13. SUPPLEMENTARY NOTES
The objective of this project consists in demonstrating that attractor models increase the chances of discovering combinations of many drugs with strong synergistic effects in lung cancer. The approach will be tested using a high throughput screening facility to compare the therapeutic effectiveness of random combinations and combinations predicted to be effective by the model.

Title: Attractor signaling models for discovery of combinatorial therapies
Total period of performance: Aug 15 2012- Aug 14 2014

Introduction

Surgery and radiation therapies are difficult to use in the treatment of lung cancer because the diagnosis often occurs when patients already have metastasis. Drug-based therapies are therefore the best option, but intrinsic and acquired drug resistance still makes the 5-year survival rate for this disease less than 15%. Over the years, many specific mechanisms associated with drug resistance in lung cancer have been pinpointed, but we are still far from understanding how to overcome it. Combination drug therapy is commonly used to enhance efficacy and overcome drug resistance in cancer, but at present the choice of drugs and doses is based on empirical clinical experience alone. In this project we have used an interdisciplinary approach based on the mathematics of complex networks to identify drug combinations that could be effective in the therapy of lung cancer.

This report describes the methods used and presents computational and experimental data that we have obtained during the period of operations.
Publications

The results of activities carried out in this project have been published in:

Summary of Key research accomplishments

- We have developed a novel computational approach to simulate the signaling dynamics in gene/transcription factor networks (see publication #1). The model allows for a direct mapping of a gene expression pattern into dynamical attractor states and can test different strategies to disrupt cancer-specific attractor patterns. We have designed algorithms to identify signaling bottlenecks, which are single nodes or strongly connected clusters of nodes that have a large impact on the signaling. Bottlenecks identify ideal targets for the rational design of robust therapeutic interventions.

- The method of publication #1 has been applied to signaling in lung cancer cell lines, specifically on A549, H358 cell lines. The method has identified targets that are predicted to be associated to a selective and robust response to therapy. The full list of targets is given in Table 1 below. Some of the genes identified are consistent with current clinical and cancer biology knowledge: TP53 is frequently mutated in lung cancer; mutations in PBX1 have been detected in non-small-cell lung cancer; MAP3K3 and MAP3K14 are in the MAPK/ERK pathway, which is a target of many novel therapeutic agents; and SRC is a well known oncogene and a candidate target in lung cancer. The method, however, has also discovered new targets, in particular kinases BMPR1B, TTN, LCK and RIPK3, which could be targeted using kinase inhibitors.

- We have developed a novel method of statistical analysis of in-vitro testing of drug combinations (see publication #2). The method integrates information contained in networks representing the signaling of drugs to their targets with experimental data from in vitro screening. The method uses the in vitro cell response to single drugs or drug combinations as a training set to build linear and nonlinear regression models and predicts the response of cells to new drug combinations. Besides predicting the effectiveness of untested drugs, the method identifies targets that are statistically associated to drug sensitivity in a given cell line.

- The method of publication #2 was applied to the A549 lung cancer cell line, and we identified specific kinases as important targets in this type of cancer (TGFBR2, EGFR, PHKG1 and CDK4). A pathway enrichment analysis of the set of kinases identified by the method showed that axon guidance, activation of Rac, and semaphorin interactions pathways are associated to a selective response to therapeutic intervention in this cell line.

- Methods in publications #1 and #2, in conjunction with other computational and experimental techniques previously developed by the two principal investigators, have been used to identify drug combinations effective in selectively killing A549 cell lines versus a fibroblast normal cell line (IMR-90) as a toxicity control. Combinations with the highest selectivity are given in Table 3 below. Overall, combinations containing relatively high doses of a PDK1/Akt1/Flt3 Dual Pathway Inhibitor (A15 in the Table) and a HSP90 inhibitor (AAG), combined with relatively low doses of a PDGFR (I11) and a WNT/BETA CATENIN/PPAR inhibitor (535) were associated with the highest selective response in A549 adenocarcinoma cell lines.
Body: Detailed description of the methods as outlined in the Statement of Work (SOW).

1. TASK1 of SOW: Collection of data for attractor models.

A lung cell interactome was constructed by combining TRANSFAC and PhosphoPOINT data (Subtask 1 of Task 1). The lung network interactome we built has ~9,000 nodes and ~45,000 edges. Gene expression data was obtained from the Gene Expression Omnibus (GEO) database for A549 adenocarcinoma, H358 non-small lung cancer, and IMR90 fetal lung fibroblast normal cell lines. The model requires Boolean gene expression states. We have defined a cutoff for the normalized expression values, and all genes with expression below the cutoff are “off” and all above are “on”. Because the signaling is based on a model with ±1 states, on states are identified by the variable $\xi^a_i = +1$ and off states by $\xi^a_i = -1$, where “a” is either normal (n) or cancer (c).

This procedure provided the configurations corresponding to dynamical attractor states in our method (Subtask 2 of Task 1). Figure 1 shows representative gene expression data and an example of how the cut-off method was implemented.

![Figure 1. Representative gene expression data used in our method](image_url)

Expression levels take continuous values, but must be made Boolean for our model. The expression level cutoff for normal lung cells (IMR90, pictured), for example, use a cutoff (dotted line) of approximately 4. This was chosen because the number of on states is of the same order as the number of off states, but more importantly the number of on and off states is not very sensitive to small changes in the cutoff. The same cutoff is used for both normal and cancer cells. The continuous distribution of expression levels is roughly the same for normal and cancer cells.

We have defined drug inhibitor-kinase links for a library containing about 300 kinase inhibitors using experimental surveys of kinase inhibitor targets. (Subtask 3 of Task 1)

2. TASK 2 of SOW: Development of attractor model based on neural network Hopfield model

After making the attractor states Boolean, we encoded the states $\xi^{n(c)} = (\xi_1^{n(c)}, \xi_2^{n(c)}, ..., \xi_N^{n(c)})$
in a signaling model defined by the coupling matrix

$$J_{ij} = A_{ij}(\xi^R_i \xi_j^N + \xi^C_i \xi_j^C),$$  \hspace{1cm} \text{Eq. (1)}

where $A_{ij}$ is the adjacency matrix of the lung cancer network interactome obtained in Task 1, and $N$ is the total number of nodes. The model calculates the total signal arriving at node $i$ at time $t$ as

$$h_i(t) = \sum_{j=1}^{N} J_{ij} \sigma_j(t),$$

where the $\sigma_i(t)$ is the state of the node $i$ at time $t$. The discrete-time update scheme for the dynamical evolution of the state of the node $i$, $\sigma_i(t)$, is given by

$$\sigma_i(t + \Delta t) = +1 \text{ if } h_i(t) > 0,$$

$$\sigma_i(t + \Delta t) = -1 \text{ if } h_i(t) < 0,$$

and chosen randomly from $\pm 1$ if the field is zero.

Note that we are left with two kinds of genes: similarity nodes, where $\xi^R_i = \xi^C_i$, and differential nodes, where $\xi^N_i = -\xi^C_i$. We have then calculated the Hamming distance between cell attractors and the dynamical state of the network (Subtask 1 of Task 2).

This distance has been used to identify the most sensitive single genes in the network using the following algorithm:

1. Begin with all genes set in the normal/cancer state.
2. Force gene $i=1$ away from the initial state and count the number of genes that flip as a result.
3. Repeat for $i=2...N$, where $N$ is the number of genes in the system.

This algorithm is effective in identifying bottleneck genes. Bottlenecks are genes which, when targeted by inhibitors, drive the cell far away from its initial state. We always try to target bottlenecks with $\xi^C_i = +1$ and $\xi^N_i = -1$ so that cancer cells are driven away from their initial state, while the normal cells are left unaltered.

We used both a one-attractor state ($p=1$) and a two-attractor state ($p=2$) signaling model. In the one attractor ($p=1$) model the $J_{ij}$ only contains one term in Eq. (1). Both models behave like a simple Ising magnet, except that the interactions are not symmetric: the expression of gene $i$ may affect the expression of gene $j$, but $j$ does not necessarily affect $i$. This asymmetry makes both the $p=1$ and $p=2$ systems more vulnerable to external control. The $p=2$ system has one property that the $p=1$ does not have, however: all edges between similarity and differential genes are effectively removed, while all edges connecting similarity genes to each other or differential genes to each other remain. The network fully separates into two independent networks, the similarity network and the differential network. When looking for nodes to target in the $p=2$ case, then, all similarity nodes can be safely ignored and the problem space is significantly reduced. Aside from the edge deletion, however, $p=1$ and $p=2$ behave very similarly. An example of genes identified by this method and their impact $I$ in terms of flipped genes in the interactome, is shown in Table 1.
Part of the software was implemented on the high performance computer cluster facility at MSU (Subtask 2 of Task 2). The algorithm however was sufficiently fast that parallelization of the code was not necessary.

Table 1. Representative genes to be targeted for a selective killing of A549 (left) and H358 (right) cell line versus a control IMR90 cell line. The impact $I$ of each gene for the $p=1$ and $p=2$ models were calculated and ranked. The constrained case (CON in the table) refers to target that are kinases and are expressed in the cancer case. The calculation is based on the selective response of $I = IMR-90$ (normal), $A = A549$ (cancer), and $H = NCI-H358$ (cancer).

3. TASK 3 of SOW: First set of experiments at the high-throughput screening facility

We have carried out a first high-throughput screening of single drug and drug pair experiments (Subtask 1 of Task 3). The original SOW only included single drug response, but we realized that a screening with pairs would give better selectivity. 244 kinase inhibitors (KIs) of the EMD drug library were screened at 1000nM individually and the treatment lasted for 72 hours. To quantify a selective response of a cancer cell line with respect to a control normal cell line, we define the selectivity $S$ of a single drug or drug combination as

$$S = \frac{v_N}{v_C}$$

where $v_N$ indicates the viability of normal cells (IMR90) after treatment, and $v_C$ the viability of cancer cells (A549) after treatment. From the screening of the 244 KIs, the top hit was PDK1/Akt1/Flt3 Dual Pathway Inhibitor (CAS # 331253-86-2) as ranked by selectivity. For the secondary screen (pair combination of drugs), we used the PDK1/Akt1/Flt3 Dual Pathway Inhibitor as the starting point and combined this compound with the other KIs as a drug pair combination. The dose of PDK1/Akt1/Flt3 Dual Pathway Inhibitor was studied to ensure proper dosing range and minimize toxicity. We used 125nM, which maintains the normal cell line IMR-90's viability >90%. For the other 243 KIs we used the standard dose of 1000nM. Several pairs in the secondary screen showed very high selectivity. The top hit from the secondary screen of the library was Alsterpaullone 2-cyanoethyl (CAS # 852529-97-0) with a selectivity of $S= 6.14$ for the pair (see Figure 2).
Figure 2: **Representative data from TASK 3 in SOW.** Experimental results of the top ten most selective drugs (1000nM) when paired with PDK1/Akt1/Flt3 Dual Pathway Inhibitor at 125nM. Selectivity is the IMR-90 to A549 viability ratio. The 3 digit codes identify the compounds: A12: Alsterpaullone, 2-Cyanoethyl (CAS 852529-97-0); D17: Cdk2/9 Inhibitor (CAS 507487-89-0); K08: K-252a, Nocardiopsis sp. (CAS 97161-97-2); O21: Staurosporine, Streptomyces sp. (CAS 62996-74-1); P15: WHI-P180, Hydrochloride (CAS 211555-08-7); E13: Go 6976 (CAS 136194-77-9); C09: Compound 56 (CAS 171745-13-4); A10: Alsterpaullone (CAS 237430-03-4); O03: AG 1478, Selective inhibitor of epidermal growth factor receptor (EGFR) protein (CAS 175178-82-2); N05: Reversine (CAS 656820-32-5).

