Standard Form 298 (Rev. 8-98)
Prepared by ANSI X3T6/9-14
the mortality rate nearly doubles as "net" cumulative fluid intake strays further from an even balance in either positive or negative direction (though not statistically significant). Controlling for other factors (age, ISS, lactate, base deficit) net cumulative fluid intake narrowly misses statistical significance as a predictor of mortality (p = 0.057). Our evidence suggests that unabated fluid resuscitation in the blunt injured, critically ill trauma patient is associated with higher mortality. It also suggests that under-resuscitation is also associated with higher mortality.

ARE HEMOGLOBIN OXIMETRY, VITAL SIGNS AND LABORATORY VALUES ABLE TO PREDICT EMERGENCY TRANSFUSION?

Colin Mackenzie1, Cheng Gao2, Peter Fu-Ming Hu3, Shiming Yang3, Amechi Anazodo3, Hegang Chen3, Raymond Fang3, Samuel Galvagno3; 1University of Maryland School of Medicine, Baltimore, MD, 2University of Maryland Baltimore OXIMEX; Baltimore, MD, 3STAR University of Maryland, Baltimore, MD

Learning Objectives: A non-invasive decision support tool for emergency transfusion decisions would benefit acute resuscitation. We tested whether 15 minutes of continuous pulse-oximetry-derived hemoglobin measurement [SpHb] can predict emergency blood transfusion better than conventional oximetry, vital signs, shock index (SI) or invasive laboratory testing (LAB). Methods: To test the hypothesis that trends of non-invasive SpHb, and conventional oximetric features predict emergency transfusion better than SI or inclusion of LAB measures, we enrolled trauma patients ≥ 18 years with pre-hospital SI > 0.61. We collected vital signs (VS = conventional and SpHb oximetry, heart rate, blood pressure) for 15 minutes and recorded emergency transfusion < 3 hours after admission. 18 transfusion prediction models selected by stepwise logistic regression including VS and LAB values were compared via Area Under Receiver Operating Curve (AUROC) and validated by leave-one-out methodology. Results: Of 677 patients, 59 were transfused. Conventional pulse oximetry, vital signs and LAB models predicted blood use with AUROC of 0.96, significantly better (p < 0.01) than use of SpHb, vital signs and LAB testing (AUROC 0.93). Predictions of transfusion based on monitoring trends of SpHb, oximetric features and vital signs alone (AUROC 0.84) were not statistically better than trends of conventional pulse oximetry features and vital signs (AUROC 0.83, p = 0.43). No models including SI were significantly better than those without SI. Conventional oximetry & LAB showed < 10% difference between training and testing predictions of transfusion based on monitoring trends of SpHb, oximetric features and laboratory values. Conclusions: Models containing only features of conventional pulse oximetry were robust and no different than models including trends and absolute values of SpHb in prediction of urgent transfusion within 3 hours of patient admission. Both models containing oximetry features performed better at predicting emergency transfusion than pre-hospital SI, the current best non-invasive vital signs transfusion predictor. POSTOPERATIVE METABOLIC ACIDOSIS ASSESSMENT IN HIGH RISK SURGICAL PATIENTS: PROGNOSTIC IMPORTANCE

João Silva Jr1, Maria Carmona2, Vivian Maia3, Amanda Oliveira2, Pedro Vianna4, Fernando Nogueira2, Luiz Malbouisson1; 1University of Sao Paulo, Sao Paulo, Brazil, 2FMUSP, Sao Paulo, Brazil, 3HSPE, Sao Paulo, Brazil, 4University of Maryland, Baltimore, MD, USAF C-STARS Baltimore, Baltimore, MD

Learning Objectives: Acidosis is a very frequent disorder in surgical patients. Therefore it is very important to evaluate the role of acidosis in outcome for high-risk surgical patients. Methods: Multicenter prospective observational study. The patients who needed postoperative ICU were included in the study consecutively. Patients with low life expectancy, hepatic failure, renal failure, and diabetic diagnosis were excluded. The patients were classified by admission from the ICU related to kind of acidosis in the immediately postoperative period. The classification evaluated metabolic acidosis by base excess ≤ -4 mmol/L and albumin-corrected anion gap and lactate, both > 12 and > 2 mmol/L, respectively. Acidosis patient’s classifications were compared among them (hyperlactatemic, high and normal albumin-corrected anion gap) and to the non-acidosis. Results: The study involved 618 patients. Overall, the acidosis incidence was 59.1% on ICU admission, the most of them 148(23.9%) were normal anion gap. The normal anion gap group presented the highest chloride level (P < 0.05) and highest administration 0.9% physiologic solution intraoperatively (P = 0.05). However, in spite of patients didn’t present difference in severity and demographic profile, acidosis patients who remain after 24 hours with acidosis depend on classification group in metabolic acidosis, last showed greater ICU complications, hyperlactatemia group 66%; high anion gap 48.1%; normal anion gap 47.9% and no acidosis 39.5%, P = 0.03. Cardiovascular, neurologic and renal dysfunctions were the main complications and hyperlactatemia group showed the highest in all of them. In related to hospital mortality rate were 30.1% (HR 1.61, 95% CI 1.02–2.53) hyperlactatemia; 24.3% (HR 1.37, 95% CI 0.76–2.46) high anion gap; 18.4% (HR 1.55, 95% CI 0.90–2.67) normal anion gap and 14.8% (HR 0.62, 95% CI 0.39–0.98) metabolitis group, P = 0.001. Conclusions: Metabolic acidosis in surgical patients is an important complication, mainly normal anion gap. Patients who developed metabolic acidosis postoperatively depend on classification group presented worst outcomes.

