SCLC cells and in response to the TCAs, we first treated the cells with inhibitors of this pathway. Treatment with KH7 (an inhibitor of soluble adenylyl cyclase) and H-89 dihydrochloride (an inhibitor of PKA) decreased the survival of SCLC cells, but not of NSCLC cells, in a dose-dependent manner (Fig. 5F and G). We next used forskolin and the phosphodiesterase inhibitor 3-isobutyl-1-methylxanthine (IBMX), which are known to activate adenylyl cyclase and raised the levels of intracellular cAMP, leading to subsequent PKA activation. Upon addition of forskolin and/or IBMX, alone or in combination, to vehicle-treated mouse and human SCLC cells, no significant increase in cell viability was observed after 24 hours (Fig. 5H). In contrast, the addition of 50 μmol/L of forskolin alone or 100 μmol/L of IBMX alone to imipramine-treated SCLC cells partially rescued the cell death phenotype; full rescue of viability was observed when forskolin and IBMX were added together (Fig. 5I). Finally, the addition of forskolin and IBMX to imipramine-treated cells reverted the elevated levels of phospho-c-Jun to the levels observed in untreated cells (Fig. 5J). These results indicate that imipramine and promethazine induce cell death of SCLC cells by affecting signaling downstream of the Goα subunits of the targeted GPCRs, thereby inhibiting the adenylyl cyclase and cAMP-dependent activation of PKA and inducing cell death via activation of the JNK/c-Jun module (42). Although the candidate drugs probably bind to multiple targets in SCLC cells, these experiments suggest that the potent effects of these drugs in the induction of cell death in SCLC cell populations are mediated at least in part by the capacity of these drugs to disrupt autocrine survival loops between neurotransmitters and their receptors at the surface of SCLC cells. These observations in SCLC led us to hypothesize that other neuroendocrine tumors may have similar signaling networks as SCLC cells and may be sensitive to the same drugs. The analysis of the few publicly available microarray experiments from other rare human neuroendocrine tumors indicates that Merkel cell carcinoma, midgut carcinoid tumors, pheochromocytoma, and neuroblastoma tumor cells also express several of the main GPCR targets of imipramine and promethazine (Fig. 6A). Indeed, we found that both drugs are efficient in inducing rapid cell death in human cell lines from most of these cancer types as well as in mouse pancreatic neuroendocrine tumor cells, but not as strongly and efficiently as in non-neuroendocrine pancreatic adenocarcinoma cells (Supplementary Fig. 5B and Fig. 6B and C). We also tested neuroendocrine large cell carcinoma cells and large cell lung adenocarcinoma cells and found that they do not undergo significant cell death in response to both imipramine and promethazine (Supplementary Fig. 5B and Fig. 6B and C). We recently developed a novel model of pancreatic neuroendocrine tumors resulting from the deletion of Rb, p53, and p130 in insulin-producing cells (RIP-Cre Rb/p53/p130, similar to the RIP-Tag model; ref. 43). These mice develop pancreatic tumors expressing insulin (Fig. 6D) and die approximately 2 months after birth (Fig. 6E). We found that treatment of these mice with imipramine starting at day 35 significantly increased survival (from 58 days for the mice injected with saline to 74.5 days for imipramine-treated mice; P = 0.024), further validating imipramine as a novel therapeutic agent against neuroendocrine tumors (Fig. 6E).

DISCUSSION

In this study, we used a systematic computational drug-repositioning strategy to identify FDA-approved TCAs and related molecules as potent inducers of cell death in SCLC cells through activation of stress pathways. We also show that the same drugs induce cell death in other types of neuroendocrine tumor cells. Together, these experiments elucidate a general mechanism of survival in neuroendocrine tumor cells and identify a common therapeutic strategy for a heterogeneous group of patients with cancer.

Our observations linking the survival of SCLC cells to the activity of GPCRs may be relevant to the biology of other tumors, including brain tumors, as suggested by epidemiologic studies (44), retinoblastoma (45), and pancreatic neuroendocrine tumors (46), which can be inhibited by drugs targeting neuronal signaling such as monoamine transmitters and receptors. Our study also illustrates the potential of drug-repositioning approaches, especially computational approaches, in the treatment of cancer. In this specific case, we were able to experimentally expand our findings in SCLC to other neuroendocrine tumors for which few gene expression profile datasets exist and for which the bioinformatics pipeline would not have been possible.