We have also carried out measurements on **random combinations** of drugs (Subtask 2 of Task 3) including compounds from the EMD library and other drugs. A representative data set of random combinations is given in Table 2.

**Table 2.** Representative data with measurements of selectivity on A549 cells versus IMR90. Drugs were combined at different doses ranked from 0 to 4. The drug combinations obtained in this table were obtained randomly.
4. TASK 4 of SOW: Running and analysis of simulations

We have run simulations to predict the therapeutic effectiveness of combinations of kinase inhibitors according to the attractor model (Subtask 1 of Task 4). We have tested our model against the experimental results discussed in the previous section. We used the available kinase inhibition profiling for a drug library to determine which kinase are shut off by each drug. We applied the drugs to both the normal and cancer cells for both $p=1$ and $p=2$, and compared the resulting viabilities from the experiment, $v_{exp}$, to the model,

$$v_{model} \sim e^{-m}$$

where “$m$” is the magnetization of the system along the attractor state (see Figure 3).

Note that the results for $p=1$ and $p=2$ are roughly the same, and only the $p=1$ result is shown. The black circles indicate the viability of the normal cells for a given drug combination, which is the drug A15 (a PDK1/AKT1/FLT3 Inhibitor) and the drug code next to the black circles, and the connected red x’s are the cancer viabilities for the same drug combination. This shows only some of the 140 drugs tested. The most remarkable result is that without any kind of fitting, ~95% of the blue lines (including those not pictured) have a positive slope, meaning that if the experiment showed that the normal/cancer cells fared better than the cancer/normal cells, our model showed that as well. Currently we cannot reproduce the rank of the effectiveness of the drug combinations, but we can quite accurately predict whether a combination will have a selectivity greater than or less than 1.

![Figure 3. Computational versus experimental viability for IMR90 and A549. All drug codes shown are combined with A15 (a PDK1/AKT1/FLT3 Inhibitor). The experimental results are compared with the $p=1$ model predictions ($p=2$ is similar). A positive slope means that there is positive correlation between the experimental and model results: the experiment showed that normal cells treated with (A15+O16), for example, fared better than cancer cells treated with the same drugs, which our model predicts as well. Note that while only 11 drug combinations are shown, 140 were tested, a promising 95% of which had a positive slope.](image-url)
We have examined combinations that are more effective using a learning machine method known as elastic net regression (Subtask 2 of Task 4). The method uses the in vitro lung cancer A549 cell line response of single drugs and drug pair combinations as a training set to build a regression model. Besides predicting the effectiveness of untested drugs, the method identifies sets of kinases that are statistically associated to drug sensitivity in lung cancer. More specifically, we built a regression model that predicts the response of a cell line to a drug or drug combination \( i \). The response we predict is the normal and cancer cell viability, from which the selectivity can be derived. For this purpose, we define a regression problem in which we use the residual activity of the kinase \( k \) under the effect of drug \( i \), which we indicate as \( A_{k,i} \), as predictors of the viability. The response can be written as

\[
v_i = \beta_0 + \beta_1 A_{1,i} + \cdots + \beta_p A_{p,i}.
\]

Equation (2) can then be used to predict the viability of a new drug that has not been tested, but of which the profiling information is available. The coefficients \( \beta_k \) provide a measure of the sensitivity of a given cell line due to alterations in the activity of kinase \( k \). The method was applied to the A549 lung cancer cell line, and we identified specific kinases known to have an important role in this type of cancer (TGFBR2, EGFR, PHKG1 and CDK4). A pathway enrichment analysis of the set of kinases identified by the method showed that axon guidance, activation of Rac, and semaphorin interactions pathways are associated to a selective response to therapeutic intervention in this cell line.

The formulation of the problem in terms of bottlenecks, as defined above has allowed us to derive some general properties on the controllability of a cellular network based on the mathematical properties of network topology. In particular, in the first publication, we have demonstrated a theorem with bounds on the minimum number of nodes that guarantee control of bottlenecks consisting of strongly connected components (Subtask3 of Task 4). This information could be important in deciding the number of proteins than needs to be targeted for an efficient therapy. We have also compared the controllability of the lung cancer network with the controllability of an algorithmically-assembled specific B cell gene regulatory network reconstructed from gene expression data (Subtask3 of Task 4). In contrast to the lung cancer network, which is generic but experimentally validated, the B cell network has a much higher connectivity, and is harder to control.

5. TASK 5 of SOW: Second set of experiments and test of hypothesis

We have carried out measurement of drug response of cells under combinations involving up to 10 drugs (Subtask 1). We have included drugs that were identified using the KIEN method above and we used a dose optimization method. Cell survival was assessed by luciferase-based assay, ATPlite™ (PerkinElmer, CA, USA), which determines viable cell numbers by measuring the presence of ATP in all metabolically active cells. For the measurement of cell viability, A549 and IMR-90 cells were plated in 384-well plates. Subsequently, the cells were treated with the drugs and 72 hours later, the ATPlite assay was performed according to the manufacturer’s protocol, and luminescence was read with an Analyst HT instrument. Each combination was measured in triplicates.

Table 3 shows representative data with results of the measurements. Some of the combinations reduce the viability of cancer cells almost to zero, still significantly preserving the viability of IMR90.
Table 3: Representative data with measurements of the highest selectivity on A549 cells versus IMR90. Drugs were combined at different doses ranked from 0 to 4. Columns labeled IMR90 and A549 indicate the viability of these cell lines treated with the combination, while selectivity is the ratio of the normal versus cancer viability.

Conclusions

In this early concepts project, we have applied mathematical tools of networks theory and nonlinear dynamics to the problem of identifying drug combinations that could be more effecting in the treatment of lung cancer. In particular, we have developed software able to calculate the effect of drug combinations on the signaling of A549 adenocarcinoma, H358 non-small lung cancer, and IMR90 fibroblast normal cell lines (Milestone 1). Two articles on the computational and theoretical results on controllability of cancer networks and identification of target genes in lung cancer have been published (Milestone 2). Experimentally, we found drugs combinations with up to 10 drugs that are very effective in killing A549 cells versus the control IMR90 cells in an in-vitro setting (Milestone 3).
Control of Asymmetric Hopfield Networks and Application to Cancer Attractors

Anthony Szedlak1*, Giovanni Paternostro2,3, Carlo Piermarocchi1,3

Abstract
The asymmetric Hopfield model is used to simulate signaling dynamics in gene regulatory networks. The model allows for a direct mapping of a gene expression pattern into attractor states. We analyze different control strategies aimed at disrupting attractor patterns using selective local fields representing therapeutic interventions. The control strategies are based on the identification of signaling bottlenecks, which are single nodes or strongly connected clusters of nodes that have a large impact on the signaling. We provide a theorem with bounds on the minimum number of nodes that guarantee control of bottlenecks consisting of strongly connected components. The control strategies are applied to the identification of sets of proteins that, when inhibited, selectively disrupt the signaling of cancer cells while preserving the signaling of normal cells. We use an experimentally validated non-specific and an algorithmically-assembled specific B cell regulatory network reconstructed from gene expression data to model cancer signaling in lung and B cells, respectively. Among the potential targets identified here are TP53, FOXM1, BCL6 and SRC. This model could help in the rational design of novel robust therapeutic interventions based on our increasing knowledge of complex gene signaling networks.

Introduction
The vision behind systems biology is that complex interactions and emergent properties determine the behavior of biological systems. Many theoretical tools developed in the framework of spin glass models are well suited to describe emergent properties, and their application to large biological networks represents an approach that goes beyond pinpointing the behavior of a few genes or metabolites in a pathway. The Hopfield model [1] is a spin glass model that was introduced to describe neural networks, and that is solvable using mean field theory [2]. The asymmetric case, in which the interaction between the spins can be seen as directed, can also be exactly solved in some limits [3]. The model belongs to the class of attractor neural networks, in which the spins evolve towards stored attractor patterns, and it has been used to model biological processes of high current interest, such as the reprogramming of pluripotent stem cells [4]. Moreover, it has been suggested that a biological system in a chronic or therapy-resistant disease state can be seen as a network that has become trapped in a pathological Hopfield attractor [5]. A similar class of models is represented by Random Boolean Networks [6], which were proposed by Kauffman to describe gene regulation and expression states in cells [7]. Differences and similarities between the Kauffman-type and Hopfield-type random networks have been studied for many years [8–11].

In this paper, we consider an asymmetric Hopfield model built from real (even if incomplete [12,13]) cellular networks, and we map the spin attractor states to gene expression data from normal and cancer cells. We will focus on the question of controlling a network’s final state (after a transient period) using external local fields representing therapeutic interventions. To a major extent, the final determinant of cellular phenotype is the expression and activity pattern of all proteins within the cell, which is related to levels of mRNA transcripts. Microarrays measure genome-wide levels of mRNA expression that therefore can be considered a rough snapshot of the state of the cell. This state is relatively stable, reproducible, unique to cell types, and can differentiate cancer cells from normal cells, as well as differentiate between different types of cancer [14,15]. In fact, there is evidence that attractors exist in gene expression states, and that these attractors can be reached by different trajectories rather than only by a single transcriptional program [16]. While the dynamical attractors paradigm has been originally proposed in the context of cellular development, the similarity between cellular ontogenesis, i.e. the development of different cell types, and oncogenesis, i.e. the process under which normal cells are transformed into cancer cells, has been recently emphasized [17]. The main hypothesis of...
this paper is that cancer robustness is rooted in the dynamical robustness of signaling in an underlying cellular network. If the cancerous state of rapid, uncontrolled growth is an attractor state of the system [18], a goal of modeling therapeutic control could be to design complex therapeutic interventions based on drug combinations [19] that push the cell out of the cancer attractor basin [20].

Many authors have discussed the control of biological signaling networks using complex external perturbations. Calzolari and coworkers considered the effect of complex external signals on apoptosis signaling [21]. Agoston and coworkers [22] suggested that perturbing a complex biological network with partial inhibition of many targets could be more effective than the complete inhibition of a single target, and explicitly discussed the implications for multi-drug therapies [23]. In the traditional approach to control theory [24], the control of a dynamical system consists in finding the specific input temporal sequence required to drive the system to a desired output. This approach has been discussed in the context of Kauffman Boolean networks [25] and their attractor states [26]. Several studies have focused on the intrinsic global properties of control and hierarchical organization in biological networks [27,28]. A recent study has focused on the minimum number of nodes that needs to be addressed to achieve the complete control of a network [29]. This study used a linear control framework, a matching algorithm [30] to find the complete control of a network [29]. This study used a linear approach to control theory [24], the control of a dynamical system consists in finding the specific input temporal sequence required to drive the system to a desired output. This approach has been discussed in the context of Kauffman Boolean networks [25] and their attractor states [26]. Several studies have focused on the intrinsic global properties of control and hierarchical organization in biological networks [27,28]. A recent study has focused on the minimum number of nodes that needs to be addressed to achieve the complete control of a network [29]. This study used a linear control framework, a matching algorithm [30] to find the complete control of a network [29].

