ABSTRACT

The stress level in the milled skin at the root of a tapered, multicell swept wing is predicted by means of a matrix-force method. The solution is achieved by minimizing the internal strain energy, and the results compared with experimental tests. A single loading, consisting of a nose-up couple, is applied to each tip rib. The loading is transferred from the tip rib to an idealized structure by means of simple torsion theory. The idealized structure represents the inboard one-half of each semi-span.

Results indicate that an accurate solution of the stress distribution in the actual wing can be achieved provided that the root boundary conditions are preserved. An extension of the analysis is suggested in order to more closely define the maximum accuracy inherent in the particular matrix-force method of solution.

FWD I B	Forward intermediate beam
F_n	Panel edge force in line of intermediate rib
F_p	Panel edge force normal to intermediate rib
f_n	Panel edge stress in line of intermediate rib
f_p	Panel edge stress normal to intermediate rib
f_s	Shear stress obtained from Equation (1)
$[G]$	$[CJ]$ matrix augmented by trivial relations
G	Shear modulus

GF	Strain Gage factor
$[H]$	Strain energy matrix
L	Spanwise length, inches
P	Axial force in bars, pounds
$\{P\}$	Column matrix of applied loads
q	Shear flow, pound/inch
R	Resistance, ohms
RB	Rear beam
RIB	Rear intermediate beam
$[S]$	Stress coefficient matrix
S	Linear distance along perimeter of cut section, inches
T	Torque, inch-pounds
t	Thickness, inches
U	Internal strain energy
V	Constant d.c. voltage source
V_o	Wheatstone Bridge output voltage
w	Panel edge length, inches
x_w	x-axis coordinate of wing, inches
y_w	y-axis coordinate of wing, inches
ϵ	Strain, micro-inches per inch
θ	Angle of twist
μ	Poisson's ratio
σ	Normal stress
τ	Shear stress

ϕ_p	Angle of principal axis measured from either y-axis of aircraft, or first gage of rosette.
Λ_{cib}	Sweep angle of CIB
Λ_p	Average sweep angle of panel
$\begin{bmatrix} \end{bmatrix}$	Square or rectangular matrix
$\begin{bmatrix} \end{bmatrix}$	Row matrix
$\{ \}$	Column matrix

INTRODUCTION

Highly swept wings of low thickness to chord ratios were first built with conventional stringer sheet methods. This introduced the problem of how to successfully predict and then to relieve the severe concentration of stress along the rear spar and aft root section skin.

The stress concentration was reduced somewhat by shifting to multi-cell construction. Multi-cell construction as used herein describes wings having closely spaced spanwise spars or webs, and relatively few streamwise ribs.

Wing analysis by customary beam bending and torsion methods was unable to accurately account for the root area stress levels unless modification factors were used. This was due primarily to the neglect of bending-torsion inter-action. However, as flight speeds increased and aspect ratios decreased, the inability of beam theory to properly define chordwise deformations caused even greater concern since thermo-aeroelastic problems replaced static stressing in order of importance.

In order to properly account for bending-torsion inter-action, chordwise curvatures, shear deflections, the increasing use of large cut-outs, and very heavy milled skin, several alternative methods of analysis have been developed. Without considering the older relaxation techniques and their iterative solutions, each depends

upon the use of a digital computer for solution. Each attempts to achieve a mathematical model which exhibits a properly deformed shape having absolute displacements comparable to the actual case.

The most prevalent of these methods treat the structure as an assemblage of elastic components, which allows matrix formulation of the solution in terms of the various energy theorems. Argyris (Ref. 1) has shown that these energy theorems derive from the two fundamental principles of virtual displacements and virtual forces, both of which originated in the work of Maxwell, Mohr, and Engesser. Since both principles are independent of elastic laws or the structural material, their application to non-linear problems or to structures where initial thermal strains exist is quite easy.

The "matrix-force" method leads to an analysis in terms of forces as the unknowns, while the "matrix-displacement" method leads to an analysis in terms of displacements. Either method provides for exact satisfaction of equilibrium and compatibility in a structure made up of discrete elements. Simplification of structural modifications during the preliminary design stage is an additional advantage which accrues from the use of discrete elements.

Each method is again categorized as to whether "lumped-parameter" or "finite element" idealization of plane panels is used. "Lumped-parameter" idealization as used herein allows distinct properties of the structure, such as direct stress, shear, bending and torsion, to be separated or concentrated at discrete locations. The web or panel may be attached to the adjacent flanges at corners, mid-points of the panel, or continuously. "Finite-element" idealization prescribes plane panels of either triangular or rectangular shape, to be attached at corners or nodes of the structure. In either idealization, panel warping must be avoided, even by slightly revising the geometry of the structure, in order to achieve a rigorous solution.

Although a complete solution, giving both forces and displacements, may be obtained from either the matrix-force or matrix-displacement method, it has been shown in Ref. 2 that if only forces are of interest, the matrix-force method is the most efficient. Conversely, if only deflections are of interest, the matrix-deflection method is the most efficient.

The degree of redundancy in the force method is less than for the displacement method. However, the stiffnesses of the elements, as used by the displacement approach, are easier to obtain than are the flexibilities of elements

required by the force approach. The force method has the additional disadvantage of neglecting Poisson's effect for that portion of the axial-load carrying skin which is lumped with the beam flanges.

Argyris (Ref. 3) has shown that while the force method is nearly always more suitable for fuselage analysis, the displacement method may often be more convenient for the analysis of complex wings, since in the displacement method structural "node points" specify the matrix size. This generally results in smaller matrices than would be required to obtain similar accuracy by the force method.

Current literature abounds with instances where the two methods, each formulated several ways, have been applied to laboratory specimens. This allows some study of parameter effects, but allows no true indication of the method applicability to an actual wing which may possess extreme and sometimes abrupt variations in skin thickness, discontinuous spars, massive ribs, skin and web cut-outs, and taper.

It is the object of this report to compare predicted stress and strain levels near the root of an actual wing (which possesses all of the aforementioned analytical obstacles) with the stresses and strains obtained experimentally. The specimen to be analyzed was obtained from a Mach 2.5 all-weather fighter project which was canceled

by the U. S. Navy before the structural test program was completed. The matrix-force method of analysis is used, and consists of a "lumped-parameter" structural idealization as proposed by Wehle and Lansing (Ref. 4). The matrix formulation of the solution is similar to the scheme proposed by Lang and Bisplinghoff (Ref. 5) and organized in considerable detail in Ref. 6. This formulation allows efficient use of the digital computer and at the same time allows intermediate results to be printed out for study. This characteristic makes changes to the structural idealization relatively simple to incorporate, and causes the effect of such a change to be readily apparent. Thus from the outset it was recognized that a follow-on analysis, using the same digital computer program, would allow investigation of the boundary conditions, and indicate the merit of the idealization with only limited additional effort.

This work was conducted at the U. S. Naval Postgraduate School, Monterey, California, during the 1962-1963 school year. The authors are deeply indebted to Professor C. H. Kahr, who conceived the need for such an investigation. Professor Kahr, together with Associate Professor U. Haupt, rendered invaluable assistance and encouragement throughout the project. The authors express their gratitude to Aeronautical Laboratory Supervisor R. E. McConnell and

assistants R. A. Besel and R. O. Cunningham, whose cooperative efforts were so essential in the procurement, fabrication and installation of all experimental apparatus. Appreciation is also expressed to Chance Vought Aircraft, Inc., for their cooperation in furnishing essential data.

II THEORETICAL ANALYSIS

1. General

The structure chosen for the analysis was the wing center section of an F8U-3, as shown in Fig. 1 below. This section consists of seven spars and one post beam per semi-span, upper and lower milled skins, two massive pivot ribs closely spaced about the aircraft center line, two intermediate ribs, and two heavy wing fold ribs located at the extremities of the center section.

Fig. 1
Sketch of F8U-3 Wing Center Section

The first requirement for the analysis was to study the pictures and drawings of the dis-assembled wing in order to establish a basis for simplifying assumptions. These simplifications would be necessary to enable representation of the structure by a mathematical model

consisting only of axial-load carrying bars and plane, shear carrying, constant thickness panels.

The first simplification was introduced by considering the pivot rib to be the root location. The pivot rib was thus assumed to be infinitely stiff and free of chordwise bending. This step was taken to simplify the mathematical model, reducing by 16 the number of components to be analyzed. This would undoubtedly reduce the accuracy of the solution. However, the effect should be predictable, and once the reduced solution is achieved, incorporation of the center section (pivot rib to aircraft center line) would require comparatively minor additional effort.

A post beam, shown in Fig. 1, extended from the pivot rib ("root") to the intermediate rib in the actual wing. Since no shear web was involved, the post beam was removed from the idealized structure and its flange area distributed to the surrounding structure. The posts themselves were ignored. The remaining structure was then represented by axially loaded bars and flat shear panels of constant thickness, as shown in Fig. 2.

It was then necessary to determine the cross-sectional areas of the bars and the thickness of the shear panels. This was done for the bars at the cross-sections located at stations $y_w = 25.095$ and $y_w = 81.98$, Fig. 3. A bar end area included the existing flange area, and the total skin

Fig. 2
Perspective of
Idealized Model

Fig. 3

GEOMETRY OF STREAMWISE CUTS
AT $y_w = 25.095$ AND $y_w = 81.98$

area perpendicular to the bar, taken from the center of the panel just ahead to the center of the panel just behind, as shown in Fig. 4. Spar web areas were not included. The concentration of axial load carrying skin at the flange locations has the effect of removing lateral contraction of the covers from much of the analysis ($\mu = 0$).

Fig. 4

Distribution of Cover Skin to Beam Flanges

Difficulty was experienced in determining the "average" skin thickness of each of the 14 cover panels due to the span-wise variation of thickness. Chordwise variation in thickness was easier to account for since the aspect ratio of the individual panels was on the order of four. Representation of the multiply tapered skin by panels of average thickness will undoubtedly penalize the accuracy of the analysis.

The un-tapered bars of the intermediate rib were formed by adding to the existing chordwise flanges. The added area consisted of a skin area equal to the local thickness times a plate width (equal to the panel width) distributed evenly on either side of the rib, as shown in Fig. 5.

Fig. 5

Distribution of Cover Skin Area to Rib Bar Area

The dimensions of the resulting elements of the idealized wing are listed in Table I.

2. Loading Method

After establishing the idealized model, it was necessary to establish a means of load application. It must transfer a load identical to the tip-applied load on the actual wing to the idealized model at the intermediate rib. As shown in Fig. 6, a nose-up (the wing is mounted

Fig. 6

Application of Couple to Wing Tip

Fig. 7

Distribution of Loads to
Idealized Wing

inverted) couple perpendicular to the C.I.B. was applied to each wing tip.

Considering only the instrumented wing, this couple must be converted to 12 cover shears, seven vertical web shears, and 14 axial flange loads on a streamwise cross-section (intermediate rib) at station $y_w = 81.98$, as shown in Fig. 7. This was accomplished by assuming simple torsion theory would be satisfactory inboard from the tip to approximately the intermediate rib. This assumption was based upon tests reported in Ref. 7.

