#### PREFACE

This Memorandum describes some results of research concerned with the preparation of management reports from sample data. It contains tables of sample sizes that should facilitate estimating mean and aggregate values of certain quantities. To mention a few examples, these tables can be used to estimate the value of inventory stored in a particular location, estimate the value of obsolete inventory, estimate dollar value and reliability of an account or accounting statement by examination of bona fide transaction documents, and verify the ledger value of an inventory account.

Complete tables are not reproduced within this Memorandum because of the large number of pages involved. If it seems desirable later on, we may publish additional parts that appear to have a broad application. These tables are limited in their use by (1) statistical considerations relative to underlying assumptions about the shape of the parent population (i.e., normally distributed) and (2) the type of sampling application (i.e., estimating the mean or aggregate unit or dollar values of a specified population).

This study will be of particular interest to the Auditor General, USAF and to other Air Force personnel concerned with the application of sampling techniques.

The author is a consultant to The RAND Corporation and is an Assistant Professor at the Harvard Graduate School of Business Administration. The suggestions and help of Max Astrachan and Murray Geisler, both of The RAND Corporation, are gratefully acknowledged.

#### SUMMARY

This Memorandum presents examples of 16 tables of random sample sizes necessary to estimate mean and aggregate values. The tables provide a readily useful tool for determining an appropriate sample size once the person designing the plan makes certain quantitative statements.

The tables were developed as an aid in using sampling methods to estimate such financial characteristics of a total inventory as its aggregate dollar value or average value per line item stored. The computed tables permit the estimator to select the amount of precision and confidence desired in the estimate of total population characteristics.

Suppose, for example, we desire to estimate the value of an inventory containing 5000 line items, and the precision desired is to be within 5 per cent of the true value, with 95 per cent confidence. If the coefficient of variation is roughly 0.5, then the sample size, according to the tables (e.g., Table 6) in this Memorandum, would be 357 line items or about 7 percent of the items in the inventory. As might be expected, the sample size would vary considerably according to the confidence sought. For the same inventory, if a precision of 5 per cent with 90 per cent confidence were desired, the sample size would fall to 257, and for a 99.9 per cent confidence with the same precision it would increase to 891.

Some advantages of the tables are:

 A person does not have to be trained in statistics to implement an estimation sampling program of this type.

-V-

#### I. INTRODUCTION

Since World War II, considerable progress in sampling theory and methodology has taken place. The successful use of acceptance sampling in statistical quality control encouraged individuals in other professions to consider applying statistical sampling to their own occupations. Frequently they found that transferring knowledge from one field to another was not as simple as it first appeared. In other applications, many sampling problems arose which simply did not fit into the decision framework of traditional industrial quality control.

For example, the accounting profession applied sampling techniques in editing data, controlling the quality of clerical activities, performing tests of transaction documents to estimate error rates, estimating inventory values, aging accounts, etc. To perform these tasks, new techniques had to be developed. Despite the availability of new methodology, successful applications have not been extensive.

This is the case principally because few non-statisticians have the training or the inclination to use unfamiliar and sometimes cumbersome statistical methods, while the statisticians have often been preoccupied with theoretical considerations. Even when the two parties occasionally get together, they find that lay and statistical jargon do not facilitate communication. An excellent example of this is the concept of confidence,\* which to the statistician has a special and restricted definition that probably fits only a small category of the lay uses of that term.

<sup>\*</sup>For a description of the differences in meaning associated with common terms see Nehemiah Jordan, <u>Decision Making Under Uncertainty and</u> <u>Problem Solving: A Gestalt Theoretical Viewpoint</u>, The RAND Corporation, P-2156, December 1, 1960, Section II.

This interdisciplinary communication problem is amplified by the impatience of both parties in learning the other's vocabulary and conceptual framework. To bridge this gap and to provide tools which can be readily used in applications of sampling methods, there have been many recent sampling tables published.\* These tables provide the layman a means of implementing probability sampling techniques without forcing him to become conversant with the complexities of statistical computations.

It is easy to become impatient with laymen who desire to use statistical methods, yet do not wish to understand the finer points of the underlying mathematics. However, this bitter pill must be swallowed. One does not need to know how to dismantle a dual carburetor in order to drive a modern automobile; similarly, the argument goes that it is not necessary to understand the refinements of statistical mathematics in order to use properly constructed sampling tables. The successful use of acceptance sampling tables such as the MIL-STD Series and the Dodge-Romig tables lends credence to this argument.