The paper is structured as follows. In Mathematical Model we present the methods from Control Strategies to lung and B cell cancers. We use two different networks for this application, two attractors are needed. Define these states as $\mathcal{F}(\sigma)$, the normal state and $\mathcal{C}(\sigma)$, the cancer state. The discrete-time update scheme is defined as

$$
\sigma(t+\Delta t) = \begin{cases} 
+1 & \text{with prob. } (1 + \exp(-h_i(t)/T))^{-1} \\
-1 & \text{with prob. } (1 + \exp(+h_i(t)/T))^{-1} 
\end{cases}
$$

where $T \geq 0$ is an effective temperature. For the remainder of the paper, we consider the case of $T = 0$ so that $\sigma_i = \sign(h_i)$. The spin of node $i$ at time $t$ is $\sigma_i(t) = \pm 1$, and indicates an expressed (+1) or not expressed (−1) gene. We encode an arbitrary attractor state $\xi$ as $\xi = (\xi_1, \xi_2, ..., \xi_N)$ with $\xi_i = \pm 1$ by defining the coupling matrix [1]

$$
J_{ij} = A_{ij} \xi_i \xi_j.
$$

The total field at node $i$ is then $h_i = h_i^{\text{ext}} + \sum_j J_{ij} \sigma_j$, where $h_i^{\text{ext}}$ is the external field applied to node $i$, which will be discussed below. The discrete-time update scheme is defined as

$$
\sigma_i(t+\Delta t) = \begin{cases} 
+1 & \text{with prob. } (1 + \exp(-h_i(t)/T))^{-1} \\
-1 & \text{with prob. } (1 + \exp(+h_i(t)/T))^{-1} 
\end{cases}
$$

where $T \geq 0$ is an effective temperature. For the remainder of the paper, we consider the case of $T = 0$ so that $\sigma_i = \sign(h_i)$, and the spin is chosen randomly from $\pm 1$ if $h_i = 0$. For convenience, we take $t \in \mathbb{Z}$ and $\Delta t = 1$. Nodes can be updated synchronously, and synchronous updating can lead to limit cycles [9]. Nodes can also be updated separately and in random order (asynchronous updating), which does not result in limit cycles. All results presented in this paper use the synchronous update scheme.

Source nodes (nodes with zero indegree) are fixed to their initial states by a small external field so that $\sigma_i(0) = \sigma_i(Q)$ for all $\forall i \in Q$, where $Q$ is the set of source nodes. However, the source nodes flip if directly targeted by an external field. Biologically, genes at the “top” of a network are assumed to be controlled by elements outside of the network.

In application, two attractors are needed. Define these states as $\mathcal{F}$ and $\mathcal{C}$, the normal state and cancer state, respectively. The magnetization along attractor state $a$ is

$$
m^a(t) = \frac{1}{N} \sum_{i=1}^{N} \sigma_i(t) \xi_i^a.
$$

Note that if $m_0(t) = \pm 1$, $\vec{a}(t) = \pm \vec{\xi}$. We also define the steady state magnetization along state $a$ as

$$
m^a = \lim_{t \to \infty} m^a(t).
$$
There are two ways to model normal and cancer cells. One way is to simply define a different coupling matrix for each attractor state $a$,

$$ J_{ij}^a = A_{ij} z_i^a z_j^a. $$

Alternatively, both attractor states can be encoded in the same coupling matrix,

$$ J_{ij} = A_{ij} (z_i z_j + z_i^c z_j^c). $$

Systems using Eqs. 6 and 7 will be referred to as the one attractor state ($p=1$) and two attractor state ($p=2$) systems, respectively. Eqs. 6 and 7 are particular cases of the general Hopfield form [1]

$$ J_{ij} = A_{ij} \sum_{k=1}^p a_k z_i^k z_j^k, $$

where $p$ is the number of attractor states, often taken to be large. An interesting property emerges when $p=2$, however. Consider a simple network composed of two nodes, with only one edge $1 \rightarrow 2$ with attractor states $z_1^a$ and $z_1^c$, and $T=0$. The only nonzero entry of the matrix $J_{ij}$ is

$$ J_{12} = a_1 z_1^a + z_2^c z_1^c. $$

Note that if $z_1^a = \pm z_1^c$, $J_{21} = 2a_1 z_1^a z_2^c$. In either case, by Eq. 3 we have

$$ \sigma_2(t+1) = \begin{cases} +z_2^c & \text{if } \sigma_2(t) = +z_1^c \\ -z_2^c & \text{if } \sigma_2(t) = -z_1^c \end{cases} $$

that is, the spin of node 2 at a given time step will be driven to match the attractor state of node 1 at the previous time step. However, if $z_1^a = \pm z_1^c$ and $z_2^c = z_2^c$, $J_{21} = 0$. This gives

$$ \sigma_2(t) = \begin{cases} +1 & \text{with probability } 1/2 \\ -1 & \text{with probability } 1/2 \end{cases} $$

In this case, node 2 receives no input from node 1. Nodes 1 and 2 have become effectively disconnected.

This motivates new designations for node types. We define similarity nodes as nodes with $z_i^a = z_i^c$, and differential nodes as nodes with $z_i^a = -z_i^c$. We also define the set of similarity nodes $S = \{i : z_i^a = z_i^c\}$ and the set of differential nodes $D = \{i : z_i^a = -z_i^c\}$. Connections between two similarity nodes or two differential nodes remain in the network, whereas connections that link nodes of different types transmit no signals. The effective deletion of edges between nodes means that the original network fully separates into two subnetworks: one composed entirely of similarity nodes (the similarity network) and another composed entirely of differential nodes (the differential network), each of which can be composed of one or more separate weakly connected components (see Fig. 1). With this separation, new source nodes (effective sources) can be exposed in both the similarity and differential networks. For the remainder of this article, $Q$ is the set of both source and effective source nodes in a given network.

**Control Strategies**

The strategies presented below focus on selecting the best single nodes or small clusters of nodes to control, ranked by how much they individually change $m_\infty$. In application, however, controlling many nodes is necessary to achieve a sufficiently changed $m_\infty$.

doi:10.1371/journal.pone.0105842.t001

$$ m_\infty = \lim_{t \rightarrow \infty} \frac{1}{t} \sum_{t=1}^T m(t). $$

There are two ways to model normal and cancer cells. One way is to simply define a different coupling matrix for each attractor state $a$,

$$ J_{ij}^a = A_{ij} z_i^a z_j^a. $$
The effects of controlling a set of nodes can be more than the sum of the effects of controlling individual nodes, and predicting the truly optimal set of nodes to target is computationally difficult. Here, we discuss heuristic strategies for controlling large networks where the combinatorial approach is impractical.

For both \( p = 1 \) and \( p = 2 \), simulating a cancer cell means that \( \sigma(0) = \hat{\xi}_{\hat{\nu}} \), and likewise for normal cells. Although the normal and cancer states are mathematically interchangeable, biologically we seek to decrease \( m^* \) as much as possible while leaving \( m^0 \) close to 1. By “network control” we thus mean driving the system away from its initial state of \( \sigma(0) = \hat{\xi}_{\hat{\nu}} \) with \( \hat{\nu}^* \). Controlling individual nodes is achieved by applying a strong field (stronger than the magnitude of the field due to the node’s upstream neighbors) to a set of targeted nodes \( T \) so that

\[
\hat{\nu}_T^{\text{ext}} = \begin{cases} 
\lim_{\alpha \to \infty} -u_{\hat{\nu}}^{\text{ext}} & \text{if } T \\
0 & \text{else.}
\end{cases}
\] (12)

This ensures that the drug field can always overcome the field from neighboring nodes.

In application, similarity nodes are never deliberately directed targeted, since changing their state would adversely affect both normal and cancer cells. Roughly 70% of the nodes in the networks surveyed are similarity nodes, so the search space is reduced. For \( p = 2 \), the effective edge deletion means that only the differential network in cancer cells needs to be simulated to determine the effectiveness of \( \hat{\nu}_{\hat{\nu}}^{\text{ext}} \). For \( p = 1 \), however, there may be some similarity nodes that receive signals from upstream differential nodes. In this case, the full effect of \( \hat{\nu}_{\hat{\nu}}^{\text{ext}} \) can be determined only by simulating all differential nodes as well as any similarity nodes downstream of differential nodes. All following discussion assumes that all nodes examined are differential, and therefore targetable, for both \( p = 1 \) and \( p = 2 \). The existence of similarity nodes for \( p = 1 \) only limits the set of targetable nodes.

**Directed acyclic networks.** Full control of a directed acyclic network is achieved by forcing \( \sigma_i = -\hat{\xi}_{\hat{\nu}} \) for all \( i \in Q \). This guarantees \( m^* = -1 \). Suppose that nodes \( i \in Q \) in an acyclic network have always been fixed away from the cancer state, that is, \( \sigma_i(t \to -\infty) = -\hat{\xi}_{\hat{\nu}} \). For any node \( i \) to have \( \sigma_i(t) = \hat{\xi}_{\hat{\nu}} \), it is sufficient to have either \( i \in Q \) or \( \sigma_i(t-1) = \hat{\xi}_{\hat{\nu}} \) for all \( j \to i, i \notin Q \).

Because there are no cycles present, all upstream paths of sufficient length terminate at a source. Because the spin of all nodes \( i \in Q \) point away from the cancer attractor state, all nodes downstream must also point away from the cancer attractor state. Thus, for acyclic networks, forcing \( \sigma_i = -\hat{\xi}_{\hat{\nu}} \) guarantees \( m^* = -1 \). The complications that arise from cycles are discussed in the next subsubsection. However, controlling nodes in \( Q \) may not be the most efficient way to push the system away from the cancer basin of attraction and, depending on the control limitations, it may not be possible. If minimizing the number of controllers is required, searching for the most important bottlenecks is a better strategy.

Consider a directed network \( G \) and an initially identical copy, \( G' = G \). If removing node \( i \) (and all connections to and from \( i \)) from \( G' \) decreases the indegree of at least one node \( j \in V(G') \), \( j \neq i \), to less than half of its indegree in network \( G \), \( \{i\} \) is a size 1 bottleneck. The bottleneck control set of bottleneck \( \{i\} \), \( L(i) \), is defined algorithmically as follows: (1) Begin a set \( L(i) \) with the current bottleneck \( i \); (2) Remove bottleneck \( \{i\} \) from network \( G' \); (3) Append \( L(i) \) with all nodes \( j \) with current indegree that is less than half of that from the original network \( G \); (4) Remove all nodes \( j \) from the network \( G' \). If additional nodes in \( G' \) have their indegree reduced to below half of their indegree in \( G \), go to step 3. Otherwise, stop. The impact of the bottleneck \( i \), \( I(i) \), is defined as

\[
I(i) = |L(i)|,
\] (13)

where \( |X| \) is the cardinality of the set \( X \). The impact of a bottleneck is the minimum number of nodes that are guaranteed to switch away from the cancer state when the bottleneck is forced away from the cancer state.