The shear flows induced at two cross-sections perpendicular to the C.I.B., and located at stations $y_w = 74.3$ and $y_w = 98.7$, were determined from

$$T = \sum 2 A q \quad (1)$$

The calculations and results are shown in Appendix A. A linear interpolation, using the planform dimensions from Fig. 8, gave the shear flow for each cell, as oriented perpendicular to the C.I.B. These individual cell shear flows were then resolved in stresses along, and perpendicular to, the streamwise intermediate rib at station $y_w = 81.98$. From Mohr's circle of stresses, shown in Fig. 9, there is:

$$\theta = (90 - 2\Lambda)$$

$$f_n = f_s \sin \theta$$

$$f_p = f_s \cos \theta$$

FIG. 8
CENTER SECTION OF F8U-3 PORT WING
(Main Structural Elements)

Fig. 9

Mohr's Circle of Stresses at Intermediate Rib

Applying these stresses to the panel edge along the streamwise rib, and taking average panel thickness t and edge distance w ; the forces F_n and F_p due to streamwise shear stress and stress normal to the rib, f_s and f_p , are:

$$F_n = f_n w t = f_w \sin \theta w t = q_s w \sin \theta$$

$$F_p = f_p w t = f_s \cos \theta w t = q_s w \cos \theta$$

It can be seen that the streamwise component may be carried by the rib flanges. However, the force component perpendicular to the rib, F_p in Fig. 10, cannot be carried by the shear panel and must be separated into a streamwise

Fig. 10

Component of Shear Force
Perpendicular to Intermediate Rib

component, Δq_n , which is additive to the force F_n , and a component Δp taken axially by the adjacent flanges, as shown in Fig. 11.

Fig. 11

Vectorial Relation Between Δq_n and Δp

One-half of the Δp component was assigned to each adjacent flange. The various load components and the resulting applied loads on the idealized model are given in Table II.

Fig. 12
Exploded View of
End Rib

3. Element Loads

Loads were assigned to the individual structural components as shown in Figs. 12 and 13. Only the redundants and sufficient loads to define the individual member flexibilities and general state of stress were included.

The statically determinate system was defined by making cuts inboard of the intermediate rib at station $y_w = 81.98$. By "cutting" the five interior beam webs and all flanges except the lower front and two rear flanges, a minimum determinate and stable structure was obtained. A cross-section of the determinate structure is shown in Fig. 14.

Fig. 14
Cross-section of Determinate System

Since the intermediate "tip" rib at station $y_w = 81.98$ was considered to be determinate, there were 16 redundant and 33 determinate loads. The load numbering system shown in Fig. 13 was established in order to facilitate organization of the analysis method, and to assist in conditioning a matrix for later inversion. Applied loads are therefore numbered P_1 through P_{33} , and the determinate reactions are numbered a_1 through a_{33} . The redundant loads were then assigned numbers a_{34} through a_{49} .

Shear panel edge loads were proportioned by first assigning a unit shear force to the outer edges of all cover panels and beam webs. Unit shear loads were assigned to the forward edge of the rib webs. By representing a typical panel as shown in Fig. 15, where a_i is the unit load, there is:

$$a_b = a_i \frac{l_b}{w_c}$$

$$a_c = a_i \frac{w_i}{w_c}$$

$$a_d = a_i \frac{l_b}{w_c}$$

Fig. 15

Proportioning of Panel Edge Loads

The geometry of the panels and the ratios necessary for determining the loads are shown in Table III.

4. Bending Torsion Interaction

Interaction between bending stresses and cover shears was accounted for by the method reported in Ref. 4. Swept panels were assumed to have parallel edges, as shown in Fig. 16. A rectangular panel was then formed with a constant shear flow equal to the average of the end shear flows, as given in Fig. 13.

Fig. 16

Allowance For Interaction of Bending Stresses and Cover Shears

The triangular segment remaining was placed in equilibrium by reacting one-half its spanwise component at each spar cap by the load P , where

$$P = q w \sin \Lambda_p$$

Interior spar caps receive a contribution from panels on either side. These loads are shown by dashed arrows in Fig. 13.

5. Equilibrium Equations

Since the redundant loads were to be obtained by minimizing the internal strain energy, 33 independent equilibrium equations were required to establish the load distribution in the determinate structure. Because there were more than 33 members in the structure, some choice was available in writing the equilibrium equations. It was decided to avoid where possible the writing of equations for those members or combinations of members where it was likely a small load would be applied or resisted.

The first six equations were obtained by expressing the equilibrium of the entire model in relation to the axis system chosen:

$$1.) \sum F_x = 0$$

$$2.) \sum F_y = 0$$

$$3.) \sum F_z = 0$$

$$4.) \sum M_{xx} = 0$$

$$5.) \sum M_{yy} = 0$$

$$6.) \sum M_{zz} = 0$$

Using the right-hand rule, each applied load and its "external" reaction may contribute incremental moments according to

$$\Delta M_{xx} = (F_z)_i Y_i - (F_y)_i Z_i$$

$$\Delta M_{yy} = (F_z)_i X_i - (F_x)_i Z_i$$

$$\Delta M_{zz} = (F_y)_i X_i - (F_x)_i Y_i$$

Cover shears at either end were assumed to act at the forward or top edge of the panel or beam web.

The delta moments are then summed and set equal to zero.

The next eleven equations were obtained from axial equilibrium of the 11 redundant beam flanges, elements 16, 18, 20, 22, 24, 29, 31, 33, 35, 37, and 39.

Ten more equations were obtained from the rib at station $y_w = 81.98$ by considering the equilibrium of inter-beam segments between the R.B. and R.I.B., R.I.B.-A.I.B., A.I.B.-C.I.B., C.I.B.-FWD.I.B., and FWD.I.B.-F.I.B. For a rib segment, looking inboard from the tip, the moments about the y-axis (lower forward corner of the segment) and forces in the x-direction were set equal to zero, giving two equations per segment.

Following Ref. 5, the vertical shear loads in the beam webs, applied at station $y_w = 81.98$ by loads P_1 through P_7 , were assumed to act through seven imaginary posts of unit cross-section, as shown in Fig. 12. The final six equations were obtained by setting all but the F.I.B. post in equilibrium.

This gave a total of 33 equilibrium equations. Each equation was arranged internally so that only the non-redundant (a_1 through a_{33}) loads appeared on the left side of the equation. The applied loads (P_1 through P_{33}) and redundants ($a_{34} - a_{49}$) appeared on the right side.

6. Matrix Formulation

Following the matrix formulation given by References 12 and 13, all at the equilibrium equations can be expressed by

$$[A]_{33 \times 33} \{a_{nr}\}_{33 \times 1} = [B]_{33 \times 49} \left\{ \begin{matrix} \cdot P \cdot \\ a_r \end{matrix} \right\}_{49 \times 1} \quad (1)$$

Solving equation (1) for the non-redundant loads a_{nr} requires the inversion of the matrix of coefficients, $[A]$. Therefore the row order of the 33 equilibrium equations was arranged to favorably condition the $[A]$ matrix by either placing the large terms on the main diagonal or symmetrically placing groups of terms about the main diagonal. This in turn fixed the arrangement of the $[B]$ matrix. The $[A]$ and the $[B]$ matrices are shown in Tables IV and V.

Since there are 16 redundants, 16 additional equations must be obtained by minimizing the strain energy of the system.

From Refs. 4 and 5, the internal strain energy of the structure may be written as

$$U = \frac{1}{2E} [a_1 \dots a_n] [F] \{a_1 \dots a_n\} \quad (2)$$

where elements of the symmetric $[F]$ matrix are the sums of the various member flexibilities. These flexibilities were obtained as shown in Appendix B. The $[F]$ matrix was designated $[UC]$ for the digital computer program, and together with the $[A]$ and $[B]$ matrices, formed the basic structural input to the digital computer program shown in Appendix C.

Referring again to equations (1) and (2) it is necessary to express the strain energy in terms of the external forces and redundant loads.

Equation (1) was re-arranged by taking the inverse of matrix $[A]$, and post multiplying the inverse $[A^{-1}]$ by matrix $[B]$, giving the equation

$$\{a_{nr}\}_{33 \times 1} = [A^{-1}]_{33 \times 33} [B]_{33 \times 49} \begin{Bmatrix} P \\ a_r \end{Bmatrix} = [CJ]_{33 \times 49} \begin{Bmatrix} P \\ \dots \\ a_r \end{Bmatrix} \quad (3)$$

The column matrix $\{a_{nr}\}$ and the $[CJ]$ matrix were increased to 49×1 and 49×49 dimensions respectively, by simply adding the trivial equations

$$\begin{aligned} a_{34} &= a_{34} \\ a_{35} &= a_{35} \\ &\vdots \\ a_{49} &= a_{49} \end{aligned} \quad (4)$$

The augmented matrix $[CJ]$ was then redesignated the $[G]$ matrix.

The transpose of matrix $[G]$ was then taken, allowing the strain energy matrix $[H]$ to be formed:

$$[H]_{49 \times 49} = [G']_{49 \times 49} [F]_{49 \times 49} [G]_{49 \times 49} \quad (5)$$

By substituting equation (5) into equation (2), the internal strain energy may now be written as

$$U = \frac{1}{2E} [P_1 \dots P_{33} \ a_{34} \dots a_{49}]_{1 \times 49} [H] \{P_1 \dots P_{33} \ a_{34} \dots a_{49}\} \quad (6)$$

The strain energy is then minimized by differentiating equation (6) and setting the result equal to zero, according to

$$\frac{\partial U}{\partial a_r} = 0 \quad (7)$$

Since $[H]$ is a symmetrical matrix, it may be shown that the operations of equation (7), as performed upon the expanded form of equation (6), may be expressed simply by

$$\{a_r\}_{16 \times 1} = - [H_{22}^{-1}]_{16 \times 16} [H_{21}]_{16 \times 33} \{P\}_{33 \times 1} \quad (8)$$

The sub-matrices $[H_{22}]$ and $[H_{21}]$ come from the partitioning of $[H]$ according to:

.

$$[H]_{49 \times 49} = \begin{bmatrix} H_{11} & H_{12} \\ \text{pxp} & \text{pxr} \\ \text{---} & \text{---} \\ H_{21} & H_{22} \\ \text{rxp} & \text{rxr} \end{bmatrix}_{49 \times 49} \quad \begin{array}{l} p = \text{applied load} = 33 \\ r = \text{redundant} = 16 \end{array} \quad (9)$$

By defining the product of $[H_{22}^{-1}]$ X $[H_{21}]$ as:

$$[EN]_{16 \times 33} = -[H_{22}^{-1}]_{16 \times 16} [H_{21}]_{16 \times 33} \quad (10)$$

the answers to the redundant loads, as given in the computer program of Appendix C, are:

$$\{a_r\}_{16 \times 1} = [EN]_{16 \times 33} \{P\}_{33 \times 1} \quad (8b)$$

The total loading system is then determined from

$$\{a\}_{49 \times 1} = [S]_{49 \times 33} \{P\}_{33 \times 1} \quad (9)$$

where the matrix $[S]$ is constructed from $[EN]$ and $[G]$ by

$$[S] = [G]_{49 \times 49} \begin{bmatrix} [I]_{33 \times 33} \\ \text{---} \\ [EN]_{16 \times 33} \end{bmatrix}_{49 \times 33} \quad (10)$$

Finally the internal strain energy is written in terms of the applied loads and the flexibility influence coefficients $[C]$ as:

$$U = \frac{1}{2} [P_1 \dots P_{33}] [C]_{33 \times 33} [P_1 \dots P_{33}] \quad (11)$$

By substituting equation (8b) into equation (6), the matrix of flexibility influence coefficients is given by

$$[C] = \frac{1}{E} \left([H_{11}] - [H_{12}] [EN] \right) \quad (12)$$

7. Computer Programming

The solution of equations (1) through (12) was adapted by a FORTRAN program to the CDC 1604 computer. The variable names and abbreviations, flow charts, programs and sub-routines are given in Appendix C.