The tables illustrated in this study are the first extensive set prepared for use in estimating mean and aggregate values.

Vance, <u>Sampling Tables for Estimating Error Rates or</u> <u>Other Proportions</u>, Bureau of Business and Economic Research, University of California, 1961; and Murray A. Geisler, <u>The Sizes of Simulation Samples Required to Compute Certain Inventory Characteristics</u> with Stated Precision and Confidence, The RAND Corporation, RM-3242-PR, August, 1962.

#### II. ESTIMATION SAMPLING

The objective of estimation sampling is to make certain quantitative inferences about the characteristics of the universe\* under study. It is possible to estimate proportion (rate) of error or mean and aggregate values. For example, an inventory of warehouse items could be taken using estimation sampling techniques. From the sample results, a quantitative estimate of the inventory's total dollar value could be made.

In a particular case of this type, if the estimation sample size derived were 357, then that number of inventory line items would be selected at random and their mean dollar value computed. This value would then be converted to the universe value by a proportion or ratio calculation. For example, if the total inventory value were desired, this mean value would be multiplied by 5000 if that was the number of line items in the universe.

In order to determine an appropriate sample size to perform tests like this, certain quantitative statements must be made: (1) the universe must be defined and delineated; (2), (3) the confidence and the precision desired in the estimate must be stated; and (4) the variability in the universe must be estimated. Since the universe is the mass from which the sample is to be selected, two of its characteristics should be determined in the early stages of the sampling process. These are the homogeneity and the size of the mass.

-3-

<sup>\*</sup>The universe is the mass of population whose characteristics are unknown, and therefore must be estimated through sampling.

The universe should be reasonably uniform throughout, both for content and processing (i.e., administrative review and recording flow). In the case study outlined in another paper,\* this was extremely difficult to determine.

Items belonging to different classes or those having materially different characteristics must be segregated for special study. An example of this might be segregation and identification of nonserviceable items from the remaining inventory.

The universe definition includes the determination of its size, which can be found in various ways. For example, internal information is often available (item count, item serial number, and so on) which would give a reasonable estimate of the total universe number. If no such information is accessible, an estimate on the high side should be made. If the mass is not readily divisible into groups, as in the case of a flow of input transactions from a key punch operation or transceiver network, or if the universe is quite large, it is reasonable to assume the universe to be of infinite size. Such an assumption should not have any major effect on the results obtained with the sampling plan. In fact, it would be possible to assume an infinite universe size in all cases, but for smaller groups this is inefficient. Reference to the sampling tables included here will clarify this relationship.

Better information can often be obtained by separating the material under examination into two or more homogeneous groups. Estimates of each group's characteristics can be made on the basis of

-4-

<sup>\*</sup>R. Gene Brown, Inductive Accounting, The RAND Corporation, P-2671, September, 1962.

separate samples, and then combined for over-all analysis. This is the procedure of stratification which usually must be done when the universe has heterogeneous elements that can be subdivided into more homogeneous groups. The decision to stratify is often based on the information developed either from pre-planned tests, or immediately following the selection of the initial sample units when it becomes apparent that more than one group exists. Whether or not it is desirable to stratify the mass, the basic problems relative to definition and delineation of the universe remain those of determining homogeneity and size.

The estimator usually selects both precision and confidence levels judgmentally. Precision specifies the maximum desired difference between the sample estimate and the true, but unknown, universe mean value.\* Confidence level measures the assurance desired that the interval calculated from the specified precision and the sample estimate will contain the actual universe mean value. For example, plus and minus \$500 might be specified as the desired precision for estimating an inventory's mean value; 95 per cent might be the confidence "level". If the resulting sample size were 1,000, it would be expected that 95 per cent of a very large number of samples of size 1,000 drawn from this universe would provide an unbiased estimate of the true mean value within \$500. Then it is reasonable to state that if, from a given sample, the estimated mean value of the universe were \$15,000, the sample would provide 95 per cent confidence that the true universe mean value is included in the interval from \$14,500 to \$15,500.

<sup>\*</sup>If the precision is specified for the aggregate inventory, the precision desired for the mean value is obtained by dividing the former value by the number of items in the universe.

For the majority of the samples possible from this universe, the sample mean estimate will actually be much closer to the true value than \$500. This is true because estimates of mean or aggregate values from a series of samples drawn from one universe will tend to be distributed normally about the actual unknown value, so that there is more sample clustering in the middle of the precision range than at its ends.