**Figure 1. Network segregation for two attractor states (\( p = 2 \)).** Every edge that connects a similarity node to a differential node or a differential node to a similarity node transmits no signal. This means that the signaling in the right network shown above is identical to that of the left network. Because the goal is to leave normal cells unaltered while damaging cancer cells as much as possible, all similarity nodes can be safely ignored, and searches and simulations only need to be done on the differential subnetwork.

doi:10.1371/journal.pone.0105842.g001
The impact is used to rank the size 1 bottlenecks by importance, with the most important as those with the largest impact. In application, when searching for nodes to control, any size 1 bottleneck \( \{i\} \) that appears in the bottleneck control set of a different size 1 bottleneck \( \{j\} \) can be ignored, since fixing \( j \) to the normal state fixes \( i \) to the normal state as well. Note that the definition given above in terms of \( G \) and \( G' \) avoids miscounting in the impact of a bottleneck.

The network in Fig. 2, for example, has three sources (nodes 1, 2 and 3), but one important bottleneck (node 6). If full damage, i.e. \( m_{\gamma} = -1 \), is required, then control of all source nodes is necessary. If minimizing the number of directly targeted nodes is important and \( m_{\gamma} > -1 \) can be tolerated, then control of the bottleneck node 6 is a better choice.

**Directed cycle-rich networks.** Not all networks can be fully controlled at \( T = 0 \) by controlling the source nodes, however. If there is a cycle present, paths of infinite length exist and the final state of the system may depend on the initial state, causing parts of the network to be hysteretic. Controlling only sources in a general directed network thus does not guarantee \( m_{\gamma} = -1 \) unless the system begins with \( n_{j} = -\gamma_{j} \).

Define a cycle cluster, \( C \), as a strongly connected subnetwork of a network \( G \). The network in Fig. 3, for example, has one cycle cluster with nodes \( V(C) = \{4,5,6,7\} \). If the network begins with \( \delta(0) = \zeta \), forcing both source nodes away from the cancer state does nothing to the nodes downstream of node 3 (see Fig. 4). This is because the indegree \( \text{deg}^{-}(4) = 4 \), and a majority of the nodes connecting to node 4 are in the cancer attractor state. At \( T = 0 \), cycle clusters with high connectivity tend to block incoming signals from outside of the cluster, resulting in an insurmountable activation barrier.

The most effective single node to control in this network is any one of nodes 4, 6 or 7. Forcing any of these from the cancer attractor state will eventually cause the entire cycle cluster to flip away from the cancer state, and all downstream nodes will flip as well, as shown in Fig. 4. The cycle cluster here acts as a sort of large, hysteretic bottleneck. We now generalize the concept of bottlenecks.

Define a size \( k \) bottleneck in a network \( G \) to be a cycle cluster \( B \) with \( |V(B)| = k \) which, when removed from \( G \), reduces the indegree of at least one node \( j \in V(G) \), \( j \notin V(B) \) to less than half of its original indegree. Other than now using the set of nodes \( V(B) \) rather than a single node set, the above algorithm for finding the bottleneck control set remains unchanged. In Fig. 3, for instance, \( V(B) = \{4,5,6,7\}, \ k = 4, \ L(B) = \{4,5,6,7,8,9,10\}, \text{ and } I(B) = 7 \). With this more general definition, we note that controlling any size \( k \) bottleneck \( B \) guarantees control of all size 1 bottlenecks \( B' \) in the control set of \( B \) for all \( k \geq 1 \).

For any bottleneck \( B \) of size \( k \geq 1 \) in a network \( G \), define the set of critical nodes, \( Z(B,G) \), as the set of nodes \( Z(B,G) \subseteq V(B) \) of minimum cardinality that, when controlled, guarantees full control of all nodes \( i \in V(B) \) after a transient period. Also define the critical number of nodes as \( n_{\text{crit}}(B,G) = |Z(B,G)| \). Thus, for the network in Fig. 3, \( Z(B,G) = \{4\}, \{6\}, \text{ or } \{7\} \), and \( n_{\text{crit}}(B,G) = 1 \).

In general, however, more than one node in a cycle cluster may need to be targeted to control the entire cycle cluster. Fig. 5 shows a cycle cluster (composed of nodes 2–10) that cannot be controlled by targeting any single node. The precise value of \( n_{\text{crit}} \) for a given cycle cluster \( C \) depends on its topology as well as the edges connecting nodes from outside of \( C \) to the nodes inside of \( C \), and finding \( Z(C,G) \) can be difficult. We present a theorem that puts bounds on \( n_{\text{crit}} \) to help determine whether a search for \( Z(C,G) \) is practical.
forcing than cancer direction, and no more flips will occur. Thus, we must have that \( h_i = -a i j^v \) for \( \alpha \geq 0 \), meaning that at least half of the nodes upstream of \( i \) must point away from the cancer state. The node \( i \) requiring the smallest number of upstream nodes to be in the normal state is the node that satisfies \( \text{deg}^- (i) = \mu \). Controlling less than \( \mu/2 \) nodes will leave all uncontrolled nodes with a field in the cancer direction, and no more flips will occur. Thus,

\[
n_{\text{crit}} \geq \left\lceil \frac{\mu}{2} \right\rceil.
\]

For the upper limit of Eq. 18, consider a complete clique on \( N \) nodes, \( C = K_N \) (that is, \( A_{ij} = 1 \) for all \( i \in V(K_N) \), including self loops) in a network \( G \). First, let there be no connections to any nodes in \( C \) from outside of \( C \) so that \( R(C,G) = \{ \emptyset \} \). For odd \( N \), forcing \( (N+1)/2 \) nodes away from the cancer state will result in the field

\[
\sum_j J_{ij} \sigma_j = \left( \frac{N-1}{2} - \frac{N+1}{2} \right) \bar{\zeta}_i^v = - \bar{\zeta}_i^v
\]

for all nodes \( i \). After one time step, all nodes will flip away from the cancer state. For even \( N \), forcing \( N/2 \) nodes away from the cancer state will result in the field

\[
\sum_j J_{ij} \sigma_j = \left( \frac{N}{2} - \frac{N}{2} \right) \bar{\zeta}_i^v = 0
\]

for all nodes \( i \). At the next time step, the unfixed nodes will pick randomly between the normal and cancer state. If at least one of these nodes makes the transition away from the cancer state, the field at all other nodes will point away from the cancer direction. The system will then require one more time step to completely settle to \( \sigma_i = -\bar{\zeta}_i^v \). Thus, we have that for \( C = K_N \) in a network \( G \) with \( R(C,G) = \{ \emptyset \} \),

\[
n_{\text{crit}}(K_N, G) = \left\lceil \frac{N}{2} \right\rceil.
\]

\( K_N \) with \( \sigma(0) = \bar{\zeta}_i^v \) gives the largest activation barrier for any cycle cluster on \( N \) nodes with \( R(C,G) = \{ \emptyset \} \) to switch away from the cancer attractor state. A general cycle cluster \( C \) with any topology on \( N \) nodes with \( R(C,G) = \{ \emptyset \} \) in a network \( G \) will have \n
\[
\text{deg}^- (i) \leq N \text{ for all nodes } i \text{, and so we have the upper bound}
\]

\[
n_{\text{crit}}(C,G) \leq \left\lceil \frac{N}{2} \right\rceil,
\]

thus proving Eq. 18 for the special case of \( R(C,G) = \{ \emptyset \} \).

Now consider a cycle cluster \( C \) on \( N \) nodes in a network \( G \) with \( |R(C,G)| \geq 0 \). Suppose all nodes in \( Z_{\text{red}}(C,G) \) are fixed away from the cancer state. By Eq. 24, \( |Z_{\text{red}}(C,G)| \leq \lceil N/2 \rceil \). For any node \( i \in (R(C,G) \cap Z_{\text{red}}(C,G)) \), \( \sigma_{i} (t \to \infty) = -\bar{\zeta}_i^v \) is guaranteed because it has already been directly controlled. Any node \( i \in (R(C,G) \cap Z_{\text{red}}(C,G)) \) has some incoming connections from nodes \( j \in V(C) \), and these connections could increase the activation barrier enough such that fixing \( Z_{\text{red}}(C,G) \) is not enough to guarantee \( \sigma_{i} (t \to \infty) = -\bar{\zeta}_i^v \). To ensure that any node \( i \in V(C) \) points away from the cancer state, it is sufficient to fix all nodes \( i \in (R(C,G) \cap Z_{\text{red}}(C,G)) \) as well as \( Z_{\text{red}}(C,G) \) away from the cancer state. This increases \( n_{\text{crit}} \) by at most \( |R(C,G) \cap Z_{\text{red}}(C,G)| \), leaving

\[
n_{\text{crit}}(C,G) \leq \left\lceil \frac{N}{2} \right\rceil + |R(C,G) \cap Z_{\text{red}}(C,G)|.
\]

\( n_{\text{crit}} \) can never exceed \( N \), however, because directly controlling every node results in controlling \( C \). We can thus say that

\[
n_{\text{crit}}(C,G) \leq \min \left( \left\lceil \frac{N}{2} \right\rceil + |R(C,G) \cap Z_{\text{red}}(C,G)|, N \right).
\]

Finally, combining the upper limit in Eq. 26 with the lower limit from Eq. 20 gives Eq. 18.