Considerable effort was required to establish the desired program within the basic computer storage capacity. Any future additions to the main program would require either use of machine language or an input-output program on peripheral equipment.

Print-outs throughout the program were made in order to establish a means for continuing accuracy checks. Although a complete hand solution of one set of data is possible in many computer programs where merely repetitious iterations are done, here only equilibrium of elements and

standard machine inversion checks could be made.

The first machine check was performed by writing a short auxiliary program named CHECK. This confirmed the accuracy of the inversion of the matrix $[A]$ as accomplished by the single-precision Gauss 3 subroutine. The matrix $[CHECK]$ was formed from

$$[CHECK]_{33 \times 33} = [A]_{33 \times 33} [A^{-1}]_{33 \times 33} = ? \begin{bmatrix} 1 & & & & \\ & 1 & & & \\ & & \ddots & & \\ & & & \ddots & \\ & & & & 1 & \\ & & & & & 1 \end{bmatrix}_{33 \times 33} \quad (13)$$

and is shown in Appendix C.

The second check was made by comparing the member loads of the statically determinate structure with values from the $[CJ]$ matrix shown in Table VI. For example consider the statically determinate structure shown in Fig. 17.

Fig. 17

Loaded Determinate Structure For $[CJ]$ Check

From statics a value of a_{22} may be obtained for a unit load P_7 . This should compare with the value $CJ_{22,7}$ in the expression

$$\{a_{nr}\}_{33 \times 1} = [CJ]_{33 \times 49} \left\{ \begin{matrix} P \\ - \\ a_r \end{matrix} \right\}_{49 \times 1} \quad (14)$$

where all terms in the column load matrix are zero except P_7 .

Setting the y-component of a_{22} equal to $(a_{22})_y$, by statics:

$$(a_{22})_y = P_7 \times \frac{(81.98 - 25.095)}{7.20} = 7.900694 P_7$$

$$a_{22} = \frac{7.900694}{.89114} P_7 = 8.86583 P_7$$

From equation (14), and the matrix $[CJ]$

$$a_{22} = P_1 (8.8660330) + \dots + P_7 (8.8660330)$$

which checks well to the fourth decimal.

By similar reasoning, the three non-redundant flanges, elements 14, 26 and 27, should react directly the loads P_{27} , P_{26} , P_{33} .

Applied loads	Reaction by $[CJ]$ matrix
$P_{27} = 1.0$	$a_{21} = 1.0000558$
$P_{26} = 1.0$	$a_{22} = 1.0000268$
$P_{33} = 1.0$	$a_{23} = 1.0000238$

Again considering a unit load at P_7 , the total shear load should be carried by the rear beam web, a_g . From the $[CJ]$ matrix, a unit load at P_7 gives

$$a_g = 1.0103419$$

Consequently, the cover panel shear loads should be zero. From the $[CJ]$ matrix,

$a_9 = .0000646$	$a_{15} = .0000437$
$a_{10} = .0000591$	$a_{16} = .0000471$
$a_{11} = .0000550$	$a_{17} = .0000511$
$a_{12} = .0000510$	$a_{18} = .0000550$
$a_{13} = .0000471$	$a_{19} = .0000591$
$a_{14} = .0000438$	$a_{20} = .0000645$

The next check was to determine the state of equilibrium of each flange and post. For example, the front post of the intermediate rib, station $y_w = 81.98$, Fig. 12, gives

$$1.0000000 - .5981273 - .4018727 = .0000000$$

for a unit load at P_1 . For the seventh post, the result from a unit load at P_7 is also zero. A maximum deviation from true equilibrium of 7.9 percent existed at the second

post from the front. It should be noted that no equilibrium equation was written for this post.

Referring to Fig. 13, a unit redundant load was applied in turn to each redundant flange. The greatest deviation from equilibrium was in element 39, where

$$\text{Error } [CJ] = - 0.0000043 \text{ lb}$$

Table VII contains the results of the CJ matrix equilibrium checks, which completes the check of the basic equations and computer operations on them, as well as the validity of the matrix inversion sub-routine.

A print-out statement was used to determine that proper partitioning of the $[H]$ matrix occurred. Since computer storage space was not available, hand calculations were performed to confirm the proper inversion of $[H_{22}]$.

An interim calculation according to equation (8b) gave the redundant load matrix $\{AR\}$. One of these values was computed by hand as a random check and found to be correct. All 16 values were then checked with the final 16 loads of the $\{AT\}$ matrix obtained from equation (9).

This completed the computer program checks. The program was then run twice and answers compared in order to detect any computer core errors. There were none.

The flexibility influence coefficient, stress influence coefficient, and load matrices, $[C]$, $[S]$, and $\{AT\}$, are listed in Tables VIII, IX, and X.

8. Theoretical Results

Compared with ordinary beam theory solutions, the accurate determination of stresses in an idealized structure by a matrix force method requires considerable engineering judgment. It has been pointed out by Warren (Ref. 9) that errors of one-hundred percent may occur in interpreting the results of such a solution. Therefore the original formulation assumptions were used in determining the results of this analysis.

The investigation was narrowed to determining the average panel stress at station $y_w = 34.5$ from the loads of the $\{A^r\}$ matrix. For each panel, the maximum normal stress, the angle of the principal axis, and the maximum shearing stress were determined. From the components shown in Fig. 18, and noting that the direction of shear flow reflects the minus sign indicated by load a_9 in the $\{AT\}$ matrix,

Fig. 18

Theoretical Root Panel Stresses

the axial load components of the skin were determined. Using the solution formulation data of Table I, the bar loads (excepting a_{10}) were re-apportioned by area ratios to the panels from which the skin came. For panel 38, shown in Fig. 18,

$$\frac{.974}{1.50} a_{44} + \frac{1.03}{3.04} a_{45} + 1.137 a_9 = \text{axial load}_{38}$$

$$.6493(5461) + .3388(8682) + 1.137(-3785) = 2184$$

or, axial panel load = 2184 lb compression. This compressive force, when divided by the panel and cross-section (taken perpendicular to the panel sweep angle, Λ_p), gives

$$\sigma_{\Lambda_p} = \frac{2184}{tw} = \frac{2184}{.145 \times 20.89 \times .73865}$$

$$\sigma_{\Lambda_p} = 978 \text{ psi (compression)}$$

The shearing stress was found by taking the average shearing force, given for either end of the panel by the {AT} matrix, and dividing it by the same tw used in determining the axial stress. The shearing stress and axial stress thus found were resolved by Mohr's circle to a

maximum principal stress, $\sigma_{\max}$, a maximum shearing stress, $\tau_{\max}$, and the angle of the principal axis, ϕ_p . These stresses and angles, as listed in Table XI, refer to the mid-plane of the skin, since average values are used for their determination. These values are shown graphically in Fig. 25.

The vertical deflections of the intermediate rib (station $y_w = 81.98$) end points were calculated from the deflection influence coefficient matrix $[C]$ by applying the theoretical vertical loads P_1 through P_7 . At the forward end of the rib (load point for P_1) the deflection was $+ .0601$ in. At load point seven, the deflection was $-.0647$ in. These values are plotted in Fig. 26.

III EXPERIMENT

1. Introduction

In order to determine the actual stresses and compare them with those predicted by theory, an experimental investigation has been carried out on the full scale F8U-3 wing acquired from Chance Vought Aircraft, Incorporated. The experimental set-up was also designed to provide the Aeronautical Structures Laboratory of the U. S. Naval Postgraduate School with a permanent specimen of modern wing construction mounted such that a variety of test-to-theory correlation experiments could be academically demonstrated.

The F8U-3 wing was structurally complete in every detail and was representative of current doubly tapered multi-cell swept wing configurations. It was divided into three major sections, the center section which extended to the wing fold rib at wing station $y_w = 152.25$ and an outer panel on either side. For this experiment the two outer panels were removed along with the leading edges and those portions of the trailing edges outside of the main structural box that were not integrally connected with its single piece skin. Hereafter the term wing will refer to the main structural elements of the center section which consisted of seven spars, hereinafter called beams, and two streamwise ribs. The section was a typical thick

milled skin construction and the skins were tapered along the span as well as in the chordwise direction.

Structural behavior was investigated with the wing subjected to two pure torque loads applied perpendicular to the elastic axis at the wing fold rib. The elastic axis is defined by the curve connecting the shear centers of all sections of the wing. Its position was taken from manufacturer's data as shown in Fig. 8. The torque loads were applied to each wing fold rib by hydraulic cylinders actuated from a common pressure manifold. The load magnitudes were measured by dynamometers connected in series with each cylinder and the torque was then easily computed knowing the fixed lever arm. Nominal torque values of 294000 in. lb and 336000 in. lb were used. These were well within the elastic range but still of sufficient magnitude to give adequate strain levels throughout the structure for repeatably accurate measurements.

Some electrical strain gages were already installed by Chance Vought Aircraft, Incorporated, at various locations, but for the purposes of this and future investigations additional SR-4 strain gage rosettes of the AR-7-2 and A-7 type were installed in particular areas. Those of immediate interest were located in the skins, beam webs and beam caps around a section perpendicular to the center

intermediate beam at wing station $y_w = 98.7$. From the wing fold to this point the elastic axis remains nearly parallel to the center intermediate beam which was used as the reference axis of the wing. Other rosettes were located around a streamwise section near the root at wing station $y_w = 34.5$. Here rosettes were placed on both sides of the very thick skin to check for differential bending effects. It was expected that the stresses that are unpredictable by simple beam theory in this area would show closer agreement with the predictions of the matrix force method of analysis. Strain gage data was programmed into a digital computer to obtain principal stresses and directions at all rosette locations.

Deflections were measured by means of scales hung from the structure along the front and rear beams and read by a transit. Jig support deflections were also measured in this manner.

2. Equipment

The variable incidence swept wing was of a conventional multi-cell construction with a quarter-chord sweep back of 42 degrees. The main structural elements are shown in Fig. 8. Fig. 19 is a photograph of the wing with the upper skin removed. Attachment was made to the fuselage at approximately wing station $y_w = 25$ by two pivot lugs located approximately 5.3 inches aft of the main box rear beam,

two bumpers located at the main box front beam and two incidence actuators located approximately 17.8 inches forward of the main box front beam. The wing fold at wing station $y_w = 152.25$ was accomplished by fittings with multiple upper and lower lugs. The upper and lower surfaces were single piece thick skins tapered along the span and chord. The front beam had numerous supporting lugs integrally machined into the beam giving it a very discontinuous variation of thickness. The structure primarily consisted of 7079-T6 thick skins and forgings with 7075-T6 sheet metal beams.

