ABSTRACT

The physical properties and thermochemistry of decomposition of SiO_2 at high temperatures has been thoroughly reviewed and detailed calculations have been made of thermodynamic properties of interest for re-entry vehicle applications. Available thermodynamic data indicate that the primary reaction involved in the vaporization of SiO_2 under neutral conditions is

$$SiO_{2(1)} \longrightarrow SiO_{(g)} + \frac{1}{2}O_{2(g)}$$
 (1)

The vapor pressure relation corresponding to this equilibrium is

$$P_{t} = 3/2 e^{-\frac{3160}{T}}$$
(2)

where p_t is total vapor pressure in atmosphere. A normal boiling point of 3085°K is predicted from this relation. If other equilibria are considered, including formation of $SiO_{2(gas)}$, dimer formation, and dissociation of oxygen, a more refined boiling point of $3070^{\circ} \pm 70^{\circ}$ K (2800°C) is obtained. This value has been compared with data in the literature and is consistent with the most reliable data available. When SiO_2 is heated from room temperature to its boiling point and decomposed at that temperature, the total heat absorption is calculated to be 6650 Btu/lb.

Many other physical properties of SiO_2 which are of interest for re-entry vehicle design purposes, have been reviewed and are summarized in an appendix at the end of the report.

I. INTRODUCTION

One of the most promising inorganic compounds for potential use as a consumable material on ablating nose cones is fused silica. ¹ To predict the behavior of this material when subjected to the high heating rates of re-entry, it is necessary to know much about its thermochemistry of decomposition at high temperatures. Once the vapor pressure of silica under equilibrium conditions is known, then it may be possible to predict its vaporization behavior under the nonequilibrium conditions of re-entry. This report presents an extensive analysis of the thermochemistry of silica. Other properties such as viscosity of the melt, thermal shock resistance, etc. are also of interest and have been included.

Although the glass industry is an old one and SiO, is one of the most plentiful compounds on the earth's crust, there exists a paucity of accurate vapor pressure data for pure SiO2 at elevated temperatures. The data of Brewer and Mastick,² and Porter, Chupka, and Inghram³ represent the most recent available data on the vapor pressure of SiO₂. Their data were all obtained below 2,000° K but in this memorandum they are shown to agree satisfactorily with vapor pressures calculated from other available thermodynamic data. The tabulated boiling points for SiO_2 , which are recorded in various hand-books, have values of 2,230° C, 2,590° C and 2,950° C. These have all been traced to the work of Ruff and co-authors. 4,5,6 All of the boiling point determinations can be criticized because they were carried out in a reducing atmosphere. Since a reducing atmosphere leads to a higher vapor pressure than would be expected, the lower boiling points are not considered to represent the properties of the material. Moreover, the two higher boiling points, 2,590° C and 2,950° C, have been based on a single vapor pressure determination -- 11 mm at 2,060° C. In their original paper, Ruff et al 5 stated that this measurement yields 2,590° C as a boiling point. Some nine years later Ruff ⁷ stated without further evidence that this was in error and should be 2,950° C. A review of Ruff's extrapolation has indicated that he was probably correct the first time in evaluating his dat: to obtain a normal boiling point of 2, 590° C. However, the original criticism that his measurement was done under reducing conditions is still valid, and the actual boiling point is probably above 2, 590° C as he himself stated in his original paper. ⁵

In the present paper various possible reactions, which can occur when SiO_2 vaporizes, have been considered. From available thermochemical data the free energy change for each reaction has been obtained as a function of temperature. Hence, equilibrium constants for these reactions can also be given as functions of temperature. It is then possible to estimate the various species or products present at equilibrium at different temperatures and pressures.

II. THERMOCHEMISTRY OF THE REACTION $\underline{SiO}_{2(1)} \xrightarrow{\longrightarrow} \underline{SiO}_{(g)} + \underline{14O}_{2(g)}$

The above reaction has been considered by Brewer $\underline{\text{et al}}^{8,2}$ and Porter $\underline{\text{et al}}^{3}$ to be the most important one occurring when SiO₂ decomposes under neutral conditions. The results of the present study are consistent with these earlier findings. Under oxidizing conditions (i.e., with excess oxygen present), the above reaction can be shifted to the left so that SiO₂ gas formation is represed.

The equilibrium constant of the reaction and the equilibrium vapor pressure of liquid SiO_2 can be obtained by calculation from the heat of reaction and entropy change of the reaction. First we calculate the heat of reaction and entropy change for the reaction from available data.

A. HEAT OF REACTION

To calculate the heat of the above reaction we can subtract the heat of formation of $SiO_{2(1)}$ from the heat of formation of the products. Since the heat of formation of the elements is taken to be zero, it is necessary to evaluate the heat of formation of $SiO_{2(1)}$ and $SiO_{(g)}$ only. For the present case, the temperature range from 2,000 to 3,000° K has been considered of primary interest. Because data for this temperature range are not available, it is necessary to use existing data for lower temperatures and calculate the thermodynamic functions at the higher temperatures by extrapolation.

1. Heat of Formation of SiO₂₍₁₎

Coughlin⁹ has tabulated values for the heat and free energy of formation of SiO₂ up to 2,000° K. His results are based on the heat of formation data of Humphrey and King.¹⁰ His heat of formation data at 2,000° K are

$$Si_{(1)} + O_{2_{(2)}} \longrightarrow SiO_{2_{(1)}} \Delta H_{2,000} \approx -215,200 \pm 1,000$$
 (3)

$$Si_{(1)} + O_{2_{(g)}} \longrightarrow SiO_{2_{(\beta Cristobalite)}} \Delta H_{2,000\%} = -217,700 \pm 250$$
 (4)

 β -cristobalite has a melting point of 1,723° C (1,996° K), according to Levin et al,¹² and a value of 1,728° C (2,001° K), according to Campbell¹¹ For convenience, we can take 2,000° K as the melting point of cristobalite with negligible error. The diagrams of Levin et al¹²

-2-

indicate that silica glass is the stable condensed species of SiO₂ above 2,000° K. In further discussions, the terms silica glass or silica liquid are used interchangeably for the range above 2,000° K.

In any thermochemical calculation, it is desirable to start with the most accurate data available. Referring to the reactions (3) and (4), it might seem preferable to start with reaction (4) rather than reaction (3) since its heat of formation is given to a greater precision. However, the uncertainty in the heat of fusion of β -cristobalite makes either reaction a suitable starting point. Thus, we take the difference between reactions (4) and (3) as the heat of fusion of β -cristobalite, $\Delta H_f = 2500$ calories/mole . From the entropy data of Kelley^{13, 14}we calculate a heat of fusion at 2,000° K of 2,060 calories/mole. A value of 3,600 calories/mole is quoted by Kubaschewski and Evans¹⁵. The NBS compilation¹⁶ gives a value of 1,840 calories/mole. The original data quoted by Kelley 17 indicates experimental values for the heat of fusion of cristobalite to be in the range of 1,000 to 3,700 calories/mole. He derives 2,100 calories/mole as an average value. This range in values for the heat of fusion shows why the data for reaction (3) are less precise, but still the best available. Therefore, the data for reaction (3) are used for the present calculations.

The heat of formation at temperatures above 2,000° K can be calculated by means of the Kirchoff relation:

$$\Delta H_{T} = \Delta H_{2000} + \int_{2000}^{T} \Delta C_{p} dT$$

$$\Delta H_{T} = \Delta H_{2000} + (H_{T} - H_{2000})_{SiO_{2(1)}} - (H_{T} - H_{2000})_{Si(1)} - (H_{T} - H_{2000})_{O_{2}}$$
(5)

The results of such a calculation at 2,000°. 2,500°, and 3,000° K are given in Table I. For this calculation, the heat content of $SiO_{2(1)}$ was estimated by assuming that its average heat capacity was 1 calorie/mole degree greater than that given by Kelley¹³ for SiO_{2(glass)} at 2,000° K. That is, C = 21.66 was assumed.

According to Kubaschewski and Evans¹⁵, a rough estimate of the heat capacity of molten liquids can be obtained by assuming that each atom contributes 7.25 calories/g. atom *K. This leads to a value of 21.75 calorie/mole *K. In the paper by Humphrey et al¹⁸, the heat capacity of liquid silica was taken to be $C_p = 24.0$. In the present case,

| | | | Temperature | ie in Degrees K | | |

CALCULATION OF HEAT OF FORMATION OF SiO2(114) TABLE I

the extrapolation to high-temperatures leads to considerable uncertainty in the heat content. The uncertainty in the heat capacity is roughly estimated to be 1 calorie/mole degree thus giving $C_{pSiO} = 21.66 \pm 1.0$.

Sources of data for the calculations of Table I are given in the table. Rough estimates of the uncertainties in the data have been made. The final values for the heat of formation in the temperature range 2,000 to 3,000° K become more uncertain as temperature rises because of the uncertainty in the heat capacity of liquid SiO_2 in this range.

2. Heat of Formation of SiO(g)

The heat of formation of $SiO_{(g)}$ at 298° K is taken to be -21,411 ± 574 calories. This value is the one recommended by Edwards and Brewer.⁸, 19 It is based on a recalculation of the work of Schafer and Hornle²⁰ who had studied the reaction

$$Si_{(s)} + SiO_{2(s)} \rightarrow 2SiO_{(g)}$$
.

Other sources of data considered by Brewer and Edwards, ⁸ are given below:

| Investigator's and Equilibrium Studied | ΔH°298 (K calorie/mole) |
|--|--|
| Grube and Speidel ²¹ | |
| $H_{2(g)} + SiO_{2(g)} \rightarrow H_2O_{(g)} + SiO_{(g)}$ | $-15,291 \pm 2,000$ |
| Brewer and Mastick ² | |
| $\operatorname{SiO}_{2(g)} \longrightarrow \operatorname{Si}_{(g)} + \frac{1}{2}\operatorname{O}_{2(g)}$ | $-21,159 \pm 2,000$ |
| Gel'd and Kochnev ²² | |
| $Si_{(g)} + SiO_{2(g)} \longrightarrow 2SiO_{(g)}$ | $-18,212 \pm 960$ |
| Schafer and Hornle ²⁰ | |
| $Si_{(s)} + SiO_{2(s)} \longrightarrow 2SiO_{(g)}$ | $-21,411 \pm 570$ |
| Tombs and Welch ²³ | |
| $H_{2(g)} + SiO_{2(g)} \longrightarrow H_2O_{(g)} + SiO_{(g)}$ | Low temperature data -26.004 ± 2.400 |
| | High temperature data |
| | $-21,269 \pm 1,500$ |

Brewer and Edwards considered each of the above sources very carefully and chose the data of Schafer and Hornle as being the best. It should be pointed out that the arguments they use, based on dissociation energies of $SiO_{(g)}$, were fortuitously correct inasmuch as more recent data shows they used too low a value for the heat of sublimation of silicon (88.9 Kcalorie/mole) and for the dissociation energy of $SiO_{(g)}$, (169 Kcalorie/ mole). A more recent value for the heat of sublimation of monatomic silicon is 105 Kcalorie/mole based on mass spectrometer measurements given by Honig²⁴ and recommended by Stull and Sinke. ²⁵ Searcy²⁶ gives a value of 112 Kcalorie/mole and Huggins²⁷ gives 100 Kcalorie/mole for the heat of sublimation. The results of a very recent study of the sublimation of SiC by Drowart, deMaria, and Inghram²⁸ lead to a value of 113 Kcalorie/mole for the heat of sublimation, in good agreement with Searcy's value by the same method. in

T

T

. .