There can be more than one \( Z_{\text{red}} \) for a given cycle cluster. Note that the tightest constraints on \( n_{\text{crit}} \) in Eq. 18 come from using the \( Z_{\text{red}} \) with the largest overlap with \( R \). If finding \( Z_{\text{red}} \) is too difficult, an overestimate for the upper limit of \( n_{\text{crit}} \) can be made by assuming that \( R \setminus Z_{\text{red}} = \{ \emptyset \} \) so that

\[
\left\lceil \frac{\mu}{2} \right\rceil \leq n_{\text{crit}}(C,G) \leq \min \left( \left\lceil \frac{N}{2} \right\rceil + |R(C,G)|, N \right).
\]

The cycle cluster in Fig. 5 has \( N = 9, R = \{2,9\}, \mu = 1 \), and one of the reduced sets of critical nodes is \( Z_{\text{red}} = \{9,10\} \), so \( 1 \leq n_{\text{crit}} \leq 6 \). It can be shown through an exhaustive search that for this network \( n_{\text{crit}} = 2 \), and the set of critical nodes is \( Z = \{9,10\} \) (see Fig. 6). Here, \( Z = Z_{\text{red}} \), although this is not always the case. Because the cycle cluster has 9 nodes and \( 1 \leq n_{\text{crit}} \leq 6 \), at most \( \sum_{n=1}^{6} \binom{9}{n} = 465 \) simulations are needed to find at least one solution for \( Z(C,G) \). However, the maximum number of

---

**Figure 3.** A network in which nodes 4, 5, 6 and 7 compose a single cycle cluster. The high connectivity of node 4 prevents any changes made to the spin of nodes 1–3 from propagating downstream. The only way to indirectly control nodes 4–10 is to target nodes inside of the cycle cluster. Targeting node 4, 6 or 7 will cause the entire cycle cluster to flip away from its initial state, guaranteeing control of nodes 4–10 (see Fig. 4). doi:10.1371/journal.pone.0105842.g003

Any externally influenced nodes cause \( n_{\text{crit}} \) to either increase or remain the same. For any node \( i \) to be able to flip away from the cancer state (although not necessarily remain there), we must have that \( {h_i} = -{a_i j^v} \) for \( \alpha \geq 0 \), meaning that at least half of the nodes upstream of \( i \) must point away from the cancer state. The node \( i \) requiring the smallest number of upstream nodes to be in the normal state is the node that satisfies \( \text{deg}^- (i) = \mu \). Controlling less than \( \mu/2 \) nodes will leave all uncontrolled nodes with a field in the cancer direction, and no more flips will occur. Thus,
simulations required to find \( Z(C,G) \) increases exponentially and for larger networks the problem quickly becomes intractable.

One heuristic strategy for controlling cycle clusters is to look for size \( k \) bottlenecks inside of \( C \). Bottlenecks of size \( k \) can contain high impact size \( k' \) bottlenecks, where \( k' < k \). Size \( k \geq 1 \) bottlenecks need to be compared to find the best set of nodes to target to reduce \( m_{x}^{c} \). Simply comparing the impact is insufficient because a cycle cluster with a large impact could also have a large \( n_{x}^{c} \), requiring much more effort than its impact merits. Define the critical efficiency of a bottleneck \( B \) as

\[
e_{\text{crit}}(B) = \frac{I(B)}{n_{\text{crit}}(B,G)}.
\]

If the critical efficiency of a cycle cluster is much smaller than the impacts of size 1 bottlenecks from outside of the cycle cluster, the the cycle cluster can be safely ignored.

For some cycle clusters, however, not all of the nodes need to be controlled in order for a large portion of the nodes in the cycle cluster’s control set to flip. Define the optimal efficiency of a bottleneck \( B \) as

\[
e_{\text{opt}}(B) = \max_{n=1,2,\ldots} \left( \frac{I\left(\bigcup_{i=1}^{n} B_{i}\right)}{n} \right)
\]

where \( B_{i} \subseteq V(B) \) are size 1 bottlenecks and \( I(B_{i}) > I(B_{i+1}) \) for all \( i \). Note that for any size 1 bottleneck \( B \), \( e_{\text{opt}}(B) = e_{\text{crit}}(B) = I(B) \). This quantity thus allows bottlenecks with very different properties \( I(B), n_{\text{crit}}(B,G), \) or \( |V(B)| \) to be ranked against each other.

All strategies presented above are designed to select the best individual or small group of nodes to target. Significant changes in the biological networks’ magnetization require targeting many nodes, however. Brute force searches on the effect of larger combinations of nodes are typically impossible because the required number of simulations scales exponentially with the number of nodes. A crude Monte Carlo search is also numerically expensive, since it is difficult to sample an appreciable portion of the available space. One alternative is to take advantage of the bottlenecks that can be easily found, and rank all size \( k \geq 1 \) bottlenecks \( B_{i} \) in an ordered list \( U \) such that

\[
U = (B_{1}, B_{2}, B_{3}, \ldots)
\]

where
for all $B_i, B_j \in U$ and fix the bottlenecks in the list in order. This is called the \textit{efficiency-ranked} strategy. If all size $k > 1$ bottlenecks are ignored, it is called the \textit{pure} efficiency-ranked strategy, and if size $k > 1$ bottlenecks are included it is called the \textit{mixed} efficiency-ranked strategy.

An effective polynomial-time algorithm for finding the top $z$ nodes to fix, which we call the \textit{best+1} strategy (equivalent to a greedy algorithm), works as follows: (1) Begin with a seed set of nodes to fix, $F$; (2) Test the effect of fixing $F \cup i$ for all allowed nodes $i \notin F$; (3) $F \leftarrow F \setminus \text{best}$, where $\text{best}$ is the best node from all $i$ sampled; (4) If $|F| < z$, go to step (2). Otherwise, stop. The seed set of nodes could be the single highest impact size 1 bottleneck in the network, or it could be the best set of $n$ nodes (where $n < z$) found from a brute force search.

\section*{Cancer Signaling}

In application to biological systems, we assume that the magnetization of cell type $a$ is related to the \textit{viability} of cell type $a$, that is, the fraction of cells of type $a$ that survives a drug treatment. It is reasonable to assume that the viability of cell type $a, v^a(m^a_z)$, is a monotonically increasing function of $m^a_z$. Because the exact relationship is not known, we analyze the effect of external perturbations in terms of the final magnetizations.

We need to use as few controllers as possible to sufficiently reduce $m^c_0$ while leaving $m^c_n \approx 1$. In practical applications, however, one is limited in the set of druggable targets. All classes of drugs are constrained to act only on a specific set of biological components. For example, one class of drugs that is currently under intense research is protein kinase inhibitors [35]. In this case one has two constraints: the only nodes that can be targeted are those that correspond to kinases, and they can only be inhibited, i.e. turned off. We will use the example of kinase inhibitors to show how control is affected by such types of constraints. In the real systems studied, many differential nodes have only similarity nodes upstream and downstream of them, while the remaining differential nodes form one large cluster. This is not important for $p = 1$, but the effective edge deletion for $p = 2$ results in many
islets, which are nodes $i$ with $A_{ij} = A_{ji} = 0$ for all $i \neq j$ (self-loops allowed). Controlling islets requires targeting each islet individually. For $p = 2$, we concentrate on controlling only the largest weakly connected differential subnetwork. All final magnetizations are normalized by the total number of nodes in the full network, even if the simulations are only conducted on small portion of the network.

The data files for all networks and attractors analyzed below can be found in Supporting Information.

**Lung Cell Network**

The network used to simulate lung cells was built by combining the kinase interactome from PhosphoPOINT [32] with the transcription factor interactome from TRANSFAC [33]. Both of these are general networks that were constructed by compiling many observed pairwise interactions between components, meaning that if $j \rightarrow i$, at least one of the proteins encoded by gene $j$ has been directly observed interacting with gene $i$ in experiments. This bottom-up approach means that some edges may be missing, but those present are reliable. Because of this, the network is sparse (\*0.057% complete, see Table 2), resulting in the formation of many islets for $p = 2$. Note also that this network presents a clear hierarchical structure, characteristic of biological networks [36,37], with many “sink” nodes [38] that are targets of

The network used for the analysis of lung cancer is a generic one obtained combining the data sets in Refs. [32] and [33]. The B cell network is a curated version of the B cell interactome obtained in Ref. [34] using a network reconstruction method and gene expression data from B cells.

doi:10.1371/journal.pone.0105842.t002
transcription factors and a relatively large cycle cluster originating from the kinase interactome.

It is important to note that this is a non-specific network, whereas real gene regulatory networks can experience a sort of “rewiring” for a single cell type under various internal conditions [39]. In this analysis, we assume that the difference in topology between a normal and a cancer cell’s regulatory network is negligible. The methods described here can be applied to more specialized networks for specific cell types and cancer types as these networks become more widely available.

In our signaling model, the IMR-90 cell line [40,41] was used for the normal attractor state, and the two cancer attractor states examined were from the A549 (adenocarcinoma) [42–46] and NCI-H358 (bronchioalveolar carcinoma) [42,43] cell lines. Gene expression measurements from all referenced studies for a given cell line were averaged together to create a single attractor. The resulting magnetization curves for A549 and NCI-H358 are very similar, so the following analysis addresses only A549. The full network contains 9073 nodes, but only 1175 of them are differential nodes in the IMR-90/A549 model. In the unconstrained \( p = 1 \) case, all 1175 differential nodes are candidates for targeting. Exhaustively searching for the best pair of nodes to control requires investigating 689725 combinations simulated on the full network of 9073 nodes. However, 1094 of the 1175 nodes are sinks (i.e. nodes \( i \) with outdegree \( \text{deg}^+ (i) = 0 \), ignoring self loops) and therefore have \( I(i) = e_{\text{opt}}(i) = 1 \), which can be safely ignored. The search space is thus reduced to 88 nodes, and finding even the best triplet of nodes exhaustively is possible. Including constraints, only 31 nodes are differential kinases with \( \xi_i = +1 \). This reduces the search space at the cost of increasing the minimum achievable \( m_c^\ast \).

There is one important cycle cluster in the full network, and it is composed of 401 nodes. This cycle cluster has an impact of 7948 for \( p = 1 \), giving a critical efficiency of at least \( \ast_{19.8} \), and \( 1 \leq n_{\text{cut}} \leq 401 \) by Eq. 27. The optimal efficiency for this cycle cluster is \( e_{\text{opt}} = 29 \), but this is achieved for fixing the first bottleneck in the cluster. Additionally, this node is the highest impact size 1 bottleneck in the full network, and so the mixed efficiency-ranked results are identical to the pure efficiency-ranked results for the unconstrained \( p = 1 \) lung network. The mixed efficiency-ranked strategy was thus ignored in this case.

Fig. 7 shows the results for the unconstrained \( p = 1 \) model of the IMR-90/A549 lung cell network. (All simulations were performed using MATLAB on a desktop computer. Running the simulations to make all curves shown below required approximately 12 hours.) The unconstrained \( p = 1 \) system has the largest search space, so the Monte Carlo strategy performs poorly. The best+1 strategy is the most effective strategy for controlling this network. The seed set of nodes used here was simply the size 1 bottleneck with the largest impact. Note that best+1 works better than efficiency-ranked.

</table>

This is because best+1 includes the synergistic effects of fixing multiple nodes, while efficiency-ranked assumes that there is no overlap between the set of nodes downstream from multiple bottlenecks. Importantly, however, the efficiency-ranked method works nearly as well as best+1 and much better than Monte Carlo, both of which are more computationally expensive than the efficiency-ranked strategy.

Fig. 8 shows the results for the unconstrained \( p = 2 \) model of the IMR-90/A549 lung cell network. The search space for \( p = 2 \) is much smaller than that for \( p = 1 \). The largest weakly connected differential subnetwork contains only 506 nodes (see Table 3), and the remaining differential nodes are idles or are in subnetworks composed of two nodes and are therefore unnecessary to consider. Of these 506 nodes, 450 are sinks. Fig. 9 shows the largest weakly connected component of the differential subnetwork, and the top five bottlenecks in the unconstrained case are shown in red. If limiting the search to differential kinases with \( \delta_{ij} = 1 \) and ignoring all sinks, \( p = 2 \) has 19 possible targets. There is only one cycle cluster in the largest differential subnetwork, containing 6 nodes. Like the \( p = 1 \) case, the optimal efficiency occurs when targeting the first node, which is the highest impact size 1 bottleneck. Because the mixed efficiency-ranked strategy gives the same results as the pure efficiency-ranked strategy, only the pure strategy was examined. The Monte Carlo strategy fares better in the unconstrained \( p = 2 \) case because the search space is smaller. Additionally, the efficiency-ranked strategy does worse against the best+1 strategy for \( p = 2 \) than it did for \( p = 1 \). This is because the effective edge deletion decreases the average indegree of the network and makes nodes easier to control indirectly. When many upstream bottlenecks are controlled, some of the downstream bottlenecks in the efficiency-ranked list can be indirectly controlled. Thus, controlling these nodes directly results in no change in the magnetization. This gives the plateaus shown for fixing nodes 9-10 and 12-15, for example.