The degree of variability existing among the individual values within the universe is the final quantitative determination required. Variability is usually expressed in terms of the standard deviation. For the sampling tables in this Memorandum, we have to use the socalled coefficient of variation, which is the universe mean divided by the universe standard deviation. Since both the mean and the standard deviation are usually unknown, we have to estimate them. A procedure for doing this follows.\*

We select randomly from the universe a pilot sample of about 30 to 50 line items, and compute its mean and standard deviation. With these data, we can then estimate the coefficient of variation. If the pilot mean is \$138.46 and the pilot standard deviation is \$25.50, the coefficient of variation to be used is 25.50/138.46 = 0.2.

In using the sample size tables, it will also be necessary to convert the absolute precision desired to relative terms. To do this we take the precision desired for the estimate of the mean value and divide it by the pilot sample mean. Thus, if the absolute precision

-6-

<sup>\*</sup>Much of the statistical development contained here has been drawn from L. L. Vance and J. Neter, <u>Statistical Sampling for Auditors</u> and Accountants, John Wiley and Sons, Inc., New York, 1956.

desired is \$10.00, and the pilot mean value is \$138.46, then the relative precision is 10.00/138.46 = 0.07 or  $\pm 7$  per cent.

Once we draw the pilot sample and make the required calculations, we have the data necessary to use the tables in the Appendix. To recapitulate, we have to know: (1) the universe size, (2) the absolute precision desired in estimating the universe mean, (3) the confidence desired in the estimate, (4) the pilot sample mean, (5) the pilot sample standard deviation. With these data, we can use the procedure illustrated in Sec. III for obtaining the required sample size from the tables.

#### III. USING THE TABLES

For purposes of illustration, assume that we want to estimate the total dollar value of the ending inventory for a given accounting period. This estimate will be used as a check on the reliability of the value shown in the general ledger.

We took a small pilot sample to provide quantitative data concerning the universe characteristics. Following this, we made decisions concerning the other parameters required to select the sampling plan. Suppose the following data were then available:

Universe size	4	,896
Pilot sample estimate of mean	\$	430.19
Pilot estimate sample of standard deviation	\$	212.65
Confidence level desired		95%
Absolute precision desired in esti- mating true mean	\$	20.00

With the above information, a sample size can then be computed or can be obtained from tables like the ones in this Memorandum. In order to use the tables, the data must be arranged to correspond to the values required to enter the tables. This results in the following:

Universe size (rounded up)	5,000
Confidence level	95%
Relative precision (\$20/\$430.19)	<u>+</u> 5% (rounded up)
Coefficient of variation (\$212.65/\$430.19)	0.5 (rounded up)

Referring to Table 6 in the Appendix, we find that a sample of 357 line items selected at random from the 4,896 item universe would satisfy this sampling plan. It is interesting to note how the sample size would change when different levels of confidence and precision are specified for the same universe size and coefficient of variation. Referring again to the tables, a universe of 5000 items and a 0.5 coefficient of variation yields the following sample sizes for the confidence levels and precision stated:

#### Table 1

Precision (+ & -)			Sample Size
0.050 0.050 0.050 0.050 0.010 0.020 0.040 0.100	90.0 95.0 99.0 99.9 95.0 95.0 95.0 95.0	2 6 10 14 6 6 6	257 357 586 891 3,289 1,623 536 95

EFFECT OF VARYING PRECISION AND CONFIDENCE LEVEL ON SAMPLE SIZE

Thus, comparative costs of different sampling plans can also be easily approximated by perusal of the tables.

Our 357 sample size example indicates the number of inventory items which have to be randomly selected and whose mean value has to be determined in order to estimate the aggregate universe value with desired precision and confidence. Suppose the mean value of the dollar amounts of the 357 items is \$420.82. Multiplying this value by 4,896 yields an estimated total inventory value of \$2,060,334. Compare this to the ending inventory value recorded in the general ledger (e.g., \$2,142,418). Since the difference is less than 4%, the accounting records could reasonably be accepted as representing fairly the actual value of the physical stock on hand. If there were serious disagreement between the sample estimate and the general ledger, several courses of action might follow, the most likely one being that a 100 per cent physical inventory would be taken.

#### IV. STATISTICAL CONSIDERATIONS

As indicated previously, the statistical basis for the sampling approach taken here is given in Vance and Neter.\* We will trace through the derivation of the main formulae used in calculating the Appendix tables. Their results depend upon the underlying statistical assumption that the characteristic measured is normally distributed. Although this requirement is probably not satisfied in all cases, the fact that our interest usually lies in measuring the mean value of some characteristic suggests that, by the Central Limit Theorem,\*\* the normality condition will be reasonably well satisfied for purposes of this application.