The wing was mounted inverted on a rigid support jig and fastened to it at four points, the two fuselage pivot lugs and the two points on the main box front beam directly opposite the bumper points. Plywood pads were used under the jig to distribute the loads to the laboratory floor. A photograph of the mounted wing is shown in Fig. 20.

The torque loads were applied through a fitting connected to the wing fold lugs as shown in Fig. 6. The fitting assembly was designed to provide a loading plane perpendicular to the plane of the wing and the elastic axis. It consisted primarily of mild steel parts designed to develop the ultimate strength of the wing fold lugs. A limiting torque of 420000 in. lb was selected which was well below the design ultimate at this station but still high

enough to ensure adequate strain levels in the wing. A 42 inch lever arm was used to permit attainment of the 420000 in. lb of torque with loads of only 10000 lb. This enabled the use of available 10000 lb dynamometers which were graduated in 100 lb increments. Instruments of larger capacity had 250 lb increments.

Only the port wing was instrumented but the torque was applied to each wing fold station for balance and to minimize warping of the structure and support jig. Each of the four loads were applied through a series linkage of attachment fittings, clevises, hydraulic cylinder and dynamometer as shown in Fig. 21. The four hydraulic cylinders were high pressure wing fold actuators and were simultaneously subjected to pressure from a common manifold to insure load equalization. Except for the dynamometers each linkage was designed for 30000 lb and was pre-tested to 15000 lb before installation.

Load magnitude was determined and monitored by two separate means. On the instrumented wing two 10000 lb Dillon Dynamometers were used to monitor equality of individual loads. They were graduated in 100 lb increments but could be accurately read to 10 lb. The final load magnitudes were determined by hydraulic manifold pressure related to pressure-load calibration curves for the cylinders as found in Appendix D. The hydraulic gage was

mounted at the data taking station and provided an excellent means of setting the load and monitoring the consistency of its magnitude throughout the run. It was a 1500 psi gage graduated in 10 psi increments and could be accurately read to 5 psi.

The dynamometers and the hydraulic system were calibrated on a 300,000 lb Riehle Tensile Testing Machine (Appendix D). The Reihle machine had exhibited a maximum calibration error of only 0.35 percent over the entire 300,000 lb range, but showed no error in the range of 7000 lb to 9000 lb, which was of concern in this case. Therefore the calibration curves represent variation from absolute values.

The up-load linkages were anchored to a three column supporting structure shown in Fig. 21. The base of this structure was arranged to accommodate attachment of the down-load linkage thereby minimizing strength requirements of the base elements. Considering future uses of this structure the base was located approximately in the plane of the load fitting such that single point loads could be applied anywhere along its reach and be readily anchored with a minimum of effort.

Hydraulic pressure was supplied by an electrically driven Vickers V-line Piston Type Pump shown in Fig. 22. It was rated at 5000 psi, 1800 rpm and 1.72 cu in. per

revolution. By means of a pressure compensator in conjunction with a volume limit hand control and relief valve, pressures could be held within 5 psi of any desired setting for long period of time and with very few adjustments. This feature enabled accurate repetition of the same loads which was essential in the data taking process.

All strains were measured with SR-4 strain gage rosettes manufactured by Baldwin-Lima-Hamilton Corporation. In Appendix E is a list of the 485 gages, their gage factors, resistances and coordinate locations in the wing. The types of gages installed by Chance Vought Aircraft were deduced from resistance tests and inspection. They were all of the AX-5 or AR-1 type. The gages installed for this experiment and for future multi-purpose investigations were either of the AR-7-2 or A-7 type. The gages of particular interest to this investigation are depicted in Fig. 23. Selected root skin rosettes are backed-up on both sides of the skin. Although additional back-up rosettes were desired throughout the inboard panels, they could not be installed because of time, laboratory priority and monetary considerations. Note that all of the gages have a gage factor very close to 2.0 and resistances of 120 ohms. This enabled the use of a single temperature compensating gage and facilitated reading all gages without adjusting any of the other instruments.

Selectivity in reading any combination of gages was made possible by routing all gage leads to a junction panel as shown in Fig. 24. Any number of gages could then be connected into either switching and balancing units or automatic scanning devices as future needs dictate. All electrical connections were soldered to minimize contact resistance except for the banana plug connections between the junction panel and the switching and balancing unit.

A 20 channel Baldwin-Lima-Hamilton Switching and Balancing Unit was used. It was connected to an external Wheatstone bridge circuit powered by a Hewlett Packard Power Supply (Model 721A). A constant 6 volts was used throughout the tests. The bridge output was amplified, then fed into a voltage-to-frequency converter and displayed as strain in units of micro-inches per inch by an electronic counter. Calibration of this equipment proceeded each run and the method is described in Appendix F.

The electronic counter was a Model 521DR manufactured by Hewlett Packard Corporation. The voltage-to-frequency converter was a Model DY-2210 manufactured by Dymec Incorporated and the amplifier was a Kintel Model 111BF. By using the electronic counter, readings could be taken faster and more accurately than with the common strain indicators. Strain indicators can normally be read to about 5 micro-inches per inch, whereas the electronic counter

indicates strains to one micro-inch per inch.

Wing deflections were measured by means of scales hung at intervals along the front and rear beams and read by a transit manufactured by Keuffel and Esser Company. The scales were graduated in .02 inch increments but could be read to .005 inch. The locations of the scales are shown in Fig. 8. Note that a single scale could be paired with one of two others such that either a streamwise chord or a section perpendicular to the center intermediate beam would be defined. For instance, scale numbers 8 and 7 define the test section perpendicular to center intermediate beam at wing station $y_w = 98.7$ and number 8 and 11 terminate the streamwise rib at wing station $y_w = 81.98$. This was believed to be of use in future investigations.

3. Experimental Procedures

The experimental procedures consisted of two tests, in each case a different magnitude of torque being applied at the wing fold rib. In the first test a nominal 294000 in. lb was applied and 336000 in. lb in the second test. These values were initially attained by dynamometer indications of 7000 lb and 8000 lb respectively, which will be the names of the two tests hereafter. The purpose of the 7000 lb test was to establish reliability of the entire 485 strain gages and to check for linearity of strain readings in the structure. The 8000 lb test was accomplished

to correlate the theoretical results. Therefore in the 8000 lb test attention was focused on approximately 150 gages of particular interest.

The procedure in conducting the tests was straight forward, but because of the large number of strain measurements the tests took considerable length of time. Only 20 gages could be read during any one run because only one switching and balancing unit was employed. Additional units were tried but the added wiring and connections, resistance peculiarities inherent in each unit and prolonged time required to adjust initial zeroes, produced an unacceptable drift in the zero rechecks. On the other hand load repeatability was very accurate and therefore a single unit was used and the number of runs increased. The sequence of operation for each run was as follows:

1. The electronic counter was calibrated before each series of runs and rechecked after completion.
2. The switching and balancing unit leads were plugged into 20 gage terminals at the junction panel.
3. All strain gages and dynamometers were zeroed.
4. The hydraulic loads were applied and adjusted by reference to previously known values of hydraulic pressure and strain gage readings from the same check gage used in each test run.
5. The dynamometers were read and compared with each

other to insure that equal couple loads were being applied to each wing.

6. The strains were read and recorded twice.

7. The loads were removed.

8. All zero values of strain were re-checked and recorded.

Extreme care was employed to achieve load and strain repeatability. The electronic counter was calibrated before each run and checked afterwards. A maximum departure from linearity over a range of 1000 micro-inches per inch was only 5 micro-inches per inch. The average departure was closer to 2 micro inches per inch. This effect on maximum strain levels encountered (approximately 200 micro-inches per inch) was therefore quite negligible.

In addition particular care was exercised to minimize the strain gage zero drift. For instance, the variable temperature effects of sunlight and outside electrical interference with the sensitive instrumentation were virtually eliminated by conducting all tests at night. At least one hour warm-up time was given all instruments to insure steady state conditions. All initial zeroes were re-checked three times before loading. All permanent electrical connections were soldered to minimize contact resistance and, as a double precaution, a test was repeated

if any electrical leads had been disturbed or if the voltage supply varied any time during the run. By reading only 20 gages per run the time per run was minimized, thereby reducing the critical time the system would be exposed to outside effects. Two strain readings at load were taken also as a double check. With such care, average zero rechecks within 1.5 micro-inch per inch were continually demonstrated.

Two strain gages were selected to act as cross-checks on the repeatability of the loads, results and test conditions. Gages 32 and 53 were monitored in each test run. The magnitudes of strain on each run were then compared to the original values. In over 40 runs the average departure from mean values of the check gages was only 1.39 micro-inch per inch. The mean value for gage 53 in the 8000 lb test was 178.6 giving an error of only 0.78 percent. Since the hydraulic pressure reading required to produce this strain level was always the same the load repeatability was also within an accuracy of one percent.

Accuracy of measuring the absolute load magnitude was then dependent only on the accuracy of the dynamometers and hydraulic pressure gage. During the weeks of testing, difficulty was encountered in re-setting the dynamometers to the same zero. Also there was noticeable differences

in readings under load conditions which verified suspicions of unreliable zero settings. On the other hand the hydraulic pressure gage readings checked consistantly with strain gage 32 and 53 readings and therefore the pressure gage was felt to be more reliable in establishing magnitudes of applied loads.

Deflection measurements were made for only the 8000 lb test condition. Since this loading condition and consequently the deflections were repeated over 20 times it was deemed necessary to only sample the deflections periodically throughout the test series. Although more deflection measurements were taken to ensure repeatability in the series only three complete sets of data were recorded.

4. Experimental Results

From the recorded strain data the only calculations required were those involved in determining the principal stresses, maximum shear stress and principal axes at each rosette location. These calculations for all rosettes in the 7000 lb test and those particular rosettes of interest in the 8000 lb test were performed on a Control Data Corporation 1604 Digital Computer. The results along with the FORTRAN program and the measured strains are found in Appendix G.

The data for the 7000 lb test was pertinent to this experiment only to show linearity of strain readings. A sampling of net strain readings from various locations for both loading conditions is shown in Table XII. Satisfactory linearity is demonstrated by noting that the average difference between measured strains for the 8000 lb test and those extrapolated from the 7000 lb test is 2.3 micro-inches per inch regardless of the magnitude of the measurement. The discrepancy is obviously quite small but it would be still further diminished if the accuracy of the applied loads were considered. Therefore it can be concluded that linearity of strain readings was indeed achieved.

Another result of the 7000 lb test was the discovery of 9 faulty rosettes. However none of the faulty rosettes hampered the results of this experiment. The faulty gages are indicated in Appendix E.