SCHEDULED 23.4% SODIUM CHLORIDE FOR INTRACRANIAL PRESSURE CONTROL IN TRAUMATIC BRAIN INJURY

Matthew Gurka1, Leslie Hamilton2, James McMillen3; 1University of Tennessee Medical Center, Knoxville, TN, 2University of Tennessee College of Pharmacy, Knoxville, TN

Learning Objectives: Controlling intracranial pressure (ICP) below 20 mmHg is regarded as optimal for maintaining cerebral perfusion and oxygenation. Hyperosmolar therapy, with either mannitol or hypertonic saline is a common method of controlling ICP in patients with severe traumatic brain injury (TBI). Currently there is no published data examining the effect of scheduled 23.4% sodium chloride on ICP control. We report two cases of the use of scheduled 23.4% sodium chloride for ICP control in TBI patients. Methods: This case series reports on two patients with severe TBI who were placed on the institution’s TBI protocol in addition to having an ICP monitor placed. Patients were treated with scheduled 23.4% sodium chloride at a dose and frequency at the discretion of the attending physician. We report on outcomes including, but not limited to: number of ICP elevations ≥20 mmHg, brain oxygen saturation (PbtO2), instances of serum osmolality ≥320 mOsm/L, instances of serum sodium ≥160 mEq/L, number of doses of 23.4% sodium chloride, and ancillary methods used to control ICP. Results: Instances of ICP elevations ≥20 mmHg were approximately 6% and 8% of recorded measurements. Scheduled 23.4% sodium chloride was continued for 12 and 15 days respectively. Both patients survived until hospital discharge; one of the two transferred to a skilled nursing facility, while the other was discharged home. Only one of the patients had a PbtO2 monitor placed, however the number of instances of PbtO2 of <20 mmHg were limited to 4% of measurements. Neither patient had serum sodium of >159 mEq/L. Serum osmolality was ≥320 mOsm/L in 10% of measurements in one of the patients and never elevated in the other. There were no instances of acute kidney injury in either patient. Conclusions: The use of scheduled 23.4% sodium chloride may be safe and effective in preventing ICP elevations in severe TBI patients, however further research is needed.

1082

PREVALENCE OF KIDNEY INJURY IN BURN PATIENTS REQUIRING FLUID RESUSCITATION

Jose Salinas1, J Waters2, Craig Fenrich1, Maria Serio-Melvin1, John Graybill1, Leopoldo Cancio1, Kevin Chung3, Ian Stewart1; 1U.S. Army Institute of Surgical Research, Fort Sam Houston, TX, 2United States Army Institute of Surgical Research, San Antonio, TX, 3US Army Institute of Surgical Research, JBSA FT SAM HOUSTON, TX

Learning Objectives: Optimal fluid resuscitation during the first 48 hours in patients with large burns is critical for improving outcomes and avoiding burn shock. However, it is unclear what the effect of fluid management is on kidney function during the resuscitation phase of care. The purpose of this study was to examine the prevalence of acute kidney injury (AKI) during resuscitation. We hypothesized that AKI is common during burn resuscitation and correlates with extent of the burn injury. Methods: We performed a retrospective review of consecutive patients admitted to our burn intensive care unit from December 2007 to April 2013 who were resuscitated using a computerized decision support system (CDSS) designed to optimize resuscitation. AKI was defined by the Acute Kidney Injury Network (AKIN) criteria and was assessed during the resuscitation period. Rates of AKIN were stratified by burn size. Results: The cohort was composed of 241 subjects. Median total body surface area (TBSA) burn was 40 ± 20%, weight was 84 ± 19 kg, and age was 46 ± 19 years. AKI occurred in 54% (n=131) of patients with 43%, 20%, and 1% meeting criteria for AKIN 1, 2, and 3, respectively. There was a significant increase in overall AKIN rates for TBSA > 30% (43% vs. 63%, p<0.01) with AKIN 1 differing significantly from 31% to 53% (p<0.01). Development of AKI was significantly correlated with increased resuscitation volume (mil/ kg/day), with increases in ICP of ≥20 mmHg or cumulative fluid intake of ≥3 ml/kg in the last 48 hours was the leading cause of potential AKIN classification (79%,...
n=104) of cases followed by low urinary output of 12 hours (19%, n=25) and low urinary output of 24 hours (2%, n=2). **Conclusions:** Based on the AKIN criteria, patients undergoing burn fluid resuscitation appear to be at risk of AKI.