It should also be mentioned that a very recent paper by Baird and Taylor²⁹ gives a heat of reaction to form SiC from liquid silicon of -19,250 Kcalorie/ mole as compared with earlier values of -23,300 Kcalorie/mole. This leads to a heat of sublimation for silicon of 116 or 117 Kcalorie/mole from the results of Searcy and Drowart et al's work.

However, these high values (112 Kcalorie/mole and greater, based on SiC dissociation data) should not necessarily be accepted in preference to Honig's value which is based on a direct measurement. A further complication in the measurements based on SiC dissociation is indicated by Baird and Taylor's statement that SiC becomes unstable relative to liquid silicon and graphite near 2,050°C.

For the dissociation energy of $SiO_{(g)}$, it is found that Barrow and Rowlinson³⁰ recommend 185 ± 6 Kcalorie/mole. This agrees with Gaydon's value³¹ of 184 ± 23 Kcalorie/mole, but is higher than the value given by Herzberg³² (171 Kcalorie/mole). By calculation from the values of 105 Kcalorie/mole for the sublimation to monatomic silicon, 117.9/2 Kcalorie for the dissociation of one-half mole of oxygen from Stull and Sinke²⁵ and a heat of dissociation of 185 Kcalorie/mole for SiO_(g), a value of -21, 100 calorie/mole is obtained for the heat of formation of SiO_(g) at absolute zero. Other possible combinations are shown in Table II-A.

* Indicates a combination of data which agree with thermochemical data.

The data in this table shows that a wide range of possible values for the heat of formation of SiO could be estimated depending on the choice of the heat of sublimation of silicon and the heat of dissociation of SiO . In view of these uncertainties it would appear that the thermochemical data reviewed by Brewer and Edwards^{8,19}are probably more reliable. Accordingly, we use their value of $\Delta H_0^\circ = -21,695$ calorie/mole or $\Delta H_{298}^\circ = -21,411 \pm 574$ calorie/mole.

It should be noted that the data of Table II-A indicates that larger heats of sublimation of silicon require larger heats of dissociation of SiO in order to give heat of formation values consistent with the Brewer value chosen above. Thus, '' a value of 117 Kcalorie/mole for silicon sublimation were to become accepted, a heat of dissociation for SiO of 197 Kcalorie/mole would be required to correspond to a heat of formation for SiO of -21.5 Kcalorie/mole. Such a value for the heat of dissociation

-7-

would be within the range estimated by Gaydon (184 \pm 23 Kcalorie/mole.) At this time, it therefore appears that thermochemical data are to be preferred to the spectroscopic data, for the heat of formation of $SiO_{(g)}$.

Having now selected our source data for the heat of formation of $siO_{(g)}$ at lower temperatures, it is necessary to extrapolate these data to high temperatures in the range 2,000° to 3,000° K. To make such an extrapolation, it is necessary to obtain heat capacity data for $siO_{(g)}$ in this temperature range.

To obtain thermodynamic data for $SiO_{(g)}$, it was necessary to make calculations with spectroscopic data. The methods followed are similar to those described by Mayer and Mayer. 33 The molecular weight was taken to be 44.09. Other spectroscopic data were taken from Herzberg. 32 No electronic levels other than the singlet ground state were of importance in these calculations. The next highest electronic state has a wave number of 42,835 cm-1, corresponding to $\frac{100}{kT}$ = 20.6 at 3,000° K; and hcω makes a very small contribution to the partition function. For the one vibrational frequency possible in this diatomic molecule, the characteristic frequency ($\omega = \omega_e - 2\omega_e \mathbf{x}_e$) is 1,230 $\rm cm^{-1}$. For the rotational contributions, the moment of inertia was taken to be I =38.6 $\times 10-40$ $g^{m}c^{m^{2}}$. The symmetry number is one since the atoms of the molecule are dissimilar. Anharmonicity corrections to the entropy were made at the higher temperatures but were still quite small.

The results of these calculations are tabulated in Table II-B. For comparison purposes the results of Brewer and Edwards^{8,19}at the lower temperatures have been included and are found to agree with our data. A further approximate check on our data is indicated by the fact that it was found that the heat capacity term due to vibration at 2,000° K was almost fully excited. Moreover, if for the diatomic gas we assume that translation, rotation, and vibration are contributing fully to the heat capacity at constant pressure, we get $C_{\rm p}=9/2R$. Therefore

$$S_{3,000} - S_{2,000} = \int_{2,000}^{3,000} \frac{C_p dT}{T} \approx 3.62 e.u.$$

1

From our results in Table II-A the entropy increment is 3.63 e.u. Calculations with the enthalpy data also lead to $H_{3000} - H_{2000}$ -8.876 calorie/mole, giving an average C_p over this temperature range of 8,876 calorie/mole degree. Thus the data appear to be self-consistent.

T

I

- 8-

With the data from Table II-B and additional data for elemental silicon and oxygen from Stull and Sinke²⁵, it is now possible to calculate the heat of formation of gaseous SiO in the temperature range of 2,000° – 3,000° K. The results of such a calculation are summarized in Table III.

The calculation was based on the relation

$$\Delta H_{T} = \Delta H_{o} + \int_{o}^{T} \Delta C_{p} dt$$

or

I

$$\Delta H_{T} = \Delta H_{o} + (H_{T} - H_{o})_{SiO_{(g)}} - (H_{T} - H_{o})_{Si} - \frac{1}{2}(H_{T} - H_{o})_{O_{2}(g)}$$

In order to make an estimate of the uncertainty in this calculation, it was necessary to take into account the accuracy of all the data used in making it. Since Stull and Sinke²⁵had not stated the accuracy of their data, we made our own estimate of their accuracy as indicated in Table III. In order to make a partial check on our computation of the heat of formation of $SiO_{(g)}$, we have tabulated the data of Coughlin⁹ and Humphrey et al¹⁸ in the second row of the table. Their data for 298° K and 2000° K are in good agreement with ours.

3. Heat of the Overall Reaction

In the previous sections, the heats of formation of $SiO_{2(1)}$ and $SiO_{(g)}$ in the range of 2,000° K - 3,000° K were evaluated. Those results can be readily used to calculate the heat of the overall reaction for the vaporization of liquid SiO_2 by means of the relation $\Delta H_T = \Delta H_f [SiO_{(g)}] - \Delta H_f [SiO_{2(1)}]$.

In Table IV are summarized the results of such calculations at 2,000° K, 2,500° K, and 3,000° K.

| | or (\pm 3,690) | or ($\pm 4,260$) | or (± 4, 835) |

Note that uncertainties at 2,500° K and 3,000° K are less than would be calculated by simple addition of the component uncertainties. (See Table V.) A second set of estimated uncertainties (indicated in parenthesis) are 1,500 calorie in excess of those not shown in parenthesis. Thus, Coughlin⁹ gave an uncertainty of 2,000 calorie for $\Delta H_{f(SiO_g)}$ at 298° K, whereas Brewer and Edwards gave 574 calorie even though they had both evaluated the same original data. To make the best estimate of the uncertainties in the heats of reaction obtained above, the sums involved in deriving the values must be considered in detail. It is shown by the following algebraic manipulations that some of the uncertainties cancel out. The remaining terms actually used in calculating the heat of reaction, can be added without regard to algebraic sign to get the true uncertainty.

For the reaction $SiO_{2(1)} \rightarrow SiO_{(g)} + \frac{1}{2}O_{2(g)}$ it follows that

$$\Delta H_{reaction} = \Delta H_{f(0_2)} + \Delta H_{f(SiO_g)} - \Delta H_{f(SiO_{2(1)})}$$

$$= 0 + \Delta H_{0}^{\circ} + (H_T - H_0)_{SiO_{(g)}} - (H_T - H_0)_{Si_{(1)}} - \frac{1}{2}(H_T - H_0)_{O_{2(g)}}$$

$$- \Delta H_{f(2,000^{\circ})} - (H_T - H_{2000})_{SiO_2} + (H_T - H_{2000})_{Si_{(1)}} + (H_T - H_{2000})_{O_{2(g)}}$$

-12-

$$\Delta H_{reaction} = \Delta H_{of}^{o} - \Delta H_{2000f}^{o} + (H_{T} - H_{o}) - (H_{T} - H_{2000}) (SiO_{2(1)}) - (H_{2000} - H_{2000}) (SiO_{2(1)}) - (H_{2000} - H_{o})_{Si(1)} + \frac{1}{2}(H_{T} - H_{2000})_{O_{2(g)}} - \frac{1}{2}(H_{2000} - H_{o})_{O_{2(g)}} - \frac{1}{2}(H_{200} - H_{o})_{O_{2(g)}} - \frac{1}{2}(H$$

Table V shows the magnitudes of the uncertainties of the quantities in the latter equation. Their sums were taken as the true uncertainty. At 3,000° K it is seen that about half of the error arises from the thermochemical data for the heats of formation of the reference materials. This may be somewhat optimistic inasmuch as the other determinations of the heat of formation of $SiO_{(g)}$ quoted by Brewer and Edwards^{8,19} indicate a possible spread of a few thousand calories per mole. Hence, it is possible that the uncertainty in ΔH° may be larger than the 574 $SiO_{(g)}$

calorie/mole given. If this uncertainty is 2,000 calories/mole, as chosen by Coughlin, then the resultant uncertainty in the overall heat of reaction at 3,000° K is about 5,000 calories/mole. The 2,000 value for the uncertainty of the heat of formation of $SiO_{(g)}$ may be more reasonable than the 574 value since other experimenters' values have had a wider spread than 574 calories. The other large uncertainty contributions arise from the estimation of heat capacity data for liquid SiO_2 and liquid silicon.

For the previous calculation of the heat of the reaction $SiO_{2(1)} \rightarrow SiO_{(g)} + \frac{1}{2}O_{2(g)}$ it might appear preferable to use heat of reaction data based on this reaction directly. However, directly determined data such as those of Brewer and Mastick² and recalculated by Brewer and Edwards⁸, 19 gives a greater uncertainty in the final heat of reaction. For example, these authors give $\Delta H_0^0 = 186,578 \pm 2,700$ calorie/mole for the reaction $SiO_{2(crist)}^{-} \rightarrow SiO_{(g)} + \frac{1}{2}O_{2(g)}^{-}$. As a check on the earlier calculations and in order to show that the Brewer Mastick work is more uncertain, it is possible to calculate ΔH_T for the first reaction above using the direct data of Brewer and Mastick in the following manner:

$$\Delta H_{T} = \Delta H_{o}^{o} + (H_{T} - H_{o})_{SiO_{(g)}} + \frac{1}{2}(H_{T} - H_{o})_{O_{2(g)}} - (H_{T} - H_{o})_{SiO_{2(1)}}$$
 referred to cristobalite at O^oK

| $\frac{1}{2}(H_{T} - H_{o}) = \frac{1}{2} 1$ | ± 80 | ± 100 | ± 125 |
| | | | |
| | ± 2,264(3,690)** | ±2,834(4,260)** | ± 3, 409(4, 835)** |

*Combined uncertainty of last two terms of equation used.