The only case in which an exhaustive search is possible is for \( p = 2 \) with constraints, which is shown in Fig. 10. Note that the polynomial-time best+1 strategy identifies the same set of nodes as the exponential-time exhaustive search. This is not surprising, however, since the constraints limit the available search space. This means that the Monte Carlo also does well. The efficiency-ranked method performs worst. The efficiency-ranked strategy is designed to be a heuristic strategy that scales gently, however, and is not expected to work well in such a small space when compared with more computationally expensive methods.

**B Cell Network**

The B cell network was derived from the B cell interactome of Ref. [34]. The reconstruction method used in Ref. [34] removes edges from an initially complete network depending on pairwise gene expression correlation. Additionally, the original B cell network contains many protein-protein interactions (PPIs) as well as transcription factor-gene interactions (TFGsIs). TFGIs have definite directionality: a transcription factor encoded by one gene affects the expression level of its target gene(s). PPIs, however, do not have obvious directionality. We first filtered these PPIs by checking if the genes encoding these proteins interacted according to the PhosphoPOINT/TRANSFAC network of the previous section, and if so, kept the edge as directed. If the remaining PPIs are ignored, the results for the B cell are similar to those of the lung cell network. We found more interesting results when keeping the remaining PPIs as undirected, as is discussed below.

Because of the network construction algorithm and the inclusion of many undirected edges, the B cell network is more dense (~0.290% complete, see Table 2) than the lung cell network. This
higher density leads to many more cycles than the lung cell network, and many of these cycles overlap to form one very large cycle cluster containing ~66% of nodes in the full network. All gene expression data used for B cell attractors was taken from Ref. [47]. We analyzed two types of normal B cells (naïve and memory) and three types of B cell cancers (diffuse large B-cell lymphoma (DLBCL), follicular lymphoma, and EBV-immortalized lymphoblastoma), giving six combinations in total. We present results for only the naïve/DLBCL combination below, but Tables 3 and 4 list the properties of all normal/cancer combinations. Again, all gene expression measurements for a given cell type were averaged together to produce a single attractor. The full B cell network is composed of 4364 nodes. For \( p = 1 \), there is one cycle cluster \( C \) composed of 2886 nodes. This cycle cluster has \( 1 \leq n_{\text{crit}}(C) \leq 1460, I(C) = 4353, \) and \( 3.0 \leq e_{\text{crit}}(C) \leq 4353 \). Finding \( Z(C) \) was deemed too difficult.

Fig. 11 shows the results for the unconstrained \( p = 1 \) case. Again, the pure efficiency-ranked strategy gave the same results as the mixed efficiency-ranked strategy, so only the pure strategy was analyzed. As shown in Fig. 11, the Monte Carlo strategy is outperformed by both the efficiency-ranked and best+1 strategies. The synergistic effects of fixing multiple bottlenecks slowly becomes apparent as the best+1 and efficiency-ranked curves separate.

Fig. 12 shows the results for the unconstrained \( p = 2 \) case. The largest weakly connected subnetwork contains one cycle cluster.
with 351 nodes, with $1 \leq n_{\text{crit}} \leq 208$. Although finding a set of critical nodes is difficult, the optimal efficiency for this cycle cluster is 62.2 for fixing 10 bottlenecks in the cycle cluster. This makes targeting the cycle cluster worthwhile. The efficiency of this set of 10 nodes is larger than the efficiencies of the first 10 nodes from the pure efficiency-ranked strategy, so the $m_{\text{cr}}$ from the mixed strategy drops earlier than the pure strategy. Both strategies quickly identify a small set of nodes capable of controlling a significant portion of the differential network, however, and the same result is obtained for fixing more than 10 nodes. The best+1 strategy finds a smaller set of nodes that controls a similar fraction of the cycle cluster, and fixing more than 7 nodes results in only incremental decreases in $m_{\text{cr}}$. The Monte Carlo strategy performs poorly, never finding a set of nodes adequate to control a significant fraction of the nodes in the cycle cluster.

**Conclusions**

Signaling models for large and complex biological networks are becoming important tools for designing new therapeutic methods for complex diseases such as cancer. Even if our knowledge of biological networks is incomplete, rapid progress is currently being made using reconstruction methods that use large amounts of publicly available omic data [12,13]. The Hopfield model we use in our approach allows mapping of gene expression patterns of normal and cancer cells into stored attractor states of the signaling dynamics in directed networks. The role of each node in disrupting the network signaling can therefore be explicitly analyzed to identify isolated genes or sets of strongly connected genes that are selective in their action. We have introduced the concept of size $k$ bottlenecks to identify such genes. This concept led to the formulation of several heuristic strategies, such as the efficiency-ranked and best+1 strategy to find nodes that reduce the overlap of the cell network with a cancer attractor. Using this approach, we have located small sets of nodes in lung and B cancer cells which, when forced away from their initial states with local magnetic fields (representing targeted drugs), disrupt the signaling of the cancer cells while leaving normal cells in their original state. For networks with few targetable nodes, exhaustive searches or Monte Carlo searches can locate effective sets of nodes. For larger networks, however, these strategies become too cumbersome and our heuristic strategies represent a feasible alternative. For tree-like networks, the pure efficiency-ranked strategy works well, whereas the mixed efficiency-ranked strategy could be a better choice for networks with high-impact cycle clusters.

We make two important assumptions in applying this analysis to real biological systems. First, we assume that genes are either fully off or fully on, with no intermediate state. Modelling the state of a neuron as “all-or-none” has long been accepted as a reasonable assumption [48], which provided the spin glass framework for the

The unconstrained (UNC) and constrained (CON) case are shown. The constrained case refer to target that are kinases and are expressed in the cancer case. I = IMR-90 (normal), A = A549 (cancer), H = NCI-H358 (cancer), N = Naïve (normal), M = Memory (normal), D = DLBCL (cancer), F = Follicular lymphoma (cancer), L = EBV-immortalized lymphoblastoma (cancer).

doi:10.1371/journal.pone.0105842.t004
Hopfield model. While similar switch-like behavior in gene regulatory networks has been proposed as an explanation of, for example, segmentation in *Drosophila* embryos [49], assigning a Boolean value to gene expression may be overly simplistic in many cases. A model which uses spins with more than two projections could prove to be more realistic and predictive. Second, we assume that all nodes update their status with a single timescale and with a single interaction strength. If the signaling timescale $t_{ij}$ for each edge in the biological network is known, simulations could be conducted in which a signal traveling along an edge $(j,i)$ reaches its target after $t_{ij}$ time steps. This would amount to a synchronous update schedule with a “queue” of signals moving between nodes. Likewise, our model gives equal weight to all edges (aside from edges that are effectively deleted in the $p=2$ case), whereas real gene regulatory networks exhibit a spectrum of interaction strengths. This can easily be integrated with our model by using a weighted, directed adjacency matrix. However, doing this would surely require a change in control strategy.

Despite these issues, our model shows promise. Some of the genes identified in Table 4 are consistent with current clinical and cancer biology knowledge. For instance, in the lung cancer list we found a well known tumor suppressor gene (TP53) [50] that is frequently mutated in many cancer types including lung cancer [51]. Mutations in PBX1 have recently been detected in non-small-cell lung cancer and this gene is now being considered as a target for therapy and prognosis [52]. MAP3K3 and MAP3K14 are in the MAPK/ERK pathway which is a target of many novel therapeutic agents [53], and SRC is a well known oncogene and a candidate target in lung cancer [54]. BCL6 (B-cell lymphoma 6) is the most common oncogene in DLBCL, and it is known that its expression can predict prognosis and response to drug therapy [55–57]. BCL6 is also frequently mutated in follicular lymphoma [58,59]. Our analysis identified BCL6 as an important drug target for both DLBCL and follicular lymphoma using either naive or memory B-cells as a control for both $p=1$ and $p=2$. RBL2 disregulation has been recently associated with many types of lymphoma [60–62]. FOXM1 is a potential therapeutic target in mature B cell tumors [63] and ATF2 has been recently found to be highly disregulated in lymphoma [64,65]. Besides BCL6 discussed above, the N/D list for DLBCL contains genes (MEF2A [66], NCOA1 [67,68], TGIF1 [69–71], NFATC3 [72]) that are all known to have a functional role in cancer, even if they have not been associated to the specific B-cell cancer types we have considered. Our predictions are for the immortalized cell lines we have selected, some of which are commonly used for in-vitro testing in many laboratories. RNAi and targeted drugs could then be used in these cell lines against the top scoring genes in Table 4 to test the disruption of survival or proliferative capacity. If experimentally validated, our analysis based on attractor states and bottlenecks could be applied to patient-derived cancer cells by
integrating in the model patient gene expression data to identify patient-specific targets.

The above unconstrained searches assume that there exists some set of “miracle drugs” which can turn any gene “on” and “off” at will. This limitation can be partially taken into account by using constrained searches that limit the nodes that can be addressed. However, even the constrained search results are unrealistic, since most drugs directly target more than one gene. Inhibitors, for example, could target differential nodes with $\zeta_i = -1$ and $\zeta_j = +1$, which would damage only normal cells. Additionally, drugs would not be restricted to target only differential nodes, and certain combinations could be toxic to both normal and cancer cells. Few cancer treatments involve the use of a single drug, and the synergistic effects of combining multiple drugs adds yet another level of complication to finding an effective treatment [27]. On the other hand, the intrinsic nonlinearity of a cellular signaling network, with its inherent structure of attractor states, enhances control [31] so that a properly selected set of druggable targets might be sufficient for robust control.

Abstract

Background: Many kinase inhibitors have been approved as cancer therapies. Recently, libraries of kinase inhibitors have been extensively profiled, thus providing a map of the strength of action of each compound on a large number of its targets. These profiled libraries define drug-kinase networks that can predict the effectiveness of untested drugs and elucidate the roles of specific kinases in different cellular systems. Predictions of drug effectiveness based on a comprehensive network model of cellular signalling are difficult, due to our partial knowledge of the complex biological processes downstream of the targeted kinases.