Our experiments suggest that inhibition of GPCRs at the surface of SCLC cells results in inhibition of PKA activity. An important aspect of future experiments will be to continue to investigate the signaling networks perturbed by these drugs in SCLC cells. We found that one important difference between SCLC and NSCLC cells is the rapid activation of the stress MAPK pathway in response to the candidate drugs. Thus, it will be interesting to determine if the engagement of different Goα subunits and downstream effectors explains the sensitivity of neuroendocrine cancer cells to these drugs. On a related note, we did not find a significant correlation between the mRNA expression levels of the candidate GPCRs and drug response in cancer cells. In particular, adenocarcinoma cells and other normal cells express these GPCRs at levels similar to SCLC cells, but do not die in response to the same drugs. It is probable that the total levels of these GPCRs on the surface of SCLC cells are not the determinant of the drug response but rather it is the activity of the molecular components of the signaling pathway downstream of the GPCRs and/or the activity of the ligands secreted by SCLC cells. Similar observations have been made recently in lung adenocarcinoma cells in which the effects of EGFR inhibition are not dependent on EGFR levels (47). Future experiments will be needed to shed light on the establishment of autocrine survival loops between...
Figure 6. TCAs inhibit the growth of several other types of neuroendocrine tumors. A, heatmaps showing the normalized RNA expression levels of the HRH1, CHRM3, ADRA1A, ADRA1B, and HTR2 in 35 human primary Merkel cell carcinomas, 42 midgut carcinoid tumors, 76 pheochromocytomas, and 88 neuroblastomas. B and C, MTT viability assays of human pancreatic adenocarcinoma (PDAC), mouse pancreatic neuroendocrine tumors (PNET), human neuroblastoma (NB), human Merkel cell carcinoma (MCC), human large cell adenocarcinoma (LCLC), and neuroendocrine large cell lung carcinoma (NE-LCLC) cultured in low serum and treated with increasing doses of imipramine (B) and promethazine (C) for 48 hours. Values from three independent experiments are shown as the mean ± SEM. *, P < 0.05; **, P < 0.01; ***, P < 0.001; ns, not significant. D, representative H&E images (top) and insulin immunohistochemistry (IHC, bottom) of sections from the pancreas of wild-type and RIP-Cre Rb/p53/p130-mutant mice. Scale bar is 50 μm. E, survival curve generated from the RIP-Cre Rb/p53/p130 mice treated daily with intraperitoneal injections of saline and imipramine starting at day 35 after birth; median survival is 58 days for saline- and 74.5 days for imipramine-treated mutant mice; P = 0.024 by the Mantel–Cox test.
GPCRs and their ligands in SCLC cells and to determine how these loops promote the survival of SCLC cells.

We have made a substantial effort to identify patients who may have been treated with TCAs incidentally as part of their routine care. Promethazine is sometimes used for nausea, but its heavily sedating effects limit its outpatient use to infrequent use. Even this drug is received only intermittently for the primary prevention of nausea from cisplatin and other chemotherapies. We have searched the electronic portion of the Stanford medical record (dating back to around the year 2000) for patients who received a TCA, and found fewer than five patients, none of whom were on the drugs chronically. Similarly, other database searches did not yield high patient numbers. On the basis of our preclinical results, prospective validation of these findings in a clinical trial setting has begun (NCT01719861—A phase IIa trial of desipramine in small cell lung cancer and other high-grade neuroendocrine tumors), but reportable results are not expected for years. An advantage of a drug-repositioning approach with approved medications for other indications is accelerated drug development times.