**Coughlin's estimate of uncertainty in $\Delta H_{f(SiO)}$, shown in parenthesis, is greater than that of Brewer and Edwards.

Values of $(H_T - H_0)_{SiO}$ and $(H_T - H_0)_{O}$ have already been obtained and listed in Table III. The heat content of liquid SiO₂ relative to cristobalite at 0° K, can be obtained from the relation

$$(H_{T} - H_{o})_{SiO_{2(1)}} = (H_{T} - H_{2000})_{SiO_{2(1)}} + \Delta H_{fusion of} + (H_{2000} - H_{298}) + (H_{298} - H_{o})_{crist.}$$

which can be evaluated as follows:

$$(H_{T} - H_{2000})_{SiO_{2}(1)} = 21,660 \pm 1,000 \text{ calorie/mole (from Table I.)}$$

$$\Delta H_{fusion} = 2,500 \pm 500 \text{ calorie/mole (see earlier discussion)}$$

$$(H_{2000} - H_{298})_{crist.} = 28,120 \pm 600 \text{ calorie/mole (K. K. Kelley^{13})}$$

$$(H_{298} - H_{o})_{crist.} = 1,667 \pm 50 \text{ calorie/mole (Edwards^{19})}$$

$$(H_{T} - H_{o})_{SiO_{2}(1)}_{referred to cristobalite at O^{o}K}$$

Substituting the latter into the expression for ΔH_T , we find that ΔH_{3000} = 170,621 ± 5,225.

This value of the heat of reaction agrees well with our previous value of $\Delta H_{3000} = 171,513 \pm 3,400$ calorie/mole. However, the earlier data of Table IV have a smaller uncertainty and are used for subsequent calculations.

4. Total Heat of Decomposition

The total heat, which can be absorbed by fused silica when it decomposes at 3,000° K by the reaction $SiO_{2(1)} \rightarrow SiO_{(g)} + \frac{1}{2}O_{2(g)}$, is now computed as follows:

$$(H_{2000} - H_{298})_{SiO_2(glass)} = 29,010 \text{ calorie/mole (Kelley 13)}$$

 $(H_{3000} - H_{2000})_{SiO_2(liq or glass)} = 21,660 \text{ calorie/mole (Table I)}$ $\Delta H_{3000} \text{ for } SiO_2 \longrightarrow SiO_{(g)} + \frac{1}{2}O_2 = 171,513 \text{ calorie/mole (Table IV)}$ Total heat of decomposing $SiO_{2(glass)}$ at 3,000° K starting from 298° K.
The equivalent value in other
units at 4,940° F starting from
77° F is = 6,650 Btu/lb

I

1

B. ENTROPY CHANGE

Stull and Sinke²⁵give the absolute entropy of $O_{2(g)}$. In Table II are given the entropy data for $SiO_{(g)}$. Kelley⁹ gives the entropy of $SiO_{2(glass)}$ at 298° K as $S_{298} = 11.2 \pm 0.4$ eu. For higher temperatures Kelley¹³gives $S_{2000} - S_{298} = 29.87$ eu. Thus $S_{2000}^{\circ} = 41.07$ eu. In order to obtain entropy data for $SiO_{2(1)}$ above 2,000° K, we have had to use our estimated heat capacity data ($C_{p} = 21.66$ calorie/mole degree). The results of these calculations are shown in Table VI.

C. FREE ENERGY CHANGE

Having obtained the heat of reaction and the entropy change in the previous sections, it is now possible to calculate the free energy change from the relation

 $\Delta F = \Delta H = T \Delta S .$

The results of this calculation are shown in Table VII.

For ΔH , the uncertainties represent maximum estimates. In estimating the uncertainties in ΔF from the data in Table IV, the uncertainties of ΔH and T ΔS do not add algebraically. Actually, discussed uncertainties cancel in part by the use of consistent heat capacity data and discussed in the following paragraphs so that the value given at 3,000° K is probably good to about \pm 4,000 calories/mole, depending again on the uncertainty of the heat of formation of $SiO_{(g)}$.

-17-

The variation of the above free energy data with temperature can be represented with sufficient accuracy by a straight line such as

$$\Delta F_{T} = 173,000 - 54.2 T (calorie/mole)$$

which is valid for the temperature range of 2,000° K to 3,000° K and accurate to \pm 4,000 calorie/mole at 3,000° K. The values from this equation fit the calculated points of Table VII sufficiently well that it can be used for the sake of simplicity in our applications. This linear equation can also be used to extrapolate slightly beyond the temperature range of the data. (2,000 - 3,000° K)

In assessing the accuracy of the free energy expression which we have obtained, we may take as a second trial a heat capacity for liquid SiO of 20.66 calorie/mole • K instead of the 21.66 calorie/mole • K as in our earlier calculations. With such a value of heat capacity, the heat of formation of at 3,000° K would be ΔH_{3000}^* = -211,467 (instead of -210,467) SiO₂₍₁₎ calorie/mole. In Table IV use of this value of ΔH_f , $SiO_2(1)$ heat of the reaction to $\Delta H \left[SiO_2(1) \longrightarrow SiO_{(g)} + \frac{1}{2}O_2(g)\right]$ will raise the = 172, 513calorie/mole (instead of 171, 513). Next, from Table VI it can be seen that the entropy of $SiO_{2(1)}$ would be lowered by the use of the smaller C_p value by an amount equal to $\Delta S_{SiO_2(1)}$ = 0.41 e.u. This would make $\Delta S_{SiO}_{2;3,000^{\circ}K}$ = 49.62 e.u. (instead of 50.03 e.u.). Consequently, the Δs of reaction at 3,000° K would be increased to 54.04 e.u. (instead of 53.63 e.u.), and (T∆S) 3000° K = 162, 120 calorie (instead of 160, 890 calorie). The corresponding free energy value is = 10,393 calorie/mole ΔF 3,000°K instead of the 10,623 calorie/mole obtained with $C_p = 21.66$ calorie/mole[•] K or a decrease below the previous value of 230 calorie/mole. The lower C_p value for SiO, indicates a slightly increased vapor pressure.

It is seen from the above discussion that the free energy does not change too rapidly with changes in the value of the heat capacity of liquid silica although its components, the heat of reaction, and the entropy do. This can be shown by the following more general treatment.

To estimate the accuracy of our free energy functions, we need to reconsider in detail how they were calculated. The discussion is based on the fundamental definition,

 $\Delta F = \Delta H - T\Delta S \quad .$

(6)

In considering the reaction

$$SiO_{2(1)} \longrightarrow SiO_{(g)} + \frac{1}{2}O_{2(g)}$$
 (7)

we have noted that at 2,000° K the free energy change is accurate to about \pm 3,000 calories/mole. This is the uncertainty estimated from Coughlin's table. Of this uncertainty about 2,000 calorie/mole is associated with contributions from the formation of SiO_(g) and 1,000 calorie/mole is associated with the formation of liquid SiO₂. To make a rough estimate of the errors to be expected at higher temperatures, we can modify the fundamental equation to obtain

$$\Delta F = \Delta H_{2000} + \int_{2000}^{T} \Delta C_{p} dT - T \left(\Delta S_{2000} + \int_{2000}^{T} \Delta C_{p} dT \right)$$

= $\Delta H_{2000} - 2000 \cdot \Delta S_{2000} - (T - 2000) \Delta S_{2000}$

+
$$\int_{2000}^{T} \Delta C_p dT - T \int_{2000}^{T} \frac{\Delta C_p dT}{T}$$

If we now designate the first two terms of this last equation as ΔF_{2000} and replace our variable of integration T by r the dummy variable (to avoid confusion with the T used as the limit of our integration) we obtain

$$\Delta F = \Delta F_{2000} - (T - 2000) \Delta S_{2000} + \int_{2000}^{T} \Delta C_{p} dr - T \int_{2000}^{T} \frac{\Delta C_{p}}{r} dr$$

-19-

$$= \Delta F_{2000} - (T - 2000) \Delta S_{2000} + T \int_{2000}^{T} (\frac{\Delta CP}{T} - \frac{\Delta CP}{r}) dr$$

The uncertainty in $\Delta F_{2,000}$ is $\pm 3,000$ calorie/mole according to our earlier estimate. Since the value of $\Delta S_{2,000} = 57.08 \pm 0.7$ e.u., the uncertainty in the second term at 3,000° K is ± 700 calorie/mole. The last integral would also contribute to the overall uncertainty if ΔC_p for the reaction were in error. For the present case, we may get a rough order of magnitude of this uncertainty if we note that

Cp for $\frac{1}{2}O_2 \cong 4.5$ calorie/mole degree, $C_{\text{pSiO}} = 9.0$ calorie/mole degree, and $C_{\text{pSiO}_2} = 21.66$ calorie/mole degree. Hence, $\Delta C_p \cong -8.0$ calorie/ mole degree. The most likely source of error in ΔC_p is C_{pSiO_2} . If this error were 1 calorie/mole degree so that actually $C_{\text{pSiO}_2} = 20.66$ and $\Delta C_p = -7.0$, then the total error would amount to an additional 220 calorie/mole. Thus at 3,000° K the uncertainties in ΔF add up to 3,920 or 4,000 calorie/mole.

As a further check on the free energy equation which we have obtained, we can compare values of the free energy at 2,000° K with those tabulated by Coughlin. He gives $\Delta F^{\circ}_{2,000} = -59,200$ calorie/mole and $\Delta F^{\circ}_{2,000}_{SiO_{(g)}}$

= -123,900 calorie/mole from which we get for the reaction $SiO_{2(1)} \rightarrow SiO_{(g)}$

+ $\frac{1}{2}O_{2(g)}$ the free energy change

 $\Delta F_{2,000} = 64,700 \pm 3,000$ calorie/mole

This compares favorably with our value of 64,600 calorie/mole based on the empirical formula.

In figure 1 are plotted the free energy data obtained by the present calculations. The empirical equation has been extrapolated above 3,000° K. This can be safely done over a narrow temperature range and will be a fair approximation at higher temperatures. From the expression

1

-20-

$$\Delta F = \Delta H - T\Delta S ,$$

with a reference temperature of 3,000° K, we find

$$\Delta F_{T} = \Delta H_{3,000} + \int_{3,000}^{T} \Delta C_{p} dT - T \Delta S_{3,000} - T \int_{3,000}^{T} \frac{\Delta C_{p} dT}{T}$$

where ΔC_p is equal to the change in heat capacity of the reaction considered, i.e.,

$$\Delta C_{p} = \frac{1}{2} C_{p_{0_{2}}} + C_{pSiO} - C_{pSiO_{2(1)}}$$

For small temperature intervals, the second and fourth terms in the free energy equation will cancel, thus justifying the extrapolation,

$$\Delta F_{T} = \Delta H_{3,000} - T\Delta S_{3,000}$$

For temperatures below 2,000° K, where solid SiO_2 is the stable phase, the data of Coughlin⁹ for cristobalite have also been plotted in figure 1. In this case his tabulated free energies of formation for SiO_2 and $SiO_{(g)}$ can be subtracted and used directly.