We make use of the following notation:

N = population size;

- n = sample size;
- $\sigma$  = universe standard deviation;
- s = sample estimate of universe standard deviation;
- $\mu$  = universe mean;
- $\bar{x}$  = sample estimate of population mean;
- v = coefficient of variation;
- d = absolute precision desired in estimating true mean;
- a = relative precision desired; and
- $t_{\alpha}$  = normal deviate corresponding to desired confidence level (thus,  $t_{\alpha}$  = 1.96 for confidence level of 95 percent)<sup> $\alpha$ </sup>.

\*Ibid., particularly Chapter 10.

\*\*William Feller, An Introduction to Probability Theory and Its Application, John Wiley & Sons, Inc., 1959, Chapter 10.

-11-

The standard deviation of any population distribution can be defined as

$$\sigma = \sqrt{\frac{\sum_{i=1}^{N} (x_i - \mu)^2}{\frac{1=1}{N}}}$$

Since the true standard deviation of the universe is not known, it is usually estimated on the basis of a pilot sample of from 30 to 50 items. The pilot sample estimate of the population standard deviation is obtained from

$$B_{p} = \sqrt{\frac{N-1}{N}} \sqrt{\frac{\sum_{i=1}^{n} (x_{i} - \bar{x}_{i})^{2}}{\sum_{i=1}^{n} (x_{i} - \bar{x}_{i})^{2}}},$$

where  $s_p$  = standard deviation of the pilot sample,  $\bar{x}_p$  = mean of the pilot sample, and  $n_p$  = pilot sample size. Once  $s_p$  is obtained, the standard deviation of the distribution of the sample mean for sample of size n can be estimated from the following formula:\*

$$\mathbf{s}_{\mathbf{X}}^{-} = \sqrt{\frac{\mathbf{N} - \mathbf{n}}{\mathbf{N} - 1}} \frac{\mathbf{s}_{\mathbf{p}}}{\sqrt{\mathbf{n}}} \cdot \mathbf{s}_{\mathbf{p}}$$

Solving the formula above for n gives

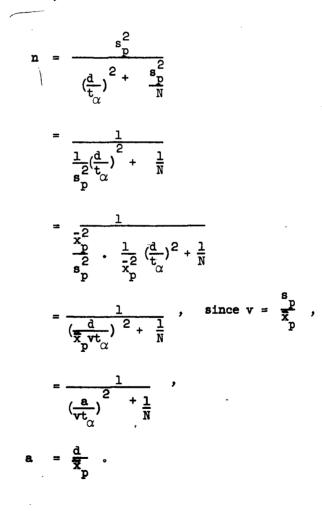

• n = 
$$\frac{\frac{N}{N-1} s_p^2}{s_x^2 + \frac{s_p^2}{N-1}}$$

\*Vance and Neter, op cit, p. 193.

Or, since N is large and the absolute precision desired, d, can be set equal to  $t_{\gamma}s_{\tilde{x}}$  for confidence level  $\alpha$ ,

(1) 
$$n = \frac{s_p^2}{\left(\frac{d}{t_\alpha}\right)^2 + \frac{s_p^2}{N}}$$

The formula can also be stated in relative terms, using the coefficient of variation. From above, we have:

where

Finally, to facilitate computation, we can invert the formula to obtain:

(2) 
$$\frac{1}{n} = \left(\frac{a}{vt_{\alpha}}\right)^2 + \frac{1}{N}$$

We have used (1) and (2) to compute the sample sizes with the data presented earlier in this Memorandum. These data were:

> Universe size ...... 4,896 Pilot sample estimate of mean ..... \$430 Pilot sample estimate of standard deviation ..... \$213 Confidence desired ...... 95 per cent Absolute precision desired..... \$20

From this information, we find that a = 0.05, v = 0.5, and  $t_{\alpha} = 1.96$ . Substituting these values in (1) gives n = 369, and in (2) gives 373. From Table 6, n = 367. The differences are due to rounding errors.

# V. BREADTH OF THE TABLES

The tables illustrated in this Research Memorandum are extracts of complete ones which were programmed and run in the Data Services Division at Norton Air Force Base. The tables reproduced herein are incomplete as to all values computed and were selected merely to illustrate the ranges of some of the computations.

The actual range of values in the complete tables is as follows:

### Table 2