TCAs have largely been replaced in the clinic by a new generation of selective serotonin reuptake inhibitors. However, the anticancer effects of TCAs are in large part due to the less-specific, “off-target” mode of action of these drugs, which target multiple molecules at the surface of cells. The monoamine oxidase inhibitors tranylcypromine and pargyline do not antagonize these GPCRs and are not efficient in inducing cell death in SCLC cells. The fact that TCAs target multiple surface molecules has important consequences for patients with cancer: first, our analysis of gene expression profiles of SCLC and other neuroendocrine tumors indicates that most, if not all, individual tumors express at least one of these GPCRs. Thus, the vast majority of neuroendocrine tumors may be at least partly responsive to TCA treatment. In addition, acquired resistance to TCA treatment may take a long time to occur. Additional experiments in preclinical mouse models and early-phase clinical trials in patients with these FDA-approved drugs may help in rapidly identifying ways to translate these observations to better treatment options for patients with neuroendocrine tumors.

Finally, we believe that imipramine and other related TCAs could potentially be used as a second-line therapy in patients with SCLC who become refractory to cisplatin/etoposide. Our studies indicate that cisplatin-resistant tumors are still sensitive to imipramine treatment. We have tested the effects of combining imipramine with cisplatin at the early stages when the tumor was still sensitive to cisplatin in vivo, but we did not observe a significantly greater decrease in tumor growth compared with imipramine alone or cisplatin alone at the concentrations used; both drugs induce apoptotic cell death and may not induce more death together (data not shown). Moreover, the side-effect profile of TCAs is not benign, and combining with chemotherapy likely will substantially increase toxicity in a patient population with often compromised functional status, further reducing potential clinical benefit. On the basis of these observations, we propose that TCAs in the platinum refractory setting or as maintenance treatment after chemotherapy may be the most useful settings for these candidate drugs in clinical trials.

METHODS

Ethics Statement

Mice were maintained according to practices prescribed by the NIH (Bethesda, MD) at Stanford’s Research Animal Facility, accredited by the Association for the Accreditation and Certification of Laboratory Animal Care (AAALAC).

Drug-Repositioning and Bioinformatics Approach

The drug-repositioning analysis was based on a systematic approach described previously (4, 5). Detailed information can be found in the Supplementary Data.

Mice, Adenoviral Infections, and Subcutaneous Xenografts

The SCLC mouse model bearing deletions in p53, Rb, and p130 (triple knockout) was previously described (15). The pancreatic neuroendocrine cancer mouse model is based on the deletion of Rb, p53, and p130 in insulin-producing cells (RIP-Cre Rb−/p53−/p130, similar to the RIP-Tag model; ref. 43). This mouse model will be described in detail elsewhere. Ad-Cre (Baylor College of Medicine, Houston, TX) infections were carried out as previously described (14). Mice were maintained at the Stanford Research Animal Facility, accredited by the AAALAC. NSG mice were housed in the barrier facility at Stanford University (Stanford, CA). For the endogenous SCLC mice, treatment started 5 months after Ad-Cre infection. Imipramine (25 mg/kg), promethazine (25 mg/kg), and bepridil (10 mg/kg) were administered intraperitoneally daily for 30 consecutive days, whereas cisplatin (5 mg/kg) was administered intraperitoneally once weekly for a total of 6 to 8 weeks until tumors became chemoresistant. Chemonaive tumors were generated after weekly injection of saline for a total of 6 weeks. Growth of these endogenous mouse tumors was monitored weekly by live imaging using Xenogen In Vivo Imaging System in the animal imaging facility at Stanford University, and quantification of the luciferase activity was calculated using the Living Image software. For subcutaneous injections, 0.5 × 10^6 mSCLC (Kp1, Kp3, saline-treated chemonaive, and cisplatin-treated chemoresistant), and 2 × 10^6 hSCLC (H187 and H82) cells were injected into the two flanks of each NSG mouse with Matrigel (1:1; BD Biosciences). Treatment with the drugs started once the SCLC tumors reached 100 to 150 mm^3 (around 10–14 days after implantation). Imipramine (25 mg/kg), promethazine (25 mg/kg), and bepridil (10 mg/kg) were administered intraperitoneally daily for 36 to 48 consecutive days. Tumor volume was measured at the times indicated and calculated using the ellipsoid formula (length × width^2). The human primary SCLC sample was obtained from the National Disease Research Interchange program at the NIH. The tumor was digested with collagenase and dispase (Roche). Cells were collected and passed through a Magnetic-Activated Cell Sorting (Miltenyi Biotec) magnetic beads column to deplete CD45^+ blood cells. The remaining cells were injected into the flank of NSG mice with Matrigel (1:1) for expansion. Single-cell suspensions (1 × 10^5 and 3 × 10^5) from this new primary cell line (NJH29) were used for the primary human xenograft studies. Treatment with the drugs started once the xenografts reached 100 to 150 mm^3. Saline, imipramine (25 mg/kg), and promethazine (25 mg/kg) were administered intraperitoneally daily for 24 consecutive days.