It is also possible to develop an empirical free energy equation for the immediate range below 2,000° K, by the use of entropy data. For example, for the reaction

$$SiO_2(cristobalite) \longrightarrow SiO_{(g)} + \frac{1}{2}O_2(g)$$

we get

0.0

$$S_{cristobalite; 2,0000 K} = S_{2980K} + (S_{2,0000K} - S_{2980K}) = 40.04 \text{ e.u.} \quad 13,14.$$

$$\frac{12}{5}S_{2;2,0000K} = 32.11 \text{ e.u.}$$

$$S_{SiO 2,000^{\circ}K} = 66.04 \text{ e.u.}$$

$$\Delta S_{2,000^{\circ}K} = S_{SiO} + \frac{1}{2}S_{O_2} - S_{SiO_2} = 58.11 \text{ e.u.}$$

Using this value of the entropy change at 2,000° K, we can now fit a curve through the 2,000° K point, since $\Delta F_{2,000} = 64,600$ calorie/mole from our previous formula. Hence,

 $\Delta F^{\circ} = 180,800 - 58.11 T (calorie/mole for 1,800 < T < 2,000^{\circ}K)$

The above relation gives $\Delta F_{1,800}^{o} = 76,200$ calorie/mole and $\Delta F_{1,900}^{o} = 70,390$ calorie/mole. These values can be compared with values calculated from Coughlin's data

 $\Delta F^{o}_{1,800} = 76,450 \text{ calorie/mole}$ $\Delta F^{o}_{1,900} = 70,650 \text{ calorie/mole}.$

This good agreement increases our confidence in the data and calculations.

D. EQUILIBRIUM CONSTANT

For the evaluation of the equilibrium constant corresponding to the reaction that is the subject of Section II, the usual relation ΔF° = -RT in K can be modified to give

$$lo_{g_{10}K} = \frac{-\Delta F}{2.303 RT} = \frac{\Delta H}{4.57T} + \frac{\Delta S}{4.57}$$

For the present case, this becomes

$$l_{0g_{10}K} = \frac{-37,900}{T} + 11.85$$

This equilibrium constant has been plotted in figure 2 as a function of 1/T. It can be seen that at higher temperatures, the equilibrium constant becomes larger.

and

E. EQUILIBRIUM VAPOR PRESSURE

In the range 2,000 - 3,000° K we have shown that the standard free energy of the reaction $SiO_{2(1)} \rightarrow SiO_{(g)} + \frac{1}{2}O_{2(g)}$ can be represented as a function of temperature by

 $\Delta F_{T}^{o} = 173,000 - 54.2T.$

1

This is related to the equilibrium constant, K by the conventional definition

$$\Delta F_{T}^{o} = -RT \ln \frac{a_{SiO_{(g)}}}{a_{SiO_{2(1)}}}$$

where $A_i = activity$ of component (or the fugacity in case of gaseous components). For liquid $SiO_{2(1)}$, the usual assumption is made that the activity is unity, i.e., any solution effects of $SiO_{(g)}$, $O_{2(g)}$ or other equilibrium species in SiO_2 are considered negligible.

For the gaseous components, it is reasonable to replace the activities by partial pressures of the species being considered as long as the gases do not deviate markedly from the perfect gas laws. This assumption is valid at low-pressures and high-temperatures. For oxygen (fugacity = 48 atm at pressure of 50 atm and 0° C, ⁶¹ critical temperature, $T_c = 154.3^{\circ}$ K, critical pressure, $P_c = 49.7$ atm) at

50 atm and 2,000° K the reduced temperature is $T_{\rm R} = \frac{T}{T_{\rm c}} = 12.95$, and the reduced pressure $P_{\rm r} = P/P_{\rm c} = 0.995$. For this case³⁴ f/P = 1.0 + and the fugacity is essentially equal to the pressure.

For SiO_(g), whose condensed properties are practically unknown, we must use some very rough approximations to estimate P_c and T_c. Hirschfelder et al⁶² list some rough empirical rules which can be used in this case. Using the condition that the melting temperature is 2/5, and the fact that Edwards¹⁹ states that the melting point of SiO must be greater than 1,975° K, we calculate T_c \cong 5,000° K. To estimate the molar volume at the critical point, we note that Vsol = 0.321 V_c. According to Edwards¹⁹ the density of solid SiO is about 2.15 gm/cm⁹ (20.5 cm³/mole). Making the assumption that the molar volume of SiO at its

-23-

melting point is equal to the molar volume (20.5 cm³/mole) given by Edwards, we find a molar volume at the critical point of $\tilde{v}_c = 64.0 \text{ cm}^3/\text{mole}$. Finally, from the fact that many molecules have a compressibility factor of 0.292 (Hirschfelder et al)², we find that $v_c = 1,870$ atm. At 50 atm. and 2,000° K, $p_c = 0.0267$, and $T_R = 0.4$. Again, estimating from the Hougen and Watson chart, it is found that $t/P \cong 0.95$. In view of the uncertainties involved in the above calculations, the results must be considered very approximate. However, they do indicate that in the pressure range of interest (1-50 atm) and from 2,000 - 3,000° K, the gas will behave ideally. For further considerations, pressures will be used instead of fugacities.

Using the simplifying assumptions discussed above, we get for the final formulas

$$\Delta F_{\rm T}^{\rm o} = - RT \ln P_{\rm SiO} PO_2 = - RT \ln K_{\rm eq} ,$$

or

$$\frac{-\Delta F^{\circ}}{RT} = e \frac{-173,000}{RT} \frac{54.2}{RT}$$

$$P_{SiO} PO_{2} = e RT = e RT = R$$

Under neutral conditions, $P_{SiO} = 2P_{O_2}$

and

$$P_{SiO} = e^{18.\zeta_1} \left(1 - \frac{3160}{T}\right)$$

The vapor pressure data for this equation are presented as the upper curve in figure 3. It gives a partial pressure of 0.667 atm for $SiO_{(g)}$ at 3,085° K (Boiling point under neutral conditions, neglecting other reactions). It should also be noted that

$$P_{\text{total}} = 1.5 P_{\text{SiO}} = 1.5 e^{-1.5 $

The vapor pressure of $SiO_{(g)}$ in equilibrium with condensed SiO_2 is plotted for a large temperature range in figure 4. The principal curve in this figure is based on the single reaction given and neglects all other equilibria.

For the case of SiO_2 decomposing in the presence of air,

$$P_{N2} = 4(P_{O_2} - P_{SiO})$$

and

$$P_{total} = P_{N2} + P_{SiO} = constant = 5PO_2 - P_{SiO}$$

From the above relation for $P_{SiO} PO_{2}$

we now find

$$P_{SiO} (p_{total}^{+} P_{UU})^{\frac{1}{2}} = e^{28.0} (1 - \frac{3110}{T})$$

These data have been plotted in figures 3 and 4 for the two cases, p = 1 atm, and p = 10 atm.

It can be seen from the above equations that the presence of the oxygen suppresses the SiO gas formation. It should also be emphasized that the data here presented assumes only the reaction $SiO_{(g)} + \frac{1}{2}O_{2(g)}$ to be important. Dissociation of oxygen has been neglected here but is included in later discussions. Nitrogen is considered to be an inert gas.

For temperatures below 2,000° K the relation for the vapor pressure P_{SiO} must be modified. Using the relation $\Delta F^{o} = 180,800 - 58.11$ T for (1,800° K<T<2,000° K)

we get

19.72 (1-3075)P_{SiO} = e T
A curve for this function has been plotted in figure 5 over the temperature range (1,800 - 2,000° K). For comparison purposes the available experimental data have also been plotted. The effusion cell measurements of Brewer and Mastick are seen to agree well with the calculated data. The mass spectrometric measurements of Porter et al 3 are high by a factor of about 6. Porter et al ³ indicated in their paper and in private communications that their absolute values of pressures could be in error by a factor of 2 or 3. A point of possible uncertainty in the work of Porter et al is the fact that they used some older vapor pressure data from Brewer, ³⁶ They had calibrated their equipment by assuming that $P_{Ag}^{107} = 1 \times 10^{-6}$ atm at 1,245° K, and that $P_{Au} = 2 \times 10^{-5}$ atm at 1,750° K. However, more recent work by Honig³⁷ gives values of 1.85 x 10^{-6} atm for Ag¹⁰⁷, and 7.9 x 10^{-5} atm for Au. All observed pressures of the various species are then increased for the appropriate temperature range by the ratios 1.85/1 and 7.9/2.0. It is not completely clear that the pressures should be increased by this much since Porter et al³ state that they checked their calibration by the vaporization of a weighed amount of Ag or Au.

To compare their data further with the present results, we have shown in Table VII-A free energy data calculated from their observed vapor pressures. It is seen that the results based on their tabulated pressures are in good agreement with our free energy data. It should also be noted that their reaction does not correspond to stoichiometric conditions. They apparently did not have neutral conditions. The free energy data, based on recalculated vapor pressures, are in poorer agreement with our calculated free energy curve given in figure 1. Further evidence that Porter's tabulated data are probably preferable will be produced when the dissociation of oxygen is considered in a following section.

In the literature given by Inuzuka and Ageha³⁸ are some additional vapor pressure data for SiO_2 . They report a vapor pressure of 1.1×10^{-7} atm for SiO_2 at $1,200^{\circ}$ C ($1,473^{\circ}$ K). They used a "Mo and W wire" to heat a fused SiO_2 tube and measured the vapor pressure by a Langmiur method. At this temperature our thermochemical calculations give a total vapor pressure of 6×10^{-10} atm (See fig. 4), a discrepancy by a factor of 180. However, it is shown in the following arguments that they were actually studying some other reaction, possibly the following:

$$1/3 \text{ Mo}_{(c)} + \text{SiO}_{2(c)} \rightarrow \text{SiO}_{(g)} + 1/3 \text{ MoO}_{3(g)}$$

-26-

TABLE VII-A

·COMPARISON OF FREE ENERGIES BASED ON DATA OF PORTER <u>et al</u> ³

| 1,800° K | PSiO(atm) | PO2 ^(atm) | $\Delta F_{(calcd)}$ (calorie/mole) | ΔF _(our curve) (calorie/mole) |
|---------------------------|-----------------------|----------------------|--|---|
| Porter data, as is | 6.8 x 10^{-6} | 5.2 x 10^{-8} | 72,400 | 76,000 |
| Porter data, corrected | 2.68×10^{-5} | 2.05 x 10^{-7} | 65,100 | |
| <u>1,900° K</u> | | | | |
| Porter data, as is, | 3.4 x 10^{-5} | 8.2 x 10^{-8} | 69,595 | 71,000 |
| Porter data, corrected | 1.34×10^{-4} | 32.4 x 10^{-8} | 61,800 | |

This reaction would tend to give a higher vapor pressure of $SiO_{(g)}$ than expected under neutral conditions. The presence of W might also reduce SiO_{2} , but it would not be expected to change the calculated pressure due to Mo by more than a small factor.