Calibration of the hydraulic system after the completion of the tests revealed that instead of 8000 lb, actually 8400 lb loads were being delivered to the linkages. Considering a gage reading accuracy of 5 psi and the slope of the calibration curve as 10.84 lb load per psi hydraulic pressure, the accuracy of the applied loads would be plus or minus 50 lb or 0.6 percent. The difference in desired and achieved magnitudes is not of real importance however

since linearity of strains enables interpolation to the desired values.

Since a degree of uncertainty always exists concerning the extent to which a pure torque loading is realized, an equilibrium check was made at the instrumented section perpendicular to the CIB at $y_w = 98.7$. At this section all rosettes were oriented such that the diagonal gages were at a 45 degree angle to the section, which facilitated shear flow calculations. Therefore theoretically calculated shear flows could be readily checked with experimental results since the theoretical calculations were all ready completed in the determination of the loading for the idealized structure as shown in Appendix A.

The experimental shear flows were calculated by considering only the strains in the diagonal gages. This essentially eliminated the effects of any normal stresses caused by unknown bending loads and the results would better represent the shear flow induced by only the effectively applied torque. From the experimental data for the 8000 lb load, shear flows were calculated using the relation,

$$q = \frac{E t \epsilon_2}{1 + \mu} \quad (15)$$

These results are listed in Table XIII and are labeled on the schematic diagram in Fig. 25. The values of shear flow in the top and bottom skin of the same cell compared closely. The average value of each cell was used as also shown in Table XIII and Fig. 25 and compared to the theoretical values. The theoretical shear flows for $T = 336000$ in. lb were 3.85 percent higher than the experimental values. The total torque resisted was then computed as the sum of the $(2Aq)$ for each cell. This value was 323,785. in. lb which is 8.2 percent lower than the 352,800 in. lb possible with an 8400 lb force acting on a 42 inch lever arm, and 3.6 percent lower than that used in the analysis.

Neglecting the accuracy of the experimental loads and shear flow determination this means that 720 lb of the applied load of 8400 lb was not effective in producing pure torque. In this regard, during the tests there had been visible evidence of streamwise twisting of the wing fold rib and a measured spanwise tilt of the entire wing. There was also an element of uncertainty regarding the exact angle of the elastic axis since it was scaled from a reproduced drawing. Coupled with understandable inaccuracies of maintaining a constant loading plane, perfectly parallel lines of force and a perfectly rigid loading jig, the amount of the bending load component is within reason. Although

no calculations were made to determine the magnitude of the bending component its existence can be qualitatively confirmed by observing the magnitudes of the strain readings for the perpendicular gages at the section being analyzed, namely rosette numbers 131, 46, 49, 52, 55, 58, etc.

Using a torque value of 323,785 in. lb the theoretical shear flows were obtained by interpolating between values computed for the 294000 and 336000 in. lb condition. They are also shown in Table XIII and Fig. 25. As would be expected the comparison with experimental values is very good. The average error in the theoretical shear flows is only 1.95 percent. Considering the loss of effective applied torque the torsional equilibrium check was believed to be quite close.

The computer program described in Appendix G solves the well known rectangular rosette equations for $\sigma_{\max}$, $\sigma_{\min}$, $\tau_{\max}$ and ϕ_p . The input to the program was the value of strain for each gage in the rosette. The lowest numbered gage was consistently called ϵ_1 , the diagonal and perpendicular gages were the next higher numbered gages respectively. The principal axis was then computed with respect to the ϵ_1 axis. To compare these results with theoretical values the orientation of the principal axes were adjusted to the y_w axis of the wing by simple arithmetic.

The root area rosettes used to compare with results of the theoretical root analysis were numbers 13, 19, 28, 367, 279 and 161 on the inside surfaces and back-up rosettes numbers 481, 478, 472, 466, 457, and 484 on the exterior surfaces. Differential bending was readily apparent in all of the root panels as seen in Table XIV by noting the differences of strain in matching gages on opposing surfaces. The effect is less in panel number 21 which lies near the elastic axis. The average of the two gage readings was taken as representative of the strain at mid-thickness of the skin. The values of $\sigma_{\max}$, $\tau_{\max}$ and ϕ_p were then hand calculated using the equations in Appendix G and are listed in Tables XI and XIV and plotted in Fig. 26.

The deflection measurements were of concern primarily in establishing test conditions. In this regard the average values of the total deflections are plotted in Fig. 26. It is clearly shown that the support jig rocks forward and the entire structure tilts right-wing-down. It was also noted during the test that the amount increased slightly with each cycle which indicated plastic yielding of the plywood pads under the support jig. Obviously any tilt would adversely affect the lines of action of the applied loads since the load linkages were positioned to accommodate only one loading plane. This would account for some of the discrepancy in achieving pure torque loads. It would be

wise to consider adjusting the load fittings and linkages such that a more symmetric loading could be realized in future tests. Furthermore it would be advantageous to replace the plywood pads with a more suitable material.

IV COMPARISON OF RESULTS

Extreme care was taken to ascertain strain and load magnitudes and insure repeatability of loads to minimize any experimental error in the determination of the comparatively low stress levels found in the critical root area. All of these errors were kept well below one percent and logically do not appreciably influence any comparison with theory.

The only experimental error that would noticeably affect the final results would be the understandable discrepancy in developing pure torque loading on which the theoretical analysis was based. The equilibrium check at the section perpendicular to QIB. at $y_w = 98.7$ indicated that the torque developed was 3.6 percent lower than that used in the analysis and nine percent lower than actually applied at the tip. This meant that about 8.6 percent of the applied load introduced unwanted bending effects that were not accounted for in the analysis. The cause of the torque discrepancy is correctly attributed mainly to the method of loading and tilting of the support jig. Other than reducing the accuracy of the experimental results to a comparatively minor degree the effect of the small bending loads would not measurably influence the comparison with theory in such a complex structure. These factors become even less important in establishing the

general validity of this analytical method to an actual complicated wing when one is reminded that the literature mentions 100 percent disagreements in comparing results of other methods applied to simplified thin-skinned laboratory specimen.

Experimental and theoretical results for the root area are listed in Table XI. Three observations may be made immediately. The sense of maximum normal stress, the orientation of the principal axis, and magnitude of stresses at the critical rear panel area agree rather well. Maximum shear stresses differ by only 25 percent, and although one of the maximum normal stresses differs by 40 percent the other is only seven percent. On the other hand, the theoretical stresses obtained at the leading edge are much too high. This is shown graphically in Fig. 27. Since the equilibrium checks made during formulation of the problem indicated excellent equilibrium existed, and agreement of theoretical and experimental results at the rear of the wing is good, the leading edge divergence was likely to be the result of an initial assumption.

Attention was immediately directed to the root boundary conditions. It was assumed that the pivot rib (considered to be the root of the idealized model) was infinitely stiff and completely resisted chordwise deformation. This is still felt to be a reasonably accurate assumption. However,

re-examination of the drawings of the pivot rib indicates that the rib width varies by decreasing from rear to front substantially. Moreover, the skin thickness varies the same way. It would therefore appear that significant twist about the streamwise axis occurs towards the front of the pivot rib. This has the effect of removing the root restraint imposed upon the theoretical analysis, and allows stress relief to occur towards the leading edge in the actual case.

The sizeable differences in back-up gage readings would further stimulate interest into investigating the plate bending and twisting effects of individual panels about their respective axes. Unfortunately, insufficient back-up gages were installed to establish any definite conclusions, but examination of the stresses at the available back-up locations and the stresses measured by neighboring rosettes on only one side of the skin evokes considerable concern in this area. Panels 25 and 30 would be particularly well suited for such an investigation in the future.

It is therefore believed that the analysis method can achieve accurate results for this wing. The boundary condition in question could be removed entirely from the analysis by moving the theoretical root to the aircraft center line. This would introduce only 16 new unknowns

to the analysis, all within the additional rib required at station $y_w = 25.095$. The addition of 16 unknowns would in turn require conversion of the computer program to machine language in order to accommodate the increased storage requirements. This could be accomplished by use of the Fortran MAP program available at the U. S. Naval Postgraduate School Computer Facility.

There were no load attachment points on the specimen corresponding to the analytical load attachment points. This could have enabled direct experimental verification of a greater portion of the flexibility influence coefficient matrix $[C]$ (Table VIII). However two node points can be compared here. The measured net vertical deflections at scale numbers 8 and 11 (Fig. 26) are compared to deflections caused by the analytically calculated vertical loads P_1 through P_7 . At scale number 8 the theoretical value differs from the measured value by only 16.8 percent and at scale number 11 the difference is only 14.8 percent. The better agreement between theoretical and measured deflections was expected (Ref. 9).

Improved accuracy in the solution could undoubtedly be obtained by reducing the size of the structural grid. This would at the least double the number of unknowns. With the additional element flexibilities required, computer programming should be extended to do more of the

labor. As has been pointed out by Rattinger and Gallagher (Ref. 2), up to three man-years may be required for completely programming a solution using a displacement method. It is felt that the force method of this report could be extended to twice the current size with about one man-month additional effort, if project familiarity were equal to that of the writers.

V CONCLUSIONS AND RECOMMENDATIONS

1. Conclusions

It can therefore be concluded that a valid comparison was achieved between experimental and theoretical stresses as predicted by the matrix force method of analysis, using a structural idealization proposed by Wehle and Lansing. Further, this analytical method gave remarkably reasonable results in the critical rear root area of the highly complex structure.

The failure of the method to agree with actual stress conditions in the forward root area is attributed primarily to the simplifying assumption that the pivot rib was infinitely rigid.

2. Recommendations

It is recommended that all cover skin rosettes, especially those between the intermediate and pivot rib, be backed-up. This would greatly enhance the experimental potentiality of the laboratory by providing means to investigate the plate phenomena of bending and twisting of individual panels about their respective axes.

In addition greater academic value could be realized from the analytical results if means were provided for applying single point loads at the intersections of the intermediate rib and the beams. This would permit further interesting academic demonstrations by utilizing the matrix

of flexibility influence coefficients produced in this analysis.

It is further recommended, to improve the accuracy of the analytical predictions along the entire root area, that the root boundary condition assumed in this analysis be eliminated by moving the theoretical root to the wing center line rib. This would not require substantial increase in analytical complexity and would greatly enhance the agreement between theory and actual measurement.

It is finally recommended that the experimental method of loading be improved to enable better development of pure torque. In this regard an exterior rib, clamped around the section perpendicular to the center intermediate rib at wing station $y_w = 143$, would eliminate the stream-wise twist of the wing fold rib. Regardless of the method of loading, the plywood pads under the wing support jig should be replaced with a more suitable material.

APPENDIX A

THEORETICAL DETERMINATION OF SHEAR FLOWS AT SECTIONS PERPENDICULAR TO CIB AT $y_w = 98.7$ AND $y_w = 74.3$

The theoretical shear flows at sections perpendicular to the CIB at $y_w = 98.7$ and $y_w = 74.3$ were calculated for two reasons. First the shear flows at both sections would be used to establish the theoretical loads at streamwise rib, $y_w = 81.98$. Secondly, the shear flows at the section perpendicular to the CIB at $y_w = 98.7$ would be determined experimentally and comparison with theoretical values would facilitate a check of the degree to which pure torque loading was achieved. Both cross-sections are shown schematically in Fig. A1. The thicknesses were average mid-panel values and the web heights were taken between the mid-panel of the upper and lower skins.