The majority of patients with a TBSA greater than 30% will develop AKI based on increases to serum creatinine during resuscitation. In AKI, AKI was rarely on increases to serum creatinine during resuscitation. In this study, AKI was rarely

**1083 PREHOSPITAL MANAGEMENT AS A PREDICTOR OF MORTALITY IN TRAUMATIC BRAIN INJURY**

Raquel Gutiérrez rodrguez,1 Maria Arias Verd,1 Ines Macias Guaraa,2 ‘Critical care unit, Carlos Haya Hospital, Malaga, Spain, 1Carlos Haya Hospital, Malaga, Spain

**Learning Objectives:** Objective: to determine the importance of intubation and sedation and other factors on mortality after traumatic brain injury.

**Methods:** Methods: a retrospective observational analytical study (TBI) in a intensive care unit of a reference Spain hospital. We study all patients admitted after severe traumatic brain injury associated with multiple trauma or just isolated TBI admitted between 2011 and 2012. The following variables were studied on admission: APACHE II, AIS severity scale, GCS score, Data Bank score, sex, age, sedation and intubation before admission. Others variables: prolonged stay, infectious complications, raised intracranial pressure at any time during the evolution, hospital mortality.

**Results:** Results: we study 147 patients, mean age of 39 ± 18 years, APACHE II 18.1, ISS 16.3, Data Bank score 2.6, GCS 7.9 on admission. Hospital mortality was 30%. The multivariate analysis showed that patients who died were older, had worse scores and were less likely to be intubated and sedated before admission, 72 vs 28%. There were significant differences, P < 0.005, when the initial CT severity according to the Data Bank score was ≥ 3 (40% mortality versus 10%, P=0.001), age more than 65 years, and when patients were not sedated or intubated before admission. No significant differences were found concerning mortality when the APACHE II was more than 15 or When the GCS score on admission was less than 8. The multivariate analysis showed that Data Bank score more than 3 and age more than 65 years were an independent risk factor for death (OR 1.9, P 0.001, CI 95% 1.3–1.9). **Conclusions:** Trauma severity score assessed by Data Bank score had more influence on mortality than sedation and intubation prior to hospital admission.

**1084 SURGERY DOES NOT MEAN STARVATION: THE SAFETY OF EARLY AND FULL TUBE FEEDINGS FOLLOWING PEG PLACEMENT**

Shawna Morrissey1, Nichole Ingalls2, Patricia Souchon3, Paul Chestovich4, Douglass Fraser5, John Fildes1; 1University of Nevada School of Medicine, Las Vegas, NV

**Learning Objectives:** Enteral nutrition plays an essential role in caring for the critically ill trauma patient. Malnutrition is present in up to 40% of intensive care unit (ICU) patients and is associated with an increased mortality. A recent study found that interruption of feeding in the ICU is associated with underfeeding, prolonged hospitalization, and ICU length of stay. One way to provide adequate and timely administration of nutrition is early enteral feeding at goal rate following PEG placement. **Methods:** We performed a retrospective study of all critically ill trauma patients that required PEG placement between February 2013 and April 2014. The patients were placed in two groups: those fed early (≤ 48 hrs) and those fed late (> 48 hrs). The two groups were similar in regards to age, gender, ISS, and mechanism. A second analysis was then performed by dividing the patients into those with enteral feeds started at goal rate and those that were slowly increased to their goal. **Results:** There were a total of 73 critically ill trauma patients that required PEG tube placement. 28 were excluded due to insufficient data, leaving 45 total patients to be analyzed. 15/45 (33%) of patients were fed early and had no associated complications. The early group reached their goal rate significantly faster (14 hrs vs 32 hrs, p-value 0.001). Of all patients who had a PEG placed, 8/45 (18%) had their tube feeds restarted post-procedure at goal, and 5 of these were in the group that had their feeding started early after PEG placement. None of the patients that had post-procedure enteral feeding started early and initiated at goal rate had complications. **Conclusions:** It has been shown that ICU patients are highly susceptible to malnutrition, and the interruption of enteral feeding can have associated morbidity consequences. Our study not only reinforces that it is safe to start enteral feeding early after PEG placement, but that it is also safe to start the feeding at the patients’ goal rate. The utilization of this strategy will provide severely injured trauma patients with the critical calories needed for faster rehabilitation.