To obtain thermochemical data for the suspected reaction with Mo, we can first use the free energy data of Coughlin for the reaction to give liquid $M_0O_3^{\circ}$, instead of the gaseous product

 $1/3 Mo_{(c)} + SiO_{2(c)} \longrightarrow SiO_{(g)} + 1/3 MoO_{3(1)}$

The free energy of this reaction is then

 $\Delta F_{1473} = \Delta F_{SiO} + 1/3 \Delta F_{MoO_3} - \Delta F_{SiO_2}$

= 63,000 cal/mole

• 5

^{*}Coughlin gives 1068°K as the melting point of NoO3.

Now it is necessary to estimate the free energy of vaporizing liquid Mo03.

 $MoO_{3(1)} \rightarrow MoO_{3(g)}$

We can estimate that $\Delta F_{1,530}^{o} = 0$ for the above vaporization process from the

fact that the normal boiling point of MoO_3 is 1,530° K according to Brewer³⁹. This assumption is probably a conservative one because Berkowitz, Inghram, and Chupka⁷ have shown that, at the boiling point, the species $(MoO_3)_3$, $(MoO_3)_4$, and $(MoO_3)_5$, are probably most important. They indicate that the monomer is present in an amount less than a few percent at the temperature of their measurements (near 900° K). On the other hand, Brewer and Elliott³⁹, 40 indicate that the monomer is probably the most important specie. For the present calculation we make the simplifying assumption that only the monomer is important. We therefore assume that $\Delta F_{1,530}^{\circ}=0$. Actually, if polymers of MoO_3 do exist at the normal boiling point, then $\Delta F_{1,530}^{\circ} \ge 0$ for the above reaction.

We can now estimate the free energy change for vaporization by assuming Trouton's constant to be 21. Therefore $\Delta F_{1473} = 400$ calorie/mole.

Now combining the last two reactions (liquid MoO₃ formation and vaporization) we find for the overall, desired reaction:

 $\Delta F_{1,473} = + 63,000 + 400 = 63,400 \text{ calorie/mole}$

Since $P_{SiO} \cdot \frac{1/3}{P_{MoO_3}} = e^{-\Delta F/RT}$

we find

 $P_{SiO} = 1.24 \times 10^{-7}$ atm.

$$P_{MoO_3} = .4 \times 10^{-7}$$
 atm.

and

 $P_{\text{total}} = 1.65 \text{ x } 10^{-7} \text{ atm.}$

-28-

This last value of that pressure is in good agreement with the value of 1.1×10^{-7} atm reported by Inuzuka³⁸. The above discussion shows that he was not studying the vaporization of pure SiO_2 in a neutral atmosphere and gives additional strength to the data used in the present report. Since Coughlin uses essentially the same heat of formation data for $SiO_{(g)}$ as we used earlier, our recalculation of Inuzuka's results further substantiate that choice.

So far we have only considered one reaction in SiO_2 decomposition as indicated in the title of this section of the report. Because fairly good agreement is obtained with experimental data in this manner, it appears probable that this reaction is the most important one. However, other additional competing or simultaneous reactions may also be important. These will now be considered in the following sections.

III. THERMOCHEMISTRY OF THE REACTION $SiO_{(a)} \rightleftharpoons SiO_{(a)}$

The equilibrium between solid and gaseous SiO is of interest because of the possibility that $SiO_{(g)}$ formation may limit the vapor pressure of $SiO_{(g)}$ to be expected from the reactions discussed in the previous sections. Data concerning properties of solid SiO are very limited. According to Brewer and Edwards^{8, 19} and Hoch and Johnson, ³⁵ SiO_(g) is unstable relative to Si_(g) and SiO_{2(g)} below 1,450°K and 1,573°K, respectively. However, above these temperatures the solid phase SiO_(g) does exist as shown by X-ray diffraction results.

The limited amount of thermodynamic data that are available for $\text{SiO}_{(s)}$ are also very uncertain. Brewer and Edwards⁸ have interpreted the results of Tombs and Welch²³ obtained over a mixture of Si and SiO₂ as referring to the reaction $\text{SiO}_{(s)} \xrightarrow{\sim} \text{SiO}_{(g)}$ in the temperature range of $(1, 573^{\circ} - 1, 920^{\circ} \text{ K})$ They state that for this temperature range $\Delta H = 58,550$ calorie/mole and $\Delta S = 25.45 \text{ e.u.}$, although they point out that the entropy data may be incorrect. If these data are used as stated, for free energy of reaction versus temperature, the approximate relation $\Delta F = 58,550 - Tx25.45$ is obtained. From this, one obtains p = 1 atm ($\Delta F = 0$) at $T = 2,300^{\circ}$ K.

i

Additional vapor pressure data calculated from this relation are plotted in figure 6 by extrapolating to temperatures above 2,000°K. This extrapolation is not considered too good in view of the entropy uncertainty.

One can also utilize the above data in another, more correct extrapolation above $2,000^{\circ}$ K. For this, the following data were taken from Brewer and Edwards: ^{8,19}

C = $10.57 + 2.98 \ge 10^{-3}T - 2.72 \ge 10^{5}T^{-2}$; P(crystalline SiO)

S⁰298(SiO crystalline) = 6.4 e.u.;

and

S^o298 (SiO amorphous) = 7.3 e.u

- 30-

With these data we find that $S_{2,000}^{\circ} = 31.1 \pm 3.0 \text{ e.u.}$ (SiO amorphous) Using our earlier result that $S_{2,000}^{\circ} = 66.04 \text{ e.u.}$, we find that for the present result is a second se

the present reaction $\Delta S = 34.94 e.u.$

If we now assume that the earlier relation $\Delta F = 58,550 - 25.45 T$ is valid at $T = 2,000^{\circ}$ K, we can fit the equation at 2,000° K with better entropy values to extrapolate to higher temperatures.

By using more realistic entropy values, we obtain

 $\Delta F = 77,530 - 34.94 T.$

The above relation corresponds to a heat of reaction of $\Delta H = 77,530$ calorie/mole in the temperature range near 2,000° K. These data are plotted in figure 1. The line is dashed above 2,000° K, because of the uncertainty in the data.

Using the data of Brewer³⁹ on the heat of formation of $SiO_{(s)}$ (- 104,600 calorie/mole), we can estimate the heat of the reaction, $SiO_{(s)} \xrightarrow{} SiO_{(g)}$ as follows:

 $\Delta H_{298} = \Delta H_{f_{SiO}(g)} - \Delta H_{f_{SiO}(s)} = -21,800 - (404,600) \text{ calorie/mole}$ = + 82,800 calorie/mole

Also,

1

I

ł

t

l

$$\Delta H_{T} = \Delta H_{298} + \int_{298}^{T} \Delta C_{p} dT$$

 $\Delta H_{T} = \Delta H_{298} + (H_{T} - H_{298})_{SiO_{(g)}} - (H_{T} - H_{298})_{SiO_{(s)}}$

- 31 -

$$= \Delta H_{298} + (H_T - H_o)_{SiO_{(g)}} - (H_{298} - H_o)_{SiO_{(g)}} - (H_T - H_{298})_{SiO_{(s)}}$$

Therefore,

$$\Delta H_{2,000} = 82,800 + 8.18 \pm 2,500 = 6.955 \pm 298 = \int_{298}^{2,000} \left[10.57 + 2.98 \pm 10^{-3} T - 2.72 \pm 10^{5} T - 2 \right] d$$

= 82,800 + 16,360 - 2,070 - 23,090

$$\Delta H_{2,000} = 74,000 \text{ calorie/mole.}$$

This value agrees well with the value of 77,530 calorie/mole given above, and thus makes the relation seem more reliable. Accordingly, the data for the relation $\Delta F = 77,530 - 34.94$ T have been taken as the best and have been plotted in figure 6.

These data lead to a larger vapor pressure of $SiO_{(g)}$ in equilibrium with $SiO_{(g)}$ than predicted by the first expression $\Delta F = 58,500 - 25.45 \,\mathrm{T}$. However, the data show that the vapor pressure of $SiO_{(g)}$, based on either expression, is much greater than the vapor pressure of $SiO_{(g)}$ in equilibrium with $SiO_{2(s)}$ under neutral conditions. It would, therefore, not be expected that $SiO_{(g)}$ could be formed from $SiO_{\gamma(g)}$ under neutral conditions.

١

5 . . .

IV. ASSOCIATION REACTIONS

Very little information is available regarding the formation of dimers and trimers of $SiO_{(g)}$. The paper of Porter, Chupka, and Inghram³ gives one measurement of the Si_2O_2 pressure in equilibrium with $SiO_{(g)}$. These pressures are 4.5 x 10⁻⁸ atm. and 1.1 x 10⁻⁴ atm., respectively, at 1,463° K.

From this it follows that $K_{eq} = \frac{P_{Si_2O_2}}{P_{SiO}^2} = 3.72 \text{ at } 1,463^{\circ} \text{ K.}$

From the above equilibrium constant, we can calculate that the free energy change for dimerization is $\Delta F_{1,463} = -3,820$ calorie/mole of $\operatorname{Si_2O_2(g)}$. To get a very rough estimate of the degree of dimerization at higher temperatures, it is necessary to estimate the entropy change for the above reaction. Data are already available for the entropy of the monomer, $\operatorname{SiO}_{(g)}$. For the dimer, however, no molecular data are available, and its entropy must be estimated by approximation methods.

The empirical equation of Kubaschewski and Evans¹⁵ can be used to estimate $S_{298} = 64.1 \text{ e.u.}$ for $Si_2O_2(g)$. Assuming that the $Si_2O_2(g)$ has about the same entropy increment as another four-atom molecule, CIF₃, whose entropy increment is $S_{1,500} - S_{298} = 29.5 \text{ e.u.}$ (according to the NBS Series III ⁴¹ tabulation), we get $S_{1,500} = 93.6 \pm 3.0 \text{ e.u.}$ for $Si_2O_2(g)$, where the uncertainty is only estimated. From the tables of Edwards⁹ we find that $S_{1,500} = 63.5 \text{ e.u.}$; and hence for the reaction as given

 $\Delta S = 93.6 - 2(63.5) = -33.4$ e.u.

I

1

l

1

Assuming that $\Delta S_{1,500} = \Delta S_{1,463}$, and using the relation $\Delta F_T = \Delta H_{1,463} - T \pm \Delta S_{1,463}$, we find that $\Delta H_{1,463} = -52,500$ calorie/mole $Si_2O_{2(g)}$. From this we find that $\Delta F_T = -52,500 + 33.4$ T. This relation is, of course, very rough and at an extrapolated temperature of 3,000° K the uncertainty may be $\pm 5,000$ calorie/mole or more. The free energy change for the reverse reaction is shown in figure 1.

At 3,000° K, a free energy change of $\pm 47,700$ calories/mole is obtained from the above equation, corresponding to an equilibrium constant of 3.46 x 10^{-4} . The expected pressure of Si₂O₂ as a function of SiO pressure is presented in Table VIII.

- 33-

TABLE VIII

PRESSURES OF Si202(g) IN EQUILIBRIUM WITH SiO(g) AT 3,000 K

| 10 | 3.46×10^{-2} |
| 100 | 3.46 atm. |

The data in Table VIII shows that the dimerization effect is probably not too important for the case where the boiling point is above 3,000° K and the ambient pressures are less than 50 atms. However, the dimerization phenomenon would be more important (for a given pressure of SiO) at lower temperatures. Again, it should be emphasized that these data do not have high accuracy.