A box structure with several cells will have one less redundant than the number of cells. In this case there is five redundant webs. It is desired to write six equations in the six unknown shear flows. This was done by equating the angle of twist of one cell with the remaining five, which gives five equations, and then writing an equilibrium of torsional moments equation.

The first five equations were obtained by equating the angle of twist per unit length, θ , of one cell with

the other five using the well known expression for a box beam,

$$\theta = \sum \frac{q}{2} \frac{\Delta s}{A} \frac{L}{t G} \quad (A1)$$

The equilibrium of torsional moments may be written as

$$T = \sum 2 A_n q_n \quad (A2)$$

In using equation (A2) the summation is carried out around the entire perimeter of each cell. The unit length L and the constant factor $2G$ drop out leaving, for cells a and b ,

$$\sum_a \frac{q}{A_a} \frac{\Delta s}{t} = \sum_b \frac{q}{A_b} \frac{\Delta s}{t} \quad (A3)$$

The value of q for any exterior web of cell a is q_{at} and for the interior web is $(q_{at} - q_{bt})$. Using the abbreviations,

$$\begin{aligned} \delta_{aa} &= \sum_a \frac{\Delta s}{t} \\ \delta_{bb} &= \sum_b \frac{\Delta s}{t} \\ \delta_{ab} &= \left[\frac{\Delta s}{t} \right]_{a \rightarrow b} \end{aligned}$$

equation A3 is rewritten.

$$\frac{q_{at}}{A_a} \delta_{aa} - \frac{q_{bt}}{A_a} \delta_{ab} = \frac{q_{bt}}{A_b} \delta_{bb} - \frac{q_{at}}{A_b} \delta_{ab} \quad (A4)$$

The terms δ_{aa} and δ_{bb} represent summation around the entire perimeter of their respective cells and δ_{ab} the value for the interior web.

For each cell the values of δ were easily calculated and are shown in Table A1. The enclosed areas were taken as the average web height times the distance between webs.

Equating the angle of twist per unit length of cell a to the remaining cells gives the following equations:

$$\begin{aligned} \frac{1}{A_a} \left(q_{at} \delta_{aa} - q_{bt} \delta_{ab} \right) &= \frac{1}{A_b} \left(q_{bt} \delta_{bb} - q_{at} \delta_{ab} - q_{ct} \delta_{bc} \right) \\ &= \frac{1}{A_c} \left(q_{ct} \delta_{cc} - q_{bc} \delta_{bc} - q_{dt} \delta_{cd} \right) \\ &= \frac{1}{A_d} \left(q_{dt} \delta_{dd} - q_{ct} \delta_{cd} - q_{et} \delta_{de} \right) \\ &= \frac{1}{A_e} \left(q_{et} \delta_{ee} - q_{dt} \delta_{de} - q_{ft} \delta_{ef} \right) \\ &= \frac{1}{A_f} \left(q_{ft} \delta_{ff} - q_{et} \delta_{ef} \right) \end{aligned} \quad (A5)$$

Substituting values of δ from Table A1, performing the indicated arithmetic and rearranging, one gets five equations in terms of the six shear flows with constant coefficients.

These are shown in Table A2 for both sections. The sixth equation is also shown in Table A2, in which case the coefficients are simply two times the cell areas.

The solution to these six simultaneous equations was obtained on the CDC 1604 Digital Computer using a FORTRAN program with a CO-OP identification of F2 UTEX LINE QN which is included herein as pages 102 through 110. It utilizes Gauss's method of elimination with row pivoting and back substitution and is designed to give solutions for one or more column vectors forming the right side of the set of equations. This means it would give solutions for one or more values of applied torque in this case. Three torque values were used as shown in Table A3. The values of 294000 in. lb and 336000 in. lb were used in the analysis. The value of 177825 in. lb was used to check the computer results. The check values of q were hand calculated using an iterative procedure suggested by Bruhn (Ref. 11) and within slide rule accuracy agree well with the computer solutions.

A. IDENTIFICATION

TITLE: Solution of Simultaneous Linear Algebraic Equations

CO-OP ID: F2 UTEX LINEQN

CATEGORY: Simultaneous Linear Equations

PROGRAMMER: C. B. Bailey

DATE: August 14, 1961

B. PURPOSE

Solve one or more sets of linear algebraic equations using Gaussian elimination with row pivoting and back substitution.

C. USAGE

1. Calling sequence:

The program is called by the program execute card, i.e. LINEQN., in the normal sequence of Fortran control cards.

2. Arguments:

The following parameters and data are read in on cards. (See 9a).

- a. N - the order of the matrix in the equations $Ax = b$, that is, the number of linear equations.
- b. M - the number of vectors b for which solution vectors x are to be obtained, that is, the number of sets of linear equations.
- c. EP - Matrix condition parameter. (See Mathematical Method.)
- d. A - the elements of the matrix of coefficients of the equations.
- e. B - the elements of the column vectors $b_1, b_2, \dots, b_m$.

3. Space required: Undetermined.

4. Temporary storage required: Space is reserved for solving 50 equations in 50 unknowns for 60 vectors b . This amounts to 8500 locations.

5. Alarms or print-outs: If the equations are inconsistent or dependent, MATRIX SINGULAR is printed.

6. Error returns: None.

7. Error stops: None.

8. Input and output tape mounting: Not applicable.

9. Input and output formats: For a more complete description of the I, E, and F formats, see 15.

a. Input (data cards)

(1) First card

Columns 1-5 contain the value of N in I5 format. Thus N is punched a right-justified fixed-point integer. Leading zeros need not be punched.

Columns 6-10 contain the value of M in I5 format.

Columns 11-20 contain the value of EP in E10.4 format.

To enter the value of 10^{-8} one can punch .1E-07 right-justified in the field.

(2) The coefficients of the matrix are read a row at a time. Each row is begun on a new card. Five coefficients per card are in 16 column fields (1-16, 17-32, 33-48, 49-64, 65-80) using F16.8 format.

The matrix of coefficients has the following form:

$$\begin{array}{cccc} a_{11} & a_{12} & \dots & a_{1N} \\ a_{21} & a_{22} & \dots & a_{2N} \\ & & \vdots & \\ a_{N1} & a_{N2} & \dots & a_{NN} \end{array}$$

Thus, for $N = 6$, the input cards would contain the following information.

Card No.	<u>Columns</u>				
	1-16	17-32	33-48	49-54	55-80
2	a_{11}	a_{12}	a_{13}	a_{14}	a_{15}
3	a_{16}				
4	a_{21}	a_{22}	a_{23}	a_{24}	a_{25}
5	a_{26}				
6	a_{31}	a_{32}	a_{33}	a_{34}	a_{35}
7	a_{36}				
.					
.					
12	a_{61}	a_{62}	a_{63}	a_{64}	a_{65}
13	a_{66}				

- (3) The elements of the column vectors $b_1, b_2, \dots, b_m$ are also read row wise in F 16.8 format. For $M = 6$, the vectors $b_1, b_2, \dots, b_6$ are assumed to be arranged in the following manner:

$$\begin{array}{cccc} b_{11} & b_{21} & \dots & b_{61} \\ b_{12} & b_{22} & \dots & b_{62} \\ & \vdots & & \\ & \vdots & & \\ b_{16} & b_{26} & \dots & b_{66} \end{array}$$

where b_{ij} denotes the j -th component of the column vector b_i . Thus, for $N = 6$ and $M = 6$, the data cards would contain the following information:

Card No.	<u>Columns</u>				
	1-16	17-32	33-48	49-54	55-80
14	b_{11}	b_{21}	b_{31}	b_{41}	b_{51}
15	b_{61}				
16	b_{12}	b_{22}	b_{32}	b_{42}	b_{52}
17	b_{62}				
.					
.					
.					
24	b_{16}	b_{26}	b_{36}	b_{46}	b_{56}
25	b_{66}				

- (4) Several sets of data may be processed at one run. To terminate the run, place one blank card after the last set of data.

b. Output

The components of the x vectors are printed row wise six per line in E20.11 format. For the above example of $N = 6$ and $M = 6$, the output values would be arranged in the following manner:

Line No.	Values					
1	x_{11}	x_{21}	x_{31}	x_{41}	x_{51}	x_{61}
2	x_{12}	x_{22}	x_{32}	x_{42}	x_{52}	x_{62}
.						
.						
.						
6	x_{16}	x_{26}	x_{36}	x_{46}	x_{56}	x_{66}

where x_{ij} denotes the j -th component of the column vector x_i .

10. Selective jump and stop settings: Not applicable.
11. Timing: Undetermined.
12. Accuracy: Not applicable.
13. Cautions to user: None.
14. Equipment configuration: Not applicable.

D. MATHEMATICAL METHOD

Gauss's method of elimination with row pivoting and back substitution is used.

Suppose we wish to solve

$$Ax = b \quad \text{and} \quad Ax = c$$

for the same matrix A . This routine is designed to give the solutions for one or more column vectors b , c , etc. simultaneously.

Consider a 3 by 3 matrix A augmented by two column vectors b and c.

$$\begin{array}{ccccc} a_{11} & a_{12} & a_{13} & b_1 & c_1 \\ a_{21} & a_{22} & a_{23} & b_2 & c_2 \\ a_{31} & a_{32} & a_{33} & b_3 & c_3 \end{array}$$

The A matrix is triangularized by adding multiples of one row to another row. For column 1 find the row containing the largest element in column 1 on or below the principal diagonal. Interchange this row with the first row. Subtract from row i (i = 2, 3) $\frac{a_{i1}}{a_{11}}$ times row 1.

$$a'_{ij} = a_{ij} - \frac{a_{i1}}{a_{11}} a_{1j} \quad j = 1, \dots, 5.$$

This eliminates the elements in column 1 below the principal diagonal. This process of pivoting and then eliminating elements below the diagonal may be repeated now on the second and third rows. The method is extendible to any number of equations.

Although only the A matrix is triangularized, the process of row interchange and addition of multiples of rows is applied to the n by n+m matrix consisting of the n by n coefficient matrix augmented by m column vectors.

Thus we have

$$\begin{array}{ccccc} d_{11} & d_{12} & d_{13} & e_{11} & e_{12} \\ 0 & d_{22} & d_{23} & e_{21} & e_{22} \\ 0 & 0 & d_{33} & e_{31} & e_{32} \end{array}$$

Back substitution is used.

$$x_{i,j} = \frac{e_{ij} - S}{d_{ii}} \quad \begin{array}{l} j = 1, \dots, M \\ i = N, \dots, 1 \end{array}$$

where

$$S = 0 \quad \text{for } i = N$$

and

$$S = \sum_{k=i+1}^N d_{ik} x_{kj} \quad \text{for } i = N-1, \dots, 1.$$

The back substitution is also extendible to any order matrix.