Results: We have developed the Kinase Inhibitors Elastic Net (KIEN) method, which integrates information contained in drug-kinase networks with \textit{in vitro} screening. The method uses the \textit{in vitro} cell response of single drugs and drug pair combinations as a training set to build linear and nonlinear regression models. Besides predicting the effectiveness of untested drugs, the KIEN method identifies sets of kinases that are statistically associated to drug sensitivity in a given cell line. We compared different versions of the method, which is based on a regression technique known as elastic net. Data from two-drug combinations led to predictive models, and we found that predictivity can be improved by applying logarithmic transformation to the data. The method was applied to the A549 lung cancer cell line, and we identified specific kinases known to have an important role in this type of cancer (TGFBR2, EGFR, PHKG1 and CDK4). A pathway enrichment analysis of the set of kinases identified by the method showed that axon guidance, activation of Rac, and semaphorin interactions pathways are associated to a selective response to therapeutic intervention in this cell line.

Conclusions: We have proposed an integrated experimental and computational methodology, called KIEN, that identifies the role of specific kinases in the drug response of a given cell line. The method will facilitate the design of new kinase inhibitors and the development of therapeutic interventions with combinations of many inhibitors.

Keywords: Drug response predictions, Kinase inhibitors, Elastic net regression, High throughput screening, Drug combination therapies

Background

The important role of kinases in cancer biology \cite{1} has spurred a considerable effort towards the synthesis of libraries of fully profiled kinase inhibitors, providing a map of the strength of each compound on a large number of its potential targets \cite{2-4}. In particular, a recently published dataset has profiled several hundred kinase inhibitors using a panel of more than 300 kinases \cite{4}. These profiled libraries define a network of interactions between drugs and their kinase targets \cite{5}, and represent a valuable resource for the development of new therapies. In this paper, we introduce a novel computational method that incorporates profiled libraries and \textit{in vitro} measurements to predict the response of cells to previously untested drugs. Besides making prediction about the cellular response to drugs, the method identifies critical kinase targets and pathways that are statistically associated to drug sensitivity in a given cell line.
Statistical inference and regression methods in conjunction with gene expression or mutations have been used to identify specific biomarkers associated with an increased sensitivity/resistance to drugs. For instance, the sensitivity to PARP inhibitors of Ewing’s sarcoma cells with mutations in the EWS gene and to MEK inhibitors in NRAS-mutant cell lines with AHR expression have been predicted using analysis of variance and the elastic net method [6] and then experimentally validated [7,8]. In these analyses, the statistical variable associated to drugs was represented by the half maximal inhibitory concentration (IC$_{50}$) in different cell lines. However, besides the IC$_{50}$, there are many other types of information that characterize chemical compounds. These types of information can enhance the statistical analyses and improve the accuracy of predictions. For instance, a method to predict drugs sensitivity in cell lines based on the integration of genomic data with molecular physico-chemical descriptors of the drugs has been recently proposed [9]. Another useful type of information is the residual activity of kinases after interacting with a compound. Kinase profiling, patient genetic profiles, and sensitivity of primary leukemia patient samples to kinase inhibitors were recently used by Tyner et al. [10] to identify functionally important kinase targets and clarify kinase pathway dependence in cancer.

In this paper, the residual activity of kinases upon drug interaction is used to make predictions of the cellular response for in vitro experiments using an elastic net [6] regression approach. This regression method reduces the number of predictors to a minimum set, providing a clear picture of the kinases involved in the response of cell lines. A primary screen (single drug) and a secondary screen (two-drug combinations) are used as the training set for the regression. The two-drug screening exhibits a broader distribution in the response and provides a good level of predictability. In fact, the model based only on single drug response did not pass the statistical cross-validation test.

We are applying this Kinase Inhibitor Elastic Net (Kien) method to predict cell viability of a lung cancer cell line (A549) and a normal fibroblast cell line (IMR-90) after drug treatment. We found that the regression can be improved through a logarithmic transformation on the data. Using the results of the regression, we identified a set of kinases that are strongly associated to a selective response of A549 and not IMR-90. Then, a pathway-based enrichment using Reactome [11] revealed ten significant pathways using this set of kinases, including axonal guidance and related semaphorin interactions as top hits.

This paper is organized as follows: Section In vitro screen of the kinase inhibitor library contains the experimental results of the primary and secondary in vitro screening corresponding to single drugs and two-drug combinations. These experimental results and residual kinase activity are analyzed with Pearson’s correlation in Section Analysis of correlations. This simple correlation analysis gives a first glance of the kinases that are statistically associated to a significant change in the viability of cancer and normal cell lines. In Section Elastic net regression, we introduce the elastic net approach and present the results of a leave-one-out cross validation for predictions on single and pairs of drugs. We also present in this section the results obtained using the logarithmic transformation on the variables and a pathway enrichment analysis using Reactome [11]. The Discussion of the results is in Section Discussion, conclusions in Section Conclusions, and Materials and Methods in Section Materials and methods.

**Results**

**In vitro screen of the kinase inhibitor library**

Our methodology begins with the high-throughput screening of single drug and drug pair experiments. The 244 kinase inhibitors (KIs) of the EMD drug library were screened at 1000 nM individually and the treatment lasted for 72 hours. To quantify a selective response of a cancer cell line with respect to a control normal cell line, we define the selectivity $S$ of a single drug or drug combination as

$$S = \frac{v_N}{v_C}$$

where $v_N$ indicates the viability of normal cells (IMR90) after treatment, and $v_C$ the viability of cancer cells (A549) after treatment. From the screening of the 244 KIs, the top hit was PDK1/Akt1/Flt3 Dual Pathway Inhibitor (CAS # 331253-86-2) as ranked by selectivity (Figure 1). For the secondary screen, we used the PDK1/Akt1/Flt3 Dual Pathway Inhibitor as the starting point and combined this compound with the other KIs as a drug pair combination. The dose of PDK1/Akt1/Flt3 Dual Pathway Inhibitor was studied to ensure proper dosing range and minimize toxicity. We used 125 nM, which maintains the normal cell line IMR-90’s viability $>90\%$ (Figure 2). For the other 243 KIs we used the standard dose of 1000 nM. Several pairs in the secondary screen showed very high selectivity. The top hit from the secondary screen of the library was Alsterpaullone 2-cyanoethyl (CAS # 852529-97-0) with a selectivity of $S = 6.14$ for the pair (Figure 3).

**Analysis of correlations**

In our second step, we analyzed the Pearson’s correlation of the primary and secondary screening with a published dataset [4] containing target profiles for 140 kinase inhibitors. Therefore, even though we had a library of 244 KIs in the experimental screening, we were limited to utilizing 140 KIs for the analysis. For each inhibitor,
the dataset provides the residual activity \(0 \leq A \leq 1\) of 291 kinases after drug treatment. This quantity is a measure of the strength of inhibition of a drug on each kinase.

For each kinase \(k\), we calculate the Pearson’s correlation, \(C_k\), between the selectivity \(S_i\) and the activities \(A_{ki}\) with \(i \in \{1, \ldots, M\}\) indicating the single drug or drug pair in the set. For drug pairs, the activity is estimated as a product of the residual activities of the two drugs. The kinases are then ranked based on the \(p\)-value of their correlation with selectivity, and we calculate the False Discovery Rate (FDR) adjusted \(p\) value [12]. The list of kinases mostly correlated to the selectivity from the primary and secondary screen are listed in Table 1. We also did calculations of the correlation between the normal or cancer cell viability and the activities. The results for the top kinase-viability correlations for the primary and secondary screen are shown in the supplementary materials (Additional file 1: Table S1).

### Elastic net regression

Next, we build a regression model that predicts the response of a cell line to a drug or drug combination \(i\). The response we predict is the normal and cancer cell viability, from which the selectivity can be derived. For this purpose, we define a regression problem in which we use the residual activity of the kinase \(k\) under the effect of drug \(i\), which we indicate as \(A_{ki}\), as predictors of the viability. The response can be written as

\[
vi = \beta_0 + \beta_1 A_{1i} + \ldots + \beta_p A_{pi} + \epsilon .
\]

A fitting procedure based on a training set of measurements produces the coefficients \((\beta_0, \beta_1, \ldots, \beta_p)\). Equation
(1) can then be used to predict the viability of a new drug that has not been tested, but of which the profiling information is available. Note that we are integrating two different types of data: kinase profiling data is obtained through enzymatic assays that probe directly the interaction between drug and kinases, while the *in vitro* cell response data is the result of complex signaling that involves many pathways downstream of the affected kinases. The coefficients $\beta_k$ can be seen as a measure of the sensitivity of a given cell line due to alterations in the activity of kinase $k$.

It is well known that the least square method does not perform well in the case of linear regression with many predictors. In our case, we would like to use a database of drugs that have been profiled on about 300 kinases. However, it would be desirable to select and keep in the final model a minimal set of the kinases that provide a simple model, useful to gain biological insight. The lasso technique [13] is a powerful method to reduce the number of predictors by imposing a penalty on the regression coefficients. However, in the presence of a group of kinase predictors with strong mutual correlation, the lasso could select only one kinase predictor from the group while missing the others. To prevent this problem, our method uses the elastic net approach. This method incorporates the lasso penalty as well as a ridge penalty to keep the regression coefficients small without completely removing them [6]. The weights of the ridge and lasso penalties in the least square procedure can be optimized for best performance of the method.

A negative correlation indicates that inhibition of that particular kinases is associated to a higher selectivity. The top two hits with negative correlation, TGFBR2 and CDK4 are known to have an important role in cell proliferation, invasion and metastasis in lung adenocarcinoma [21,22].
We show in Figure 4(a) and (b) the results of a leave one out cross validation (LOOCV) method for the primary (a) and secondary screen (b). For each of the 140 drugs, we apply the elastic net method using the remaining 139 drugs and then we compare the result to the measured value. This cross validation method is a particular case of the more general $k$-fold cross validation procedure in which $k$ is equal to the size of the training set [14]. The cross LOOCV shows that the information contained in the primary screen is not sufficient to define a predictive model. The fact that some kinases in Table 1 show some significant correlation with the response when considered individually is in general not a sufficient condition for defining a predictive, multiple regression model. On the other hand, the secondary screen is able to reproduce the viability of many drugs, especially the ones with the stronger effect on both cell lines. Overall, the data from the secondary screen presents a much broader distribution with a tail representing a few drug combinations particularly effective. The regression works better in identifying these highly effective pairwise combinations and the relative ranking of their strengths. Data is not particularly informative for drugs and drug pair combinations that are not effective, which concentrate in the neighborhood of $\sim 1$.

Data transformations can represent a powerful strategy to improve regression. We applied a logarithmic transformation, which is consistent with the hypothesis of an independent action on the total viability. In this case we assume that the viability can be rewritten in the form

$$v_i = e^{\beta_0} (A_{1, i})^{\beta_1} \cdot (A_{2, i})^{\beta_2} \cdot \ldots \cdot (A_{p, i})^{\beta_p}. \quad (2)$$

By applying a log transformation on both sides of Eq. (2) we reduce the problem to a linear regression, to which the elastic net strategy can be applied. We show in Figure 5 the results of the LOOCV for the primary and secondary screen using the logarithmic data transformation. As in the linear case, we find that the method fails the cross validation procedure if we use data from the primary screen, while the secondary screen with log transformed data gives better $R^2$.