V. OXYGEN DISSOCIATION

Because of the fact that dissociation of oxygen may lead to a higher effective pressure in an equilibrium mixture of SiO₂, which is decomposing to form SiO_(g) and O_{2(g)}, a brief review of the dissociation of O₂ in the temperature range of 2, 900 - 3, 100° K has been made. The data of Stull and Sinke²⁵have been used in the present case. It was necessary to extrapolate the free energy data from 3,000° K to 3,100° K to obtain an equilibrium constant at the higher temperature. (The extrapolated data agree with the earlier NBS Series III ⁴¹ data.) The values of the equilibrium constants obtained are shown in Table IX.

TABLE IX

EQUILIBRIUM CONSTANTS FOR THE REACTION $40_{2(g)} = 0_{(g)}$

| Temperature | к = ^Р О |
|-------------|--------------------|
| () | P02 |
| 2,900 | 0.079 |
| 3,000 | 0.112 |
| 3,100 | 0.157 |

From the equilibrium constants shown in Table IX, values of the PO_2/PO_1 ratio have been obtained for various selected oxygen pressures. The results of these calculations are plotted in figure 7 where it is seen that at an oxygen pressure of 0.01 atm at 2,960° K the pressure of oxygen atoms, in equilibrium, is also about 0.01 atm. For the case of 0.333 atm O_2 at 3,100° K, there will be an atomic oxygen pressure of $PO_{(g)} = 0.09$ atm \cdot The dissociation of $O_{(g)}$ will contribute a significant (although smaller) amount to the total pressure in the case of decomposition of SiO₂ to SiO and O_2

To cover an even wider temperature range, the data of Stull and Sinke below 3,000° K and of the NBS above 3,000° K have been used to obtain the free energy change and equilibrium constants for the dissociation reaction. To get an approximate linear relation for the free energy change of the reaction at 3,000° K, the data of Stull and Sinke²⁵was used. From their heat of reaction and entropy data, the following relation is obtained: $\Delta F = 61,348 - 16.11$ T. This relation gives a free energy change of 29,129 calorie/mole at 2,000° K, whereas Stull and Sinke's²⁵tabulation gives 29,091 calorie/mole. The above in figures 1 and 2.

1

The data on the dissociation of oxygen are well known and provide a test of the reliability of the SiO_2 decomposition data reported by Porter et al, inasmuch as their mass spectrometric measurements included both O_2 and O. At 1,900° K they give

$$P_O = 2.2 \pm 10^{-7}$$
 atm. and $P_{O_2} = 8.2 \pm 10^{-8}$ atm.

for the reaction $\frac{1}{2}O_2 \rightarrow O_{(g)}$. This corresponds to

$$K_{1,900} = 7.7 \pm 10^{-4} = \frac{PO}{PO_{2}^{1/2}}$$

Hence $\Delta F_{1,900} = 27,065$ calorie/mole . For the same dissociation reaction, Stull and Sinke²⁵ give

| Temperature, 'K | Log10K | ΔF^{o} , celorie/mole |
|-----------------|------------------|-------------------------------|
| 1,900 2,000 | -3.529 -3.178 | 30,678 29,091 |
| 2,100 | -2.859 | 27.477 |

Thus, we see that Porter's free energy value of 27,065 calorie/mole, based on his reported pressure measurements, is low by 3,613 calorie/mole at 1,900° K.

If we had attempted to correct Porter's vapor pressures by using the more recent gold vapor pressure data, then the pressures would have been increased by a factor of 3.95. This would increase the equililibrium constant at 1,900° K to a value of $log_{10}K = -2.815$, thus making the standard free energy change $\Delta F_{1,900} = 24,400$ calorie/mole

However, this value is in error by 6,300 calories at 1,900° K, whereas the actual value reported by Porter, et al, is in error by only 3,600 calories/mole. Therefore, it seems that there may have been either compensating errors in Porter's reported data, in their choice of cross sections, or the newer gold vapor pressure data may be in error. In any case, at this time it appears more logical to accept Porter's tabulated pressure data as being correct because it yields free energy values in better agreement with the known values on the O_2 dissociation reaction.

t

- 36-

To estimate the importance of the $_{SiO}$ dissociation reaction to yield $_{Si_{O}}$ we can use the following free energy and entropy of formation data at 3,000° K:

For $Si_{(g)}$, $\Delta F_{3,000} = 10,618$ calorie/mole (Ref. 25, Stull a. d Sinke) using $Si_{(1)}$ as reference state,

For $O_{2(g)}$, $\Delta F_{3,000} = 0$ (Since O_2 is reference state),

For the formation of $SiO_{(g)}$ (i.e., for the reaction $Si_{(1)} + \frac{1}{2}O_{2(g)} \rightarrow SiO_{(g)}$),

 $\Delta F_{3,000} = \Delta H_{3,000} - T \Delta S_{3,000} = -38,954 - 3,000 (\Delta S_{3,000}) calorie/mole$

$$\Delta S_{3,000} = S_{Si0} - \frac{1}{2} S_{0_{2(g)}} - S_{Si_{(1)}} = 10.17 \text{ e.u.}$$

and

ļ

 $\Delta F_{3.000} = 69,464$ calorie/mole (for SiO_(g) formation)

where the entropies of $Si_{(1)}$ and O_2 are from Stull and Sinke²⁵ and that of $SiO_{(g)}$ from our calculations. Assuming that ΔH and ΔS do not depend upon temperature, we find that $\Delta F = -38,954 - 10.17$ T for this reaction in the temperature range of 2,000° K to 3,000° K. From these data, we find that, for the first reaction given above, (i.e. $SiO_{(g)} \rightarrow Si_{(g)} + \frac{14}{2}O_{2(g)}$)

 $\Delta F_{3,000} = + 80,082 \text{ calorie/mole}$

and

 $\Delta S_{3,000} = \frac{1}{2} S_{O_{2(g)}} + S_{Si(g)} - S_{SiO_{(g)}} = 16.31 \text{ e.u.}$

Hence, $\Delta F = 129,000 - 16.31 \text{ mear } T = 3,000^{\circ} \text{K}$,

Now we can calculate the equilibrium constant at 3,000° K,

$$\Delta F_{3,000} = -RT \ln K = 80,082$$

or K = 1.45 x 10^{-.6} = $\frac{P_{Si}PO_2}{P_{SiO}}$

If we consider the case where $P_{SiO} = 0.4 \text{ atm.}$ and $P_{O_2} = 0.2 \text{ atm.}$, (i.e., the approximate vapor pressures under neutral conditions at 3,000° K from figure 3) we find that

$$P_{Si} = 1.30 \pm 10^{-6}$$
 atm.

It can be seen that a negligible amount of monomeric Si(g) vapor exists under these conditions. Dimers and larger aggregates of Si would also be negligible under these conditions since the equilibrium studies of Honig²⁴ show the monomer to be the most important species, even when the condensed phase of silicon is present. The calculated partial pressure of silicon is far removed from such saturation conditions inasmuch as Stull and Sinke²⁵ report a boiling point of Silicon of 2,950°K and Honig³⁷ gives 3,060°K.

1

A. GENERAL

For estimation of thermochemical quantities involved in vaporization of liquid SiO₂ to gaseous SiO₂, the most pertinent available data are those of Porter, Chupka, and Inghram.³ They have made a mass spectrometric study of the decomposition of cristobalite at 1,800°K and 1,900°K.

SiO2(cristobalite) -> SiO2(g) .

They found that $\Delta H_{298}^{o} = 136 \pm 8$ Kcalorie/mole, from slopes of their log $\sum_{vs 1/T}$ data. However, in a personal communication Porter has stated that more accurate heat of reaction data (and hence free energy data) could be obtained for the above reaction with a suitable estimate of the entropy change in combination with their published pressures. Brewer and Searcy ⁴² have also discussed the value of this type of calculation.

B. ESTIMATE OF ENTROPY FOR $sio_{2(g)}$

Since there is little published information about $SiO_{2(g)}$, it has been necessary to make some assumptions about the configuration of the molecule. Knowledge about the CO_2 molecule is used as the basis for estimating properties of the SiO₂ molecule.

Since the CO_2 molecule has a linear structure, it has been assumed that SiO_2 is also linear. In estimating the interatomic distances the following data were considered:

| Molecule | <u>re</u> (A) | Ref. |
|--------------------|---------------|------------------------|
| SiO | 1.510 | Herzberg ³² |
| со | 1.1284 | Herzberg ⁴³ |
| $CO_2 (r_{C} = 0)$ | 1.1615 | Herzberg ⁴³ |

Ο

From these data we estimate the interatomic distance (Si=0) of linear SiO₂ to be 1.54A.

The estimation of the vibrational frequencies for the linear siO_2 molecule has also been done by analogy with CO_2 . In Table X are shown some

- 39-

vibrational frequency data for CO_2 , CS_2 , CO, and CS molecules. It is seen that for the diatomic molecules the ratio of the vibrational frequencies, ${}^{\nu}CS/{}^{\nu}CO} = 0.59$ which agrees qualitatively (maximum error = 17 percent) with the corresponding ratios for the triatomic molecules CO_2 and CS_2 . The corresponding ratio of vibrational frequencies for the diatomic SiO and CO was obtained from Herzberg's book 32 which gives $\nu SiO/\nu CO = 0.572$. This ratio was then used to calculate the vibrational frequencies of SiO_2 from the corresponding frequencies for CO_2 . This calculation is approximate and the calculated vibrational frequencies might be in error by as much as 15 to 20 percent.

TABLE X

VIBRATIONAL FREQUENCY DATA ESTIMATED FOR SiO2(8)

| Mode | coz | CS ₂ | Ratio $\nu CS_2 / \nu CO_2$ | Ref. |
|----------------------------------|-------------------------|----------------------------------|-------------------------------|------------------------|
| Stretching, v1 | $1,342 \text{ cm}^{-1}$ | 656.5 | 0.49 | Herzberg ⁴³ |
| Bending, ν_2 (degenerate) | 667 | 396 | 0.59 | Herzberg ⁴³ |
| Stretchi'.;, 13 | 2, 349 | 1,523 | 0.65 | Herzberg ⁴³ |
| | co | <u>cs</u> | Ratio vCS/vCO | |
| ν1 | 2,170 | 1,285 | 0.59 | Herzberg ³² |
| | co | SiO | Ratio vsi0/vC0 | |
| v 1 | 2,170 | 1,242 | 0.572 | Herzberg ³² |
| | coz | SiO ₂ (calculated) | Ratio vSiO2/vCO2 (assumed) | |
| ۲ 1 | $1,342 \text{ cm}^{-1}$ | 767 | 0. 572 | |
| ¥2 | 667 | 382 | 0.572 | |
| ¥3 | 2, 349 | 1,340 | 0.572 | |

-40-

For the moment of inertia of the SiO_2 molecule, we used the relation given by $Herzberg^{43}$ for the moment of inertia of a symmetrical molecule.

$$I_B = 2M_o r_{Si}^2 = 0$$

where M_0 is the mass of the oxygen atom and $r_{Si} = 0$ is the interatomic distance

 $M_o = 16 \times 1.66 \times 10 - 24$ gm

$$^{t}Si = 0 = 1.54A^{\circ} = 1.54 \pm 10^{-8}$$
 cm,

Hence, we estimate for SiO₂ that

$$I_{\rm B} = 1.26 \times 10^{-38} \, {\rm gm} - {\rm cm}^2$$
.