**1085 ACUTE RESPIRATORY DISTRESS SYNDROME AFTER TRAUMATIC HEMORRHAGIC SHOCK: MORE THAN JUST VENT SETTINGS**

John Hwabei1, Christine Nembhard1, Tolulope Oyetunji2, Suryanarayana Siram1, Edward Cornel2, Wendy Greene2; 1Howard University Hospital, Washington, DC, 2Howard University Hospital - Dept. of Surgery, Washington, DC

**Learning Objectives:** The cornerstone of management of acute respiratory distress syndrome (ARDS) is ventilator support. We hypothesize that in blunt trauma patients with hemorrhagic shock who develop ARDS, multiple factors serve as a “lethal double hit” and increase mortality risk. **Methods:** The Glue Grant database was analyzed. All patients who developed ARDS were included in the analysis and all further analyses were performed in this subset only. Survivors and non-survivors were compared. Univariate and multivariate analysis were used to determine predictors of mortality. **Results:** Out of 1976 patients, 465 (24%) developed ARDS. The mean age of the ARDS group was 46 years, 72% were males and 89% were Whites. Overall mortality in ARDS was 19.4% compared to 15.0% in those without ARDS (P=0.025). Compared to non-survivors, survivors were slightly younger (45 ± 17 vs. 50 ± 22, p=0.027), had lower multiple organ dysfunction score (7.4 ± 10 vs. 3 ± 3, p<0.0001), higher ER systolic BP (116 ± 31 vs. 108 ± 31, p=0.02), lower ER lactate (4.7 ± 2.6 vs. 5.7 ± 3.0, p=0.001), and received less blood (2677 ± 2343 vs. 4745 ± 5050, p=0.001), crystalloids (12773 ± 6641 vs. 14639 ± 8675, p=0.023) and fresh frozen plasma (915 ± 1124 vs. 1480 ± 1505, p<0.001). Non-survivors were more likely to develop abdominal compartment syndrome (p=0.008), cardiac arrest (p=0.001), DVT (p=0.002) and MI (p=0.12). Predictors of mortality include multiple organ dysfunction score (OR: 1.86, CI 95% 1.3–1.9), cardiac arrest (OR: 32.41, CI: 8.89–118.07, p<0.001) and angiographic embolization (OR: 4.14, CI: 1.74–9.85, p=0.001). Open non-femoral fixation was associated with decreased mortality (OR: 0.276, CI: 0.12–0.64, p=0.002) **Conclusions:** Open non-femoral fixation specifically reduce mortality risk in this patient population. Identifying and addressing the potential differences between survivors and non-survivors and addressing these may improve outcome

**1086 INTENSIVE CARE UTILIZATION OF PEDIATRIC PATIENTS UNDERGOING LAPAROTOMY AFTER ABDOMINAL TRAUMA**

Bruce Tran1, Julia Grabowski2, Mary Hilfiker1, David Shellington3; 1University of California - San Diego, San Diego, CA, 2University of California, San Diego, San Diego, CA, 3University of California, San Diego, CA

**Learning Objectives:** Trauma remains the leading cause of death in children. Despite abdominal injuries accounting for a significant portion of pediatric trauma, our experience has shown that few pediatric patients require operative intervention. Little data is available to describe the course of illness after major abdominal injury in the pediatric population. We hypothesize that abdominal exploration in pediatric trauma patients is rare, but requires significant utilization of intensive care resources. **Methods:** We retrospectively surveyed the pediatric trauma registry at the Rady Children's Hospital of San Diego to identify trauma admissions between July 2006 and December 2013. Patients < 14 years of age presenting to the pediatric trauma bay for evaluation of traumatic injury were included for analysis. Data collected included demographics, mechanism of injury, operative interventions, pre- and post-operative laboratory values, length of stay, ventilator days, vasopressor requirements, and positive bacterial cultures. **Results:** Of 8499 trauma admissions, we identified 55 pediatric patients (0.6%) who underwent laparotomy or laparoscopy after traumatic injury. Common etiologies of trauma requiring abdominal intervention were motor vehicle accident (53%), bicycle accidents (20%) and stabbings (15%). Average time to laparotomy was 19h36m (+/- 5l3h56m). Average ISS of patients requiring surgical intervention was 18.69 (+/- 17.43). Six laparoscopies were performed, of which 4 required laparotomy. Re-exploration was required in 14.5%, 63% of which were planned after damage control laparotomy. 42% of patients required transfusion, 44% of patients required mechanical ventilation for 7.5 (+/- 7.3) days, and 26% of patients required vasopressors for 6.1 (+/- 7.0) days. Intra-abdominal bacterial contamination was found via positive culture in 19% of patients, with