If the equations are either inconsistent or dependent (or nearly so), then some diagonal element of the triangularized matrix will be zero or nearly zero. In this case exponential overflow or even division by zero may occur in the back substitution phase. The alarm print-out (see C.5) is set off when a diagonal element of the triangularized matrix is less than or equal to argument EP (see C.2.c). Thus, EP is that value which the user is willing to call zero. It should be larger than the round-off error which can occur.

APPENDIX B

DETERMINATION OF INDIVIDUAL MEMBER FLEXIBILITIES REQUIRED FOR MATRIX $[F]$

I. Development of Equations

The symmetric matrix $[F]$ of equation (2) is obtained by formulating the strain energy in terms of internal forces. For example, the un-tapered bar ($A_1 = A_2$) of Fig. B1 is attached to a web, and acted upon by an external axial load, P , and an internal axial load, a_3 .

Fig. B1

The strain energy of such a bar may be expressed (Ref. 8) in terms of the end loads as

$$U = \int_0^l \frac{p(y)^2}{2AE} dy \quad (B1a)$$

For a load equal to

$$p(y) = u + (v - u) \frac{y}{\ell}$$

the strain energy becomes

$$U = \frac{\ell}{3AE} (u^2 + uv + v^2) \quad (B1b)$$

Upon placing the bar of Fig. B1 in equilibrium the end loads may be expressed in terms of the internal forces as

$$u = -2 a_1 + a_3 \quad (B2a)$$

$$v = 0 a_1 + a_3 \quad (B2b)$$

By substituting equations (B2) into (B1) the internal strain energy can be written as

$$2 EU = \frac{\ell}{3A} (4\ell^2 a_1^2 - 6 \ell a_1 a_3 + 3 a_3^2) \quad (B3)$$

Now referring again to equation (2),

$$2 EU = [a_1 \dots a_3] \begin{bmatrix} F_{11} & F_{13} \\ F_{31} & F_{33} \end{bmatrix} \{a_1 \dots a_3\} \quad (2)$$

it can be shown by taking partial derivative of the energy that the $[F]$ matrix terms are merely coefficients of squared and cross terms such as:

$$2 EU = a_1^2 F_{11} + F_{13} a_1 a_3 + F_{31} a_1 a_3 + a_3^2 F_{33} \quad (2a)$$

Due to the symmetry required of $[F]$, F_{13} is exactly one-half the coefficient of the cross-term, $a_1 a_3$.

Three factors, f_{11} , f_{12} , and f_{22} are now introduced,

$$\left. \begin{aligned} f_{11} &= \frac{l}{3A_1} = f_{22} \\ f_{12} &= \frac{l}{6A_1} \end{aligned} \right\} \quad (B4)$$

where f_{11} and f_{22} will refer to the squared terms, and f_{12} refers to the cross-terms.

The coefficients of a_1 and a_3 in equations (B2) are now identified by

$$\begin{aligned} u &= \alpha_1 a_1 + \alpha_3 a_3 \\ v &= \beta_1 a_1 + \beta_3 a_3 \end{aligned} \quad (B5)$$

so that the member flexibilities can be found from

$$\left. \begin{aligned} F_{11} &= f_{11}\alpha_1^2 + 2f_{12}\alpha_1\beta_1 + f_{22}\beta_1^2 \\ F_{33} &= f_{11}\alpha_3^2 + 2f_{12}\alpha_3\beta_3 + f_{22}\beta_3^2 \\ F_{13} &= f_{11}\alpha_1\alpha_3 + f_{22}\beta_1\beta_3 + f_{12}(\beta_1\alpha_3 + \alpha_1\beta_3) \end{aligned} \right\} \quad (B6)$$

Using the values of and from equations (B2)

$$\begin{aligned} F_{11} &= \frac{4l^3}{3A} \\ F_{13} &= -\frac{l^2}{A} = F_{31} \\ F_{33} &= \frac{l}{3A} \end{aligned}$$

II. Application to Tapered Bars

For linearly tapered bars the coefficients f_{11} , f_{12} , and f_{22} were modified by the functions of A_1/A_2 , ϕ_{11} , ϕ_{12} , and ϕ_{22} , according to the method shown in Ref. 4, giving:

$$\left. \begin{aligned} f'_{11} &= f_{11} \phi_{11} \\ f'_{12} &= f_{12} \phi_{12} \\ f'_{22} &= f_{22} \phi_{22} \end{aligned} \right\} \quad (B7)$$

Equations (B7) are then used directly in equations (B6).

Consider the tapered bar shown as element number 29 in Fig. 13, and re-drawn below in Fig. B2. The bar

Fig. B2

geometry is obtained from Table I. Using the ratio A_1/A_2 , the ϕ functions are obtained from Fig. 4 of Ref. 4, giving

$$\begin{aligned} f_{11} &= \frac{l\phi_{11}}{3A_1} = 4.4387 \\ f_{12} &= \frac{l\phi_{12}}{6A_1} = 1.8001 \\ f_{22} &= \frac{l\phi_{22}}{3A_1} = 3.0188 \end{aligned}$$

From the loading system upon the bar, as shown in Fig. 13, the alpha (α) and beta (β) equations are respectively:

$$q_1 = -4.7055 a_{13} + 4.1502 a_{14} + 7.8009 a_{38} - a_{49}$$

$$q_2 = - .4483 a_{13} - .4286 a_{14} + 0 = a_{49}$$

Substituting into equation (B6), $F_{13,13}$ becomes

$$F_{13,13} = 4.4387(-4.7055)^2 + 1.8001(-4.7055)(-.4483) + (3.0188)(-.4483)^2 = \underline{102.6485}$$

III. Application to Symmetrical Shear Panel

For the case of the symmetrical shear panel, shown in Fig. B3, the strain energy can be written as in equation (B8):

Fig. B3

Symmetrical Shear Panel

$$2EU = \left[\frac{b(w_1 + w_2)}{w_1^2 t} \left(\frac{1}{6} \left(\frac{w_1 - w_2}{b^2} \right)^2 + (1 + \nu) \right) \right] q_1^2 \quad (B8)$$

and

$$F_{11} = \frac{\partial^2 U}{\partial q_1^2} \quad 9$$

giving for element number 13, Fig. 13:

$$F_{8,8} = 1/tE \left[\frac{63.8339(13.50)}{51.84} \left(\frac{1}{6} \left(\frac{.900}{63.8339} \right)^2 + 1.32 \right) \right] 1.0^2$$

or:

$$E [F_{8,8}] = E(109.7173)$$

IV. Application to Skewed Shear Panels

Skewed panels are treated according to the method of Garvey (Ref. 10), and as used in Ref. 6.

Fig. B4

The energy of the swept panel shown in Fig. B4 may be written as

$$2 EU = \left[(1 + \gamma) \frac{(a_1 + a_2)}{L} \sin^2 \delta \left(1 + \frac{2}{3(1+\gamma)} \delta \right) \right] q_4^2 \quad (B9)$$

where gamma is written as

$$\delta = \cot^2 \beta + \cot \delta \cot \beta + \cot^2 \beta$$

Take for example element number 38. There is

$$F_{9,9} = \frac{\partial^2 U}{\partial q_4^2} \quad \text{giving}$$

$$F_{9,9} = \left[\frac{1.32(35.2288)(.5764)(1 + .50505 \times 2.5108)}{9.9549} \right] (3.5868)^2$$

$$F_{9,9} = \frac{1}{E} (78.5635)$$

It should be noted that for both the bars and the panels, the terms of the $[F]$ matrix are usually made up from flexibilities of several elements. In addition, all main diagonal terms (F_{ii}) are positive. All non-zero terms of the flexibility matrix $[F]$ are given in the computer program data input, Appendix C.

APPENDIX C

FORTRAN PROGRAM FOR CDC 1604 DIGITAL COMPUTER

1. FORTRAN NAMES, SYMBOLS, AND DEFINITIONS

A	Matrix of coefficients of determinate loads, basic input data, size 33x33
AI	Inverse of Matrix A, obtained by Gauss 3 single-precision subroutine
AR	Matrix of redundant loads, output, size 33x1
AT	Matrix of all loads, output, size 49x1
B	Matrix of coefficients of applied and redundant loads, basic input, size 49x33
C	Matrix of deflection influence coefficients, output, size 33x33
CJ	Matrix product of (AI)(B), size 33x49
EN	Negative of matrix product (H22I)(H21), size 16x33
ENP	Matrix product of (H22I)(H21), size 16x33
G	(CJ) matrix augmented by trivial relations, size 49x49
GT	Transpose of (G) matrix
H	Matrix triple product of (GT)(UC)(G), size 49x49

H11 Matrix of first 33 columns and rows of (H),
 obtained during partitioning, size 33x33
 H12 Matrix of last 16 columns (through first
 33 rows) of (H) matrix, size 33x16
 H21 Matrix of last 16 rows (through first 33
 columns) of (H) matrix, size 16x33
 H22 Remainder of (H) matrix, size 16x16
 H22I Inverse of (H22) matrix
 H12N Matrix product of (H12)(EN), size 33x33
 KER Gauss 3 subroutine error flag, where
 assigned value of 2 indicates singular matrix
 LIST Numbering index
 P Column matrix of applied loads, size 33x1
 S Matrix of stress coefficients, size 49x33
 UC Matrix of flexibilities, referred to in
 text as (F) matrix, basic input data,
 size 49x49
 UNITN Matrix formed by placing unit diagonal
 matrix on top of matrix (EN), giving
 matrix size of 49x33

MATRIX [CHECK]

Sample Showing First 10 Columns Correct to Sixth Decimal

The image displays a series of ten horizontal rows, each featuring a dot grid pattern. Each row is composed of two distinct sections: a top section of small circles and a bottom section of dots. The circles are arranged in a grid, while the dots are arranged in a single row. The pattern is repeated ten times, with each row having a unique arrangement of dots and circles.

APPENDIX D

CALIBRATION CURVES FOR DILLON DYNAMOMETERS AND HYDRAULIC PRESSURE SYSTEM

APPENDIX E

Coordinate Location of Strain Gages

F8U-3 Wing Center Section

- Note: 1. $X_w = 0$ = Intersection of the center section droop leading edge and the center line of the airplane.
2. $Y_w = 0$ - The center line of the airplane.

Notes

1. a) Gages 1-2, 3-4, 5-6, 7-8, 9-10, 11-12 mounted by Chance-Vought and oriented with one leg parallel to Y_w and the other leg perpendicular to Y_w .
b) No gage factor or other information available.
2. a) All AR 7-2 gages mounted at USNPS and oriented with one leg perpendicular to C.I.B., 45° gage pointing outboard and toward trailing edge, other leg parallel to C.I.B.
b) All gages from lot B-31, $120.5 \pm .5$ ohms, $1.97 \pm 2\%$,
b factor = -200.
3. a) All A-7 gages mounted at USNPS and oriented parallel to C.I.B.
b) All gages from lot B-31, $120.0 \pm .3$ ohms, $1.99 \pm 2\%$.
4. a) Gages 25-26-27, 28-29-30 mounted by Chance-Vought and oriented approximately the same as USNPS mounted AR 7-2 gages.
b) No gage factor or other information available.