For the temperature ranges of possible interest in this calculation (T <5,000° K), electronic contributions are assumed to be negligible. It is assumed that only a single electronic ground state is occupied because the SiO_2 molecule has an even number of electrons. Dr. Beckett, of the National Bureau of Standards in a private communication has stated that very roughly speaking the n. higher state would probably be at least 5 e.v. above the ground state. Since 5 e.v. corresponds to a value of RT = 115,300 calorie, or T = 58,000° K, it can be seen that contributions to the partition function will be negligible at the temperatures under consideration here and essentially only the ground electronic state will be occupied.

The calculation of the entropy for $SiO_{2(g)}$ was made with the statistical mechanical formula given by Kelley¹⁴ for linear polyatomic molecules.

 $S = 3/2 R \ln_e M + 7/2 R \ln_e T - R \ln P + R \ln I - R \ln \sigma - + \Sigma S (Einstein) + S_{el}^{o} + 175.385$

The present calculation is for atmosphere pressure and so the third term above does not contribute to S. The symmetry number σ has the value two for the SiO₂ molecule. Evaluation of the Σ S(Einstein) contribution must be

made for the four vibrational degrees of freedom for a linear triatomic molecule.

Terms for ν_1 and ν_3 contribute once each to this sum whereas those for ν_2 (the bending vibration) contribute twice. The tables of Taylor and Glasstone⁴⁴ have facilitated evaluation of the vibrational terms. No attempt has been made to incorporate refinements such as Fermi resonance which apply to the CO₂ molecule.

Enthalpy calculations were made with the relation

.

 $\frac{(H - H_0)}{T} = 7/2 R = 6.954$ Translation + rotation + el

The terms due to vibration can again be added from Taylor and Glasstone's 44 tables.

In Table XI are listed the resulting heat capacity, enthalpy, and entropy data calculated for the linear $SiO_{2(g)}$ molecule.

TABLE XI

HEAT CAPACITY, ENTHALPY, AND ENTROPY DATA

FOR THE ASSUMED, LINEAR SiO_{2(g)} MOLECULE

| | | $(H-H_0)$ | | - (8) | |

| 2,000 | 14.67 | 13.06 | 26,120 | 23, 578 | 80.06 |
| 2,500 | 14.73 | 13.40 | 33, 500 | 30,958 | 83.37 |
| 3,000 | 14.79 | 13.62 | 40,860 | 38, 318 | 85.96 |

-42-

The heat capacity data obtained in Table XI are plotted in figure 8. For comparison purposes the heat capacity of $CO_{2(g)}$ has been included. It is seen that above 2,500° K the heat capacity of CO_2 exceeds the estimated heat capacity for $SiO_{2(g)}$. This probably occurs because such complicating factors in CO_2 as the Fermi resonance (or accidental degeneracy) and other refinements have not been considered in the present calculation.

1 m

From Porter et al's paper³, we obtain for the reaction $SiO_{2(crist)} \rightarrow SiO_{2(g)}$ the vapor pressure data shown in Table XII. The free energies shown were calculated from their vapor pressure data.

TABLE XII

DATA FOR $SiO_{2(crist)} \rightarrow SiO_{2(g)}$

| | <u>1,800° K</u> | 1,900° K |
|--|----------------------|----------------------|
| PSiO ₂ (atm.) | 1.6×10^{-8} | 1.0×10^{-7} |
| ΔF =-RT ln PSiO ₂ (calorie/mole) | +64,214 | +60,860 |
| S _{SiO_{2(g})} (from Table XI) e.u. | 78.57 | 79.37 |
| ^S SiO _{2(crist)} (from Kelley ^{1,9}) e.u. | 38.15 | 39.12 |
| ∆ S e.u. | 40.42 | 40.25 |
| TAS calorie/mole | 72,756 | 76,475 |
| $\Delta H_{T} = \Delta F + T\Delta S$ calorie/mole | 1 36, 970 | 137,335 |

To convert the heat of reaction data at 1,800° and 1,900° K to heat of reaction data at 298° K, we can use the values from Table XI for the heat content of SiO_{2(g)} and those from Kelley¹³ for that of cristobailite at 1,800° K. In this way, one obtains

$$\Delta H_{298} = \Delta H_{T} - (H_{T} - H_{298})_{SiO_{2(g)}} + (H_{T} - H_{298})_{SiO_{2(crist)}}$$

 $\Delta H_{298} = 140,822$ calorie/mole

Also, from data at 1,900° K, we obtain

 $\Delta H_{298} = 141,516$.

.

The average of these two results is $\Delta H_{298} = 141,169$ calorie/mole. This value is somewhat higher than the original value reported by Porter et al of 136,000 ± 8,000 calorie/mole but falls within their range of uncertainty.

 $\Delta H_{2,000}$ for the reaction $SiO_{2(crist)} \rightarrow SiO_{2(g)}$, is calculated as follows:

$$\Delta H_{2,000} = \Delta H_{298} + (H_T - H_{298})_{SiO_{2(g)}} - (H_T - H_{298})_{crist.,}$$

ΔH2,000 = 136,627 calorie/mole

By taking into account the heat of fusion of cristobalite (2, 500 calorie/mole), we can calculate the heat of vaporization of liquid silica

$$SiO_{2(1)} \longrightarrow SiO_{2(g)} \Delta H_{2,000} = 134,127$$
 calorie/mole

from the above.

For the heat of this reaction at higher temperatures we have

.

1

1.

.

1 ...

6.

$$\Delta H_{T} = \Delta H_{2,000} + (H_{T} - H_{2,000})_{SiO_{2(g)}} - (H_{T} - H_{2,000})_{SiO_{2(1)}}$$

The additional necessary data for calculations of ΔH_T are in Table I and Table XI. Results of such a calculation are summarized in Table XIII.

TABLE XIII

HEAT OF VAPORIZATION OF LIQUID SiO2

| | $SiO_{2(1)} \rightarrow SiO_{2(g)}$ | 2 500° V | 3 0000 |
|--|-------------------------------------|----------|-----------------|
| | 2,000 1 | 2, 500 K | <u>3,000° K</u> |
| $(H_{T} - H_{2,000})_{SiO_{2(1)}}$ | 0 | 10,830 | 21,660 |
| (calorie/mole) | | | |
| $(H_T - H_{2,000})_{SiO_{2(g)}}$ (calorie/mole) | 0 | 7,380 | 14,740 |
| ΔH (calorie/mole) | 134,127 | 130,677 | 127,207 |

Likewise, to calculate the entropy change for the last reaction, the data of Table VI and Table XI can be used as shown in Table XIV.

The free energy data given in Table XIV, have been plotted in figure 1, where it can be seen $\Delta F = 0$ ($F_{SiO_2} = 1 \text{ atm.}$) at T= 3,540° K. These data show that at 3,000° K, $\Delta F = 19,416$ calorie/mole and

$$P_{SiO_2} = e \frac{-19,416}{Rx3,000} = 0.039$$
 atm.

TABLE XIV

....

I

 $SiO_{2(g)}$ pressures as a function of 1/T are shown in figures 2 and 11. In this case the equilibrium constant is equal to the partial pressure of $SiO_{2(g)}$ in atmospheres. If SiO_2 vaporizes according to the above reaction at 3,000° F, then the total amount of heat absorbed, including the sensible heat of solid and liquid SiO_2 from 298° to 3,000° K, is

 $\Delta H_{\text{rotal}} = (H_{3,000} - H_{298})_{\text{SiO}_2(1)} = \Delta H_{(\text{vaporization})}_{3,000\%}$

= $(H_{2,000} - H_{298})_{SiO_2(glass)}$ + $(H_{3,000} - H_{2,000})_{SiO_2(1)}$ + $\Delta H_{vaporization}$

ΔH_{rotal} = 177,877 calorie/mole (5,336 Btu/lb). 3,000°K

-46-

The sensible heat (the first two terms in the second equation) contributes 50,670 calorie/mole (1,520 Btu/lb.), and the vaporization contributes 127,207 calorie/mole (3,816 Btu/lb). It should be noted that simple vaporization of $SiO_{2}(g)$ at 3,000° K gives a total heat absorption of only 5,336 Btu/lb as against the value of 6,650 Btu/lb found for the case of $SiO_{2}(g)$ and $O_{2}(g)$ formation.

VIII. SiO₂ IN REDUCING ATMOSPHERES

In a reducing atmosphere decomposition of SiO_2 , to produce $SiO_{(g)}$, occurs at a much lower temperature than under neutral or oxidizing conditions. Three typical reducing agents, for which data are available, include elemental silicon, carbon, and hydrogen. Since the reducing reactions occur at lower temperatures they are of possible interest for at least two important reasons. First, a re-entry vehicle might be constructed out of a mixture of SiO₂ and a reducing agent. This might permit decomposition of SiO₂ to occur at a lower temperature where its viscosity is still high. Second, knowledge of the effect of reducing reactions is important because many of the current testing procedures in arcs are being carried out under reducing conditions. That is, arc testing done with carbon electrodes which yield carbon atoms in the plasma may really correspond to a reducing atmosphere when carbon is present in excess of oxygen or if the other ingredients of the plasma are present in stoichiometric amounts of reducing and oxidizing agents. Also, if a test specimen in the arc is subject to stoichiometric amounts of H atoms and OH atoms (reducing agent and oxidizing agent respectively), the higher mobility of the H atoms may effectively make the specimen "see" a reducing atmosphere.

The reaction between stoichiometric amounts of silicon and silica leads to the reaction:

 $Si + SiO_2 \rightarrow 2 SiO_{(e)}$

Although Si + SiO₂ in a closed system will decompose at a lower temperature than either material separately, it cannot be concluded that the reaction is independent of oxygen pressure. This arises from the fact that the simultaneous reaction Si + O₂ must be considered. In the dynamic case involving decomposition of the re-entry vehicle surface, it is possible and, very likely, that the reaction Si + SiO₂ will be the most important. However, if one is discussing an equilibrium case where an unlimited amount of oxygen is available, then the process reverts to a decomposition of SiO₂ in an oxidizing atmosphere. 1

Į,

-

T.

Some typical vapor pressure data for the Si-SiO₂ reaction taken from Humphrey, Todd, Coughlin, and King¹⁸ are plotted in the lower curve of figure 9.

For the reducing reaction between carbon and silica, one of the possible reactions is that for the formation of $SiO_{(g)}$ and $CO_{(g)}$.

-48-

 $SiO_{2(g)} + C_{(g)} \rightarrow SiO_{(g)} + CO_{(g)}$

ł

T

16

L

1

İ.