Drugs and Inhibitors

Imipramine, promethazine, clomipramine, bepridil, necrostatin-1, azelastine, epinephrine, acetycholine, serotonin, the histamine analog 2-(2-pyridyl) ethylamine, forskolin, and IMX were all purchased from Sigma-Aldrich. Z-VAD-FMK, ritanserin, 4-DAMP, doxazosin mesylate, H89 dihydrochloride, KG7, and GF109203X were all purchased from Tocris Bioscience. The JNK inhibitor SP600125 was purchased from LC Laboratories. Fluo-3AM was purchased from Invitrogen. All these powders were dissolved in the appropriate solvent according to the manufacturer’s instructions.
Cell Lines and Tissue Culture

Mouse SCLC cells (Kp1, Kp2, and Kp3) were grown in RPMI-1640 media containing 10% bovine growth serum (Fisher Scientific; ref. 15) or dialyzed FBS (dFBS; Fisher Scientific), NCH H82, NCI-H69, and NCI-H187 human SCLC cells were obtained from ATCC (ATCC) and cultured in RPMI media containing 10% serum. For the original cellular assays, we used the H82 cells because they grow very rapidly and enough cells can be obtained to conduct most of these assays. However, because they are the least sensitive of all three human SCLC cell lines, we used the other cell lines in the subsequent mechanistic experiments to investigate the mechanism of action of the drugs. The NSCLC cell lines A549 and LKR13 were a generous gift from Dr. A. Sweet-Cordero’s laboratory (Stanford University). The NE-LCLC cell line H1L55 was a generous gift from Dr. J. Minna’s laboratory (UT Southwestern). Human pancreatic adenocarcinoma cell line Panc1, human neuroblastoma cell line HTB1, and LCLC NCI-1915 were obtained from ATCC and cultured in the same conditions described above. The Merkel cell carcinoma cell line was a generous gift from Dr. P. Nghiem’s laboratory (University of Washington). The neuroendocrine mouse pancreatic cancer cells (MIN-6 and β-TC, both insulinosomas) was a generous gift from Dr. S. Kim’s laboratory (Stanford University) and were cultured in Dulbecco’s Modified Eagle Medium containing high glucose (Thermo Scientific) and 15% serum. All mouse SCLC cell lines were generated in the Sage Laboratory and were authenticated by genotyping for the mutant alleles and the expression of neuroendocrine markers. All human cell lines were either repurchased from ATCC or given to us by other laboratories, except for N1H29, which was generated in the Sage Laboratory; no further authentication was carried out on these cell lines.

MTT Assays and Calcium Measurement

For MTT assays (Roche), floating cells were seeded at 8 × 10 4 (2% serum) or 1 × 10 5 (0.5% serum) per well in 96-well plates at day 0, and drugs were added on day 1. MTT reagents were added on day 2 or 3 depending on the experiments. The percentage survival was determined as the ratio of treated cells versus vehicle control. For all the rescue experiments, cells were pretreated with the various drugs or exogenous ligands for 30 minutes before the addition of imipramine or promethazine. Calcium measurements using the indicator Fluo-3AM were carried out per the manufacturer’s instructions (Invitrogen). Briefly, trypsinized cells treated with the drugs in 2% serum at different time points were stained with 2.5 μmol/L Fluo-3AM for 30 minutes in RPMI media at 37°C. Cells were then washed in indicator-free RPMI media and then resuspended in PBS directly before being run through an Aria Analyzer fluorescence-activated cell sorting machine.