Bottom Skin and Beam Assembly (continued)

Notes

I. BEAM GAGES

1. a) All AR 1 gages mounted on vertical webs of beams, outboard of pivot rib, were mounted by Chance-Vought and are oriented with center leg of strain gage pointing inboard and on the center line of the web. Other legs 45° each side. (Note: Gage 178-179-180 is an AR 7-2 mounted at USNPS, but oriented same as above gages.)
- b) All AR 1 gages mounted on vertical web of pivot rib were mounted by Chance-Vought and are oriented with center leg of strain gage pointing aft and on the center line of the web. Other legs 45° each side.
- c) All AR 1 gages mounted on vertical webs of center section beams were mounted by Chance-Vought with center leg of strain gage pointing inboard and on the center line of the web. Other legs 45° each side.
- d) All AR 7-2 gages mounted on vertical webs of beams, outboard of pivot rib, were mounted at the USNPS and are oriented with one leg perpendicular to CIB, and other legs pointing outboard and up or down depending on whether it is a "walk-around" gage or a "back-up" gage.
- e) All AR 1 gages mounted on vertical web of Intermediate Rib were mounted by Chance-Vought and are oriented with the center leg of the strain gage pointing forward and on the center line of the web. Other legs 45° each side.

II. LOWER SKIN

1. a) AX 5 gages were mounted by Chance-Vought and are oriented with one leg parallel to the center line of the skin between the beams and other leg rotated 90° away.

Bottom Skin and Beam Assembly (continued)

- b) All AR 1 gages (361 thru 375) were mounted by Chance-Vought and are oriented with one leg (the first number on each rosette) parallel to the center line of the skin between the beams; the second leg (second number of sequence) rotated 45° counter-clockwise; and the third leg (third number of sequence) rotated another 45° counter-clockwise, making it perpendicular to first leg. The entire rosette points inboard.
 - c) All AR 7-2 gages were mounted at USNPS and oriented with one leg perpendicular to CIB and the entire rosette pointing outboard and forward.
- 2. No gage factor or other information available on gages mounted by Chance-Vought on either the beams or the lower skin.
 - 3. All AR 7-2 gages mounted at USNPS are from lot B-31, 120.5 ± 0.5 ohms, $1.97 \pm 2\%$ gage factor, b factor ≈ -200 .

Fig. E1

APPENDIX F

STRAIN GAGE INSTRUMENTATION

The method of taking strain readings employed common Wheatstone bridge circuitry shown in Fig. F1. The unique part of the method was the use of a digital counter to indicate bridge unbalance and give a visual display of the strain directly in units of micro-inches per inch.

For the special case considered here where all four legs of the bridge have the same known resistances R , and for a small change of resistance in one leg ΔR , it can be shown that the standard Wheatstone bridge equation for output voltage V_O reduces to

$$V_O = \frac{V R_O \Delta R}{4 R (R + R_O)} \quad (F1)$$

where R_O is a constant resistance across terminals AC and V is the constant voltage source. Further, the expression for the gage factor (GF) that relates strain and change of resistance is

$$(GF)\epsilon = \frac{\Delta R}{R} \quad (F2)$$

By substituting equation (F2) into (F1) it is immediately apparent that the output voltage is a linear function of strain,

$$V_O = \left[\frac{V (GF) R_O}{4 (R + R_O)} \right] \epsilon = (\text{Constant}) \epsilon \quad (F3)$$

Utilizing this fact it was then easy to calibrate the electronic counter in units of strain.

Considering again the basic bridge circuit, a shunt resistance R_c across one of the legs effectively unbalances the bridge. Its effect on the basic balanced bridge equations is developed below.

$$(GF)\epsilon = \frac{\Delta R}{R}$$

$$\Delta R = R (GF)\epsilon \quad (F4)$$

$$R - \Delta R = \frac{1}{\frac{1}{R} + \frac{1}{R_c}} = \frac{R R_c}{R + R_c}$$

$$\Delta R = R - \frac{R R_c}{R + R_c} = \frac{R^2}{R + R_c} \quad (F5)$$

Substituting equation (F5) into (F4) and solving for R_c gives,

$$R_c = R \left[\frac{1}{\epsilon (GF)} - 1 \right] \quad (F6)$$

From equation (F6) the shunt resistance necessary to produce an equivalent strain of 0.001 in. per in. when R is 120 ohms and (GF) equals 2.0 is then,

$$R_c = 120 \left[\frac{1}{(0.001)(2.0)} - 1 \right] = 59780 \text{ ohms.}$$

If on the other hand a more standard 60000 ohm resistor were used for R_c , the equivalent strain would be 998 micro inches per inch. This feature was used to calibrate the electronic counter.

A Wheatstone bridge circuit was permanently constructed into which precision 120 ohm ($\pm .25\%$) resistors were readily connected to form the four legs. A precision 60000 ohm ($\pm .05\%$) shunt resistor was connected with a switch as shown in Fig. F1. In addition a precision 50000 ohm potentiometer was provided through connection CE as a variable resistance for any delicate balancing.

With the switching and balancing unit and the switch F disconnected, the amplifier connected across terminals AC and the variable resistance connected across CE, we have the special bridge circuit described previously. The variable resistance was then adjusted to exactly balance the bridge and consequently give a zero indication on the electronic counter. Switch F was then closed and the amplifier gain adjusted to give a 998 reading on the counter. The counter had been previously set to repeatably indicate the integrative result of a one second sampling of V_0 which greatly enhanced smooth readings.

Repeating this procedure and noting the consistency of returning to zero with switch F open and to 998 with the switch closed insured the establishment of a linear calibration of the counter to read in units of micro-inches per inch.

After calibrating the counter, switches E and F were opened and resistances R_1 and R_2 were replaced by the switching and balancing unit leads for the active and compensating gages respectively as shown in Fig. F1. The active and compensating gages also had 120 ohm resistances. Each of the 20 gages connected through the switching and balancing unit was then zeroed on the switching and balancing unit in the conventional manner prior to subjecting them to load. At any time during the test run switch F could be closed and a change of 998 observed on the counter. This gave a continual check on the calibration of the counter.

APPENDIX G

EXPERIMENTAL PRINCIPAL STRESSES AND AXIS ORIENTATION

The magnitudes of principal stresses and the orientation of the principal axes were calculated for all rosette locations of interest. Experimental strain readings are listed in Table G1. Calculations were performed on the C.D.C. 1604 Digital Computer utilizing a FORTRAN program named ROSRED shown in Tables G2 and G3. The computer output is listed in Table G4.

The equations solved by the program were the relations between rectangular rosette readings and principal stresses found in any standard text on the subject.

$$\sigma_{\max} = \frac{E}{2} \left[\frac{\epsilon_1 + \epsilon_3}{(1-\mu)} + \frac{1}{(1+\mu)} \sqrt{(\epsilon_1 - \epsilon_3)^2 + [2\epsilon_2 - (\epsilon_1 + \epsilon_3)]^2} \right]$$

$$\sigma_{\min} = \frac{E}{2} \left[\frac{\epsilon_1 + \epsilon_3}{(1-\mu)} - \frac{1}{(1+\mu)} \sqrt{(\epsilon_1 - \epsilon_3)^2 + [2\epsilon_2 - (\epsilon_1 + \epsilon_3)]^2} \right]$$

$$\tau_{\max} = \frac{E}{2(1+\mu)} \sqrt{(\epsilon_1 - \epsilon_3)^2 + [2\epsilon_2 - (\epsilon_1 + \epsilon_3)]^2}$$

$$\phi_p = \frac{1}{2} \arctan \left[\frac{2\epsilon_2 - (\epsilon_1 + \epsilon_3)}{\epsilon_1 - \epsilon_3} \right]$$

ϕ_p is the angle from the axis of ϵ_1 to the maximum normal stress axis and ϵ_1 , ϵ_2 and ϵ_3 are strain readings in the respectively numbered gages shown in Fig. G1. Rosettes used in this experiment were numbered with three consecutive numbers and the lowest number identified the rosette. Logically then ϕ_p is the angle from the axis of the lowest numbered gage in each rosette to the maximum normal stress axis. A positive value indicates an angle in the direction of ϵ_2 .

The input to program ROSRED (Table G1) was designed to accommodate this notation. Only the rosette identifying number is listed which is also the gage number for which the first column of strains are listed. The second and third columns are then the values of strain on the next two consecutive numbered gages comprising the rosette.

The results listed in Table G4 are identified by the rosette numbers which quickly orients the axis reference for ϕ_p .

It should be pointed out that the program was designed for specific values of E and μ , namely 10.3×10^6 psi and 0.32 respectively.

TABLE G2
LIST OF SYMBOLS USED IN
ROSRED PROGRAM

Computer Coded Name	Definition
EP1	ϵ_1 , strain in lowest numbered gage of rosette
EP2	ϵ_2 , strain in diagonal gage
EP3	ϵ_3 , strain in perpendicular gage
SIGMAX	σ_{max} , maximum principal stress
SIGMIN	σ_{min} , minimum principal stress
TAUMAX	τ_{max} , maximum shearing stress
PHIP	ϕ , angle from the ϵ_1 axis to σ_{max} axis.
GAGE	Rosette number (lowest numbered gage in rosette)
N	Number of rosettes furnished as data input

Table G3

FORTRAN PROGRAM

"ROSRED"

```

C      PROGRAM ROSRED
C      PROGRAM TO OBTAIN PRINCIPAL STRESSES AND AXIS ORIENTATION FROM
C      RECTANGULAR ROSETTE STRAIN DATA
C      DIMENSION EP1(400),EP2(400),EP3(400),SIGMAX(400),SIGMIN(400),
C      TAUMAX(400),PHIP(400),GAGE(400)
C      READ 1,N
C      1 FORMAT(I3)
C      READ 2, (GAGE(I),EP1(I),EP2(I),EP3(I), I=1,N)
C      FOR EACH ROSETTE, LOWEST NUMBER GAGE IDENTIFIES ROSETTE AND
C      GIVES REFERENCE POINT FOR ANGLE PHIPRINCIPAL, WHERE POSITIVE
C      ANGLE IS MEASURED TOWARDS GAGE 2 OF ROSETTE
C      STRAIN DATA IS MICRO-INCHES/INCH
C      2 FORMAT (I3,3F8.0)
C      DO 20 I = 1,N
C      A(I)= EP1(I)+ EP3(I)
C      B(I)= EP1(I)- EP3(I)
C      R(I)= SQRTF(B(I)**2 + (EP2(I)*2.0 -A(I))**2)
C      SIGMAX(I) = (10.3/2.0)*((A(I)/.68) +(1.0/1.32)*R(I))
C      SIGMIN(I)= 5.15 *((A(I)/.68)-(1.0/1.32)*R(I))
C      TAUMAX(I)= (10.3/2.64)*R(I)
C      20 PHIP(I)= ((ATANF((2.0*EP2(I) -A(I))/B(I)))/2.0) * 57.3
C      PRINT 30
C      30 FORMAT (43H1 MAX MIN MAX P)
C      PRINT 31(GAGE(I),SIGMAX(I),SIGMIN(I),TAUMAX(I),PHIP(I) I =1,N)
C      31 FORMAT (1X,I3,3F10.0,1F10.2)
C      STOP
C      END
C      END

```