In addition to a regression model that can be used to predict the efficacy of drugs that have not been tested, the $\beta_i$ coefficients can be used to rank kinases in terms of their relevance in the regression. Therefore, these coefficients identify the kinases whose inhibition is associated to a decrease in the cell viability. A ranking based on the differential $\beta_{N_i}^C - \beta_{N_i}^N$, where the index $N$ and $C$ identify the regression model of the cancer and normal cells, gives insight on specific pathways important for a selective response of cancer cells. Table 2 shows a list of kinases ranked in terms of $|\beta_{N_i}^C - \beta_{N_i}^N|$, where the coefficients have been obtained using the logarithmic data transformation on the secondary screen.

In order to test whether selected pathways were significantly enriched for the identified kinase genes in Table 2, a pathway-based enrichment analysis was performed.

![Figure 4](https://example.com/figure4.png)

**Figure 4** Leave-one-out Cross Validation of the elastic net regression model based on the primary (top) and secondary (bottom) screens for normal and cancer cell lines. Each of the 140 point in these figures corresponds to one of the 140 drug. "Regression" refers to the viability predicted by the regression model using all data from the other 139 drugs as training set, while "Measured" refers to the actual viability measured for the drug or drug combination. Note that only the secondary screen leads to predictive models with significant $R^2$ for the two cancer cell types.
conducted using the results from the elastic net kinase analysis and Fisher exact tests. Ten pathways from Reactome were identified as significant ($p < 0.05$) using this kinase list, including axon guidance, activation of Rac, and semaphorin interactions as top hits (Table 3).

**Discussion**

Drug-kinase profiling represents a controller-target network [5] that when combined with *in vitro* testing, can be used in regression models to predict drug response and to identify pathways statistically associated to drug sensitivity. Network methods in biology are often based on the analysis of large datasets from high-throughput experiments. An example is given by gene regulatory networks, which presents many challenges either when restricted to a homogeneous set of data [15,16] or when it includes different classes of data [17-20]. In our KIEN method, information from the drug-target network and experimental query of the biological system are integrated. The goal is not a reconstruction of a regulatory network, but to identify a set of kinases linked to a therapeutic response in a given cell line. In order to establish associations, the system has to be perturbed by the use of kinase inhibitor drugs. The response to these single drugs or drug combinations becomes a training set that when combined with the kinase profiling, can lead to predictions.

The elastic net method is one of the most widely used regularization techniques. Regularization techniques are used in statistical and machine learning models to achieve an optimal tradeoff between accuracy and simplicity. Simplicity makes a model less prone to overfitting and more likely to generalize. In our analysis, we found that the elastic net regressions based on single drug responses were not successful, while drug pair data provided statistically significant predictions. A possible explanation for this finding is the following: single drugs might be less able to overcome the robustness of biological networks [5]. The phenotypic signal is therefore blunted and not easily measured. If a second drug is added, any compensatory capacity is already stretched and the effects from the inhibition of each kinase can be seen more clearly. Using data from drug pairs, we found that noise can be better filtered out and stronger statistical associations between kinases and therapeutic response are revealed. Clearly, if a different training set with higher variance in efficacy measures were used in the primary screen, it is likely that also single drug *in vitro* response would have given a significant predictive model.

We identified several kinases that are implicated in lung cancer that gives biological significance to our KIEN method. In particular, TGFBR2 appears as a top hit both in the correlation and in the elastic net methods. This finding is consistent with recent siRNA experiments on A549 cell lines [21], which demonstrated that silencing of this receptor reduces cell proliferation, invasion, and metastasis. The Cyclin-dependent kinase 4 (CDK4) appears as a second top target in the correlation analysis, and is also highly significant in the KIEN analysis. Experiments using lentiviral-mediated shRNA to inhibit CDK4 in A549 have shown inhibited cell cycle
progression, suppressed cell proliferation, colony formation, and migration [22], and there is an ongoing clinical trial using a CDK4/6 inhibitor in lung cancer [23]. The KIEN analysis identified EGFR, which is known to be overexpressed in the majority of non-small cell lung cancers [24]. Furthermore, RNAi experiments targeting EGFR demonstrated cancer growth suppression in A549 xenograft in mice [25]. The third kinase in Table 2, PHKG1 has also been found to be upregulated in human tumor samples, including lung adenocarcinoma, and aberrations in its gene copy number is a feature of many human tumors [26].

The pathway-based enrichment provides a broader view on the role of the kinases identified by our method in Table 2. Among the top three pathways shown in Table 3 are activation of Rac and Semaphorin interactions. Rac proteins play a key role in cancer signaling and they belong to the RAS superfamily [27]. We also identified a set of semaphorins in our analysis that is represented in the top significantly enriched pathways. Semaphorins, previously known as collapsins, are a set of proteins containing a 500-amino acid sema domain among others (including PSI and immunoglobulin type domains), which can be transmembranous or secreted [28]. It is known that Sema3E cleavage promotes invasive growth and metastasis in vivo [28]. These genes also have selective targeting by Rac and Rho family members. This generates hypotheses of possible pathways that could be targeted therapeutically. However, these hypotheses need to be validated by further experiments with different inhibitors for the same targets or with alternative methods, e.g. using siRNA.

**Conclusions**

We have introduced an integrated experimental and computational methodology that identifies the role of specific kinases in the drug response of a given cell line. The key element of our KIEN methodology is a multiple regression procedure that uses \textit{in vitro} screen data as a training set. If a new library of kinase inhibitor compounds were to be synthetized and profiled, then our model would be able to immediately estimate the effect of these drugs on \textit{in vitro} experiments on a given cell line. We have shown an application to a lung cancer cell

A larger difference is associated with a selective response of A549 upon inhibition. Note that in addition to TGFBR2 and CDK4, which were identified with the correlation approach of Table 1, additional kinases known to have an important role in lung cancer such as EGFR [24,25] and PHKG1 [26] are found using the elastic net approach.

Ns indicates the number of kinases that are found significant in the regression analysis, while Nt is the total number of kinases in the pathway. The top ten pathways with Fisher exact test p < 0.051 are shown. These pathways are identified from S18. Reactome pathways containing at least one of the kinases identified in Table 2.

The 9 kinases in the axon-guidance pathway are EGFR, PAK1, ERBB2, CDK5, GSK3B, PAK2, RP56KA2, FGRF1 and PAK7.
line, but our method can be extended to different cell lines. The method will facilitate the design of new kinase inhibitors and the development of therapeutic interventions with combinations of many inhibitors [29]. The procedure could be extended to three drug combinations, if measurements for these larger combinations were available. Finally, the method could be extended to regression models that are specific of cancer cells with the same set of mutations, or it could be directly used with patient-derived primary cells to identify a personalized treatment.

**Materials and methods**

**Materials**
The primary screening of a kinase inhibitor (KI) library comprised of 244 KIs was purchased from EMD Chemicals, and diluted with DMSO to 2 mM concentrations for high-throughput screening purposes. The KI library was stored at −80°C. Additionally, PDK1/Akt1/Flt3 Dual Pathway Inhibitor (CAS # 331253-86-2) was ordered from EMD. Only 140 out of 244 were used in the drug-target network reconstruction because the drug profiling information was available only for these compounds. One kinase inhibitor known to affect the kinase targets indirectly was excluded. We provide in Additional file 2 the chemical structure of kinase inhibitors with highest selectivity in the primary and secondary screening.

**Cell culture**

Cell lines IMR-90 (normal lung fibroblast) and A549 (lung adenocarcinoma) were cultured in RPMI 1640 (Hyclone) supplemented with 10% Canadian characterized fetal bovine serum (Hyclone), 1% 200 mM L-glutamine (Omega), and 1% penicillin/streptomycin (Omega). The media for the cells were renewed every 3 days and kept at 80–90% confluency. Cells were maintained in a humidified environment at 37°C and 5% CO₂.

**Kinase inhibitor experiments**

IMR-90 (1500 cells/well) and A549 (750 cells/well) were seeded on 384-well microplates (Grenier Bio-One) and incubated for 3 hours before the addition of kinase inhibitor(s). The reason that IMR-90 was seeded at double the cell density of A549 is due to the difference in cell division. IMR-90’s doubling time is 36–48 hours whereas A549’s is 22 hours. We wanted to make sure that the cells have divided at least once during the 72 hr drug treatment. Furthermore, both A549’s and IMR-90’s final confluency at 72 hrs is 90–95% and within the range of the ATPlite 1step assay. Additional file 1: Figures S1 and S2 show the growth curve for both cell lines. IMR-90 and A549 cell lines were tested on the same day with three replicates and the experiment was repeated three times with randomized well positions to reduce biases.

ECHO 555 Liquid Handler (Labcyte) was used to dispense nanoliter volumes of each KI to 384-well plates with cells attached (wet dispense). The final volume in the plate is 40uL and cells were incubated for 72 hours with KI treatment.

**ATP measurements**

ATPlite 1Step (Perkin Elmer) was used to evaluate the cell number and cytotoxicity. ATP measurements were done by dispensing 20 uL of the ATPlite 1Step solution to each well to a final volume of 60 uL. The plate was placed on a shaker at 1100 rpm and the luminescence activity was detected by Analyst GT Plate Reader. The percent (%) of control is the quantity of ATPlite 1step activity was detected by Analyst GT Plate Reader. The plate was read immediately.

**Computational methods**

Correlations between selectivity/viability and kinase activity were calculated using the python scipy linregress function, which also provide p-values. Ranking the p-values and directly applying the Benjamini–Hochberg procedure gave us the FDR values. The elastic net regression was carried out using the Scikit-learn package [30] which finds the coefficients β that minimize the function

\[
F = \frac{1}{2M} ||v−Aβ||_2^2 + aρ||β||_1 + \frac{1}{2}(1−ρ)||β||_2^2
\]

where \(v\) is the vector of the observed viabilities and \(A\) is the matrix containing the residual activity of the kinases from the profiling, and \(M\) is the total number of drugs or drug combinations used. The parameters \(a\) and \(β\) determine the relative weights of the lasso and ridge penalties quantified using \(L^1 (|| |_1 )\) and \(L^2 (|| |_2 )\) norm, respectively. We used \(a = 0.15\) and \(ρ = 0.01\) in the results of Figures 4 and 5 and in Table 2. We also tried other values of these parameters, which did not give a significant difference in the results.

**Pathway-based enrichment**

Reactome pathways were downloaded using a newer build of the ‘biomaRt’ library (v2.12.0) in Bioconductor/R (v2.15.0). Gene symbols from the kinase list were converted to Entrez gene identifier numbers (entrezgene) and mapped against the gene ids in each Reactome pathway. For each pathway, the set of significant genes enriched within any given pathway was computed using a Fisher exact test. The procedure computes the significance (p-value) of observing significant kinases, as deemed significant by our method, within the selected
pathway. These pathways are identified from 518 Reactome pathways. Given that our gene set consists entirely of kinases and would be generalized towards kinase-specific effects, the set of all kinases (~300) were selected for background adjustment and more sensitive enrichment of the pathways. This procedure was repeated for each pathway to generate p-values and pathway rankings. False discovery rate [FDR] values were later generated to further restrict significance.