Immunoblot Analysis and Immunostaining

For immunoblotting, SCLC cells were homogenized using lys buffer containing 1% NP-40, 50 mmol/L HEPES KOH pH 7.8, 150 mmol/L NaCl, 10 mmol/L EDTA, and a cocktail of protease inhibitors. The antibodies used were phospho-stress-activated protein kinase (SAPK)/JNK Thr183 and Tyr185 (p-JNK), JNK, phospho-c-Jun Ser63 (p-c-Jun), c-Jun, phospho-CREB Ser133 (p-CREB antibody also recognizes p-ATF1), CREB, pan-phospho-PKC βII Ser660 (p-PKC), PKC, and cleaved caspase-3 (all purchased from Cell Signaling technology), Karyopherin β1 (Santa Cruz Biotechnology), and α-tubulin (Sigma). We used 5-μm paraffin sections for H&E staining and immunostaining. Paraffin sections were dewaxed and rehydrated in the Trilogy reagent (Cell Marque). The primary antibodies used were phosphohistone 3 Ser10 (p-H3; Millipore), cleaved caspase-3 (C3C; Cell Signaling Technology), insulin (DAKO), and synaptophysin (SYN; NeuroMics). Alexa Fluor secondary antibodies (Invitrogen) were used for antibody detection. Fluorescent images were captured on the Leica fluorescence microscope. For quantification of the number of CC3- and p-H3-positive cells, tumors of similar size and area ranging between 1,000 and 30,000 pixel units were included. Very small and very large tumors of areas measuring below or above this range were excluded.

Image Analysis and Statistics

Analysis of tumor areas and fluorescent images was conducted using ImageJ software by measuring pixel units. Mice were scored as having significant liver metastases if they had more than three metastases with at least 50 cells each. Statistical significance was assessed by a Student t test with the Prism GraphPad software (two-tailed unpaired and paired t test depending on the experiment). *P < 0.05; **P < 0.01; ***P < 0.005; ns, not significant. Data are represented as the mean ± SEM. For the survival curve analysis and comparison, we used the Mantel-Cox test.

Disclosure of Potential Conflicts of Interest

Patents have been filed and are pending on the use of specific tricyclic antidepressants in neuroendocrine tumors. A.J. Butte, J.T. Dudley, J. Sage, and N.S. Jahchan have filed patents and are inventors on the patent, and could benefit with royalties. The intellectual property has been licensed to NuMedii, a company further developing these drugs. A.J. Butte and J.T. Dudley are founders and shareholders in NuMedii.

Authors’ Contributions

Acknowledgments

The authors thank Dr. Anton Berns for the Tryp23™ mice, Dr. Luis Parada for helpful comments, the Sweet-Cordero Laboratory for suggestions throughout the project, cell lines, and antibodies, Dr. Brian Kobulka and Dr. Pawel Niewiadomski for helpful discussions on GPCR signaling, Andrew Kruse for conducting the binding assay to measure the number of mAChR, Dr. Paul Nghiem for the MCC cell line, Dr. Seung Kim for the pancreatic neuroendocrine cell lines, Alex Augustyn and Dr. John Minna for the neuroendocrine large cell lung cancer cell lines, and members of the Sage Laboratory for their help throughout the course of this study.

Grant Support

This work was supported by the Lucile Packard Foundation for Children’s Health (to J. Sage), the Department of the Army (W81XWH-13-1-0211; to J. Sage), the National Library of Medicine (NLM) Biomedical Informatics Training Grant (T15 LM007033) to Stanford University (to J.T. Dudley), the National Institute of General Medical Sciences (NIGMS) R01 GM079719 (to A.J. Butte), the National Cancer Institute (5R01CA138256-04; to A.J. Butte and J. Sage), the Stanford Dean’s Fellowship, NSRA T32 Academic Research Training in Pulmonary Medicine, and a California Tobacco Related Disease Research Program (TRDRP) postdoctoral fellowship (to N.S. Jahchan), and a Stanford Cancer Institute Developmental Cancer Research award (to J.W. Neal and J.W. Riess).