Į,

The data for this reaction were taken from Humphrey's tables¹⁸ and plotted in figure 9. The upper curve gives the CO pressure while the lower curve is again assumed to represent the actual SiO pressure in the system because of disproportionation to Si_(s) and SiO_{2(s)}. Reference to these data would indicate that a pressure of one atm ($P_{CO} = 0.89$ atm, $P_{SiO} = 0.11$ atm) is reached at a temperature of 1,845° K. The assumption that the SiO pressure is fixed by the Si-SiO₂ equilibrium appears to be quite valid since if it had been ignored higher SiO pressures would have been obtained by calculation. Of course, the SiO_(s) = SiO_(g) equilibrium instead of the Si-SiO₂ equilibrium may fix the SiO_(g) pressure in the present case. Actually these two equilibria are probably quite similar (i.e., give the same SiO_(g) pressure at temperatures near 1,700° to 1,800° K) if we assume, as discussed in section II, that SiO_(s) becomes stable near 1,450° to 1,573° K.

Another reducing reaction of interest is that of SiO₂ with H₂. The applicable experimental data of Grube and Speidel²¹, as given by Edwards¹⁹, have been plotted in figure 10. Here, it can be seen that their tabulated vapor pressure data for SiO_(g) are in agreement with those determined by Tombs and Welch²³. Figure 10 also shows expected vapor pressures of SiO_(g) corresponding to the vaporization of SiO_(s) or Si₍₋₎ + SiO_{2(s)}. It should be noted that in an H₂ atmosphere the pressure of SiO_(g) is less than either of these equilibria would predict and hence SiO gas will be formed rather than a solid phase. These results show that decomposition of SiO₂ under these conditions occurs at much lower temperatures than under oxidizing or neutral conditions.

IX. SUMMARY OF CALCULATED VAPORIZATION DATA FOR SiO₂₍₁₎

AND COMPARISON WITH PUBLISHED VALUES

In the preceding sections various equilibria, involving SiO_2 , have been considered. The data show that the first reaction, $SiO_{2(1)} \rightarrow SiO_{(g)} + \frac{1}{2}O_{2(g)}$.

is most important for neutral conditions. However, the reaction $SiO_{2(1)} \rightarrow SiO_{2(g)}$, makes a significant contribution to the vapor pressure. It becomes even more important under oxidizing conditions.

For each of the reactions considered, a standard free energy of reaction has been obtained. Simple approximate formulas have been developed to express these free energies as functions of temperature. The resulting formulas are summarized in Table XV. From these approximate relations or the somewhat more accurate data obtained earlier in this paper for a few of the reactions, equilibrium constants have been calculated by means of the relation

 $K = e^{-\Delta F^{0}/RT}$. The results are plotted in figure 2.

Although vaporization phenomena were discussed in terms of the single reaction, $SiO_2 \rightarrow SiO_{(g)} + \frac{1}{2}O_{2(g)}$, it is now possible to consider an addi-

tional reaction, the dissociation of oxygen. The effect of the latter can be evaluated both for the case of neutral conditions and for the case of oxidizing conditions.

A. NEUTRAL CONDITIONS

For the case of neutral conditions we start with the reactions

$$SiO_{2(1)} \neq SiO_{(g)} + \frac{1}{2}O_{2(g)}$$
 K_1 , (8)

and let

PSiO = partial pressure of SiO,

 $PO_2 = Partial pressure of O_2,$

TABLE XV

FREE ENERGY RELATIONS FOR VARIOUS REACTIONS

| Reaction | Free Energy Change, calories/mole | Estimated Uncertainty calories/mole | Temperature Range, *K | Remarks and Sources of Data |
|---|---|---|--------------------------|--|
| SiO ₂ (crist) SiO(g) + 1/20 _{2(g)} | ÅF* = 180, 800-58, 11T | ± 3000 | 1800 - 2000 | Data based on Schafer and Hornle |
| SiO ₂₍₁₎ SiO _(g) + 1/20 _{2(g)} | ÅF = 173, 000-54. 2T | ± 4 000 | 2000 - 4000 | |
| SiO _(s) → SiO _(g) | ΔF* = 77, 530-34. 9T | ★ 8000 | 1800 - 2000 | May be used at higher temperatures. Melting point of SiO _(s) is unknown. ¹ Uncertainty is a guess. |
| Si ₂ O _{2(g)} → 2SiO _(g) | ÅF• = +52, 500-33, 4T | ± 10,000 | 1500 - 3000 | Data based on Porter et al. |
| 1/20 _{2(g)} | ÅF• = 61, 348-16. 11T | 400 | 2000 - 4000 | For tabulated data, see Stull and Sinke. ²⁵ $(\Delta H_0^{\circ} = 58, 980)$ or older NBS tables $(\Delta H_1^{\circ} = 58, 586)$. |
| SiO ₂₍₁₎ | ÅF = 127, 200-36.0T | ¢ 6000 | 2000 - 4000 | Data based on Porter et al. |
| Si ₍₁₎ + O _{2(g)} | ÅF [•] = -38, 954-10, 17T | ≠ 3000 | 1700 - 2950 | |
| SiO(g) - Si(g) + 1/20 _{2(g)} | ÅF [•] = 129, 000-16, 31T | ± 3000 | near 3000 | |

Po - partial pressure of O.

Under our assumed conditions, we have the additional relations

$$P_{O_2} + \frac{1}{2}P_O = \frac{1}{2}P_{SiO},$$
 (10)

$$\mathbf{K}_{1} = \mathbf{P}_{\mathrm{SiO}} \cdot \mathbf{P}_{\mathrm{O}_{2}}^{\frac{1}{2}}, \qquad (11)$$

and

$$K_2 = \frac{P_0}{P_0 \frac{1}{2}}$$
 (12)

The above three equations are sufficient to determine the three unknowns in terms of the two equilibrium constants, P_{SiO} , P_{O_2} , and P_O .

Rearranging equation (12) to

$$P_{O} = K_2 P_{O_2}^{1/2}$$
 (13)

and substituting into equation (10), we obtain,

$${}^{2}P_{O_{2}} + {}^{K_{2}}P_{O_{2}} = {}^{P}SiO$$
 (14)

Finally, we substitute (14) into (11) and obtain the cubic equation,

$$2 P_{O_2}^{3/2} + K_2 P_{O_2} - K_1 = 0$$
 (15)

for P_{O_2} in terms of K_1 and K_2 .

For the case where K_2 is small, i.e., where the dissociation of O_2 is negligible, we can solve equation (15) readily to obtain

$$P_{O_2} \cong (K_1/2)^{2/3} \qquad (K_1 < < K_2 P_{O_2})$$
 (16)

- 52-

For the case where we cannot neglect dissociation of O_2 , equation (15) must be solved.

After solving equation (15) for P_{O_2} we can obtain P_O from equation (13) and P_{SiO} from equation (10).

From selected values of the equilibrium constants K_1 and K_2 at 2,000°; 2,500°, 3,000°, 3,500°, and 3,750° K, it has been possible to calculate corresponding values of the partial pressures of SiO, O₂, and O as described above. The resulting calculated partial pressures, based on neutral conditions and including dissociation of oxygen, have been plotted in figure 11.

Referring to the data in figure 11, one can see that a total pressure of one atmosphere is obtained at 3,070°K. This corresponds to the normal boiling point of SiO₂. By reading partial pressures of the various components from the graph at 3,070°K, one obtains the following:

| $P_{SiO} = 0.62$ atm | (+0.6) or -0.2 , |
|------------------------------------|-----------------------------|
| $P_{O_2} = 0.26 \text{ atm}$ | (+0.25 or -0.08), |
| $P_0 = 0.074 \text{ atm}$ | (+0.07 or - 0.002), |
| $P_{SiO_2} = 0.058 \text{ atm}$ | (+0.12 or -0.002), |
| $P_{Si_2O_2} = 0.0001 \text{ atm}$ | (+0.0003 or - 0.00003), |
| $P_{total} = 1.012$ | (+ 1.04 atm or - 0.28 atm) |

The uncertainties in the partial pressures are indicated in parentheses. For example, P_{SiO} may possibly have values from 0.42 to 1.22 at 3,070° K.

It is seen that within the accuracy of these data, a total pressure of one atmosphere is obtained at 3,070° \pm 75° K for a neutral equilibrium mixture. The accuracy of this boiling point can be determined from the fact that the free energy function of importance here is

 $\Delta F^{\circ} = 173,000 - 54.2 T$

where

T

I

F

t

1

-53-

 ΔF° is accurate to \pm 4,000 calories/mole near 3,000° K. Using this uncertainty in ΔF° we obtain $\frac{d(\Delta F^{\circ})}{dT}$ = 54.2, from which it follows that ΔT = \pm 75° K.

A more complete analysis of the expected equilibrium gaseous species at 3,000° K is as follows:

| Species | Pressure (atm) |
|--------------------------------|----------------------|
| SiO | 0.43 |
| SiO2 | 0.04 |
| Si ₂ O ₂ | 5×10^{-5} |
| (SiO) _z | unknown |
| 0 ₂ | 0.18 |
| 0 | 0.05 |
| Si | 1.3×10^{-6} |
| Ptotal | 0.70 atm |

The results summarized in both of the above tables show that SiO and O_2 are the predominant species. In the neutral, equilibrium mixture Si and Si₂O₂ are present in minor amounts. However, significant amounts of SiO₂ and O are also present.

As we have just seen, a normal boiling point of 3,070° K is predicted for SiO₂. If all the other reactions had been neglected and only the decomposition reaction $SiO_{\overline{2}} \rightarrow SiO_{(g)} + \frac{1}{2}O_{2(g)}$ had been considered, then a boiling point of 3,085° K would have been predicted, as discussed earlier. Thus, the other reactions have only a small effect on the predicted boiling point. The possibility of reactions, other than those already discussed, should not be completely overlooked, but they are not likely to be important. In the absence of further information and in view of the fact that the observed reactions predict vaporization phenomena in agreement with experiments at lower temperatures, it does seem likely that the present calculations should give a fair figure for the boiling point.

- 54-

Table XVI contains values of boiling points given in the literature which can be compared with ours.

TABLE XVI

1

TABULATED BOILING POINTS FOR SiO₂

| Temperature | Original Reference | Date | Quoted by |
|-------------|--------------------------------|------|---|
| 2,230° C | Ruff and Schmidt ⁴ | 1921 | (Lange ⁴⁵ -Handbook of Chemistry) (Handbook of Chemistry and Physics ⁴⁶) (Int. Critical Tables ⁴⁷) |
| 2, 590° C | Ruff and Konschak ⁵ | 1926 | (Handbook of Chemistry and Physics ⁴⁶) (Sidgwick ⁴⁸ , Eitel ⁴⁹) |
| 2,800° C | Present work | | |
| 2,950° C | O. Ruff ⁶ | 1935 | (A. Silverman ⁵⁰) (Campbell ¹¹) |
| 3, 500° C | W. R. Mott ⁵¹ | 1918 | |

In reviewing the above data it was found that $Brewer^{39}$ has rightfully criticized the boiling point data of Ruff and Schmidt⁴ because the measurements were carried out in a carbon vapor (reducing) atmosphere. The original paper by Ruff and Konschak⁵ also shows uncertainty of the same type. Although they used an iridium container, it was inside a graphite vessel. Under such conditions they observed rapid attack of the iridium container and were able to obtain only a single measurement at 2,060° C. They used this measurement to obtain their extrapolated boiling point. In view of the fact that their container was subject to such rapid attack, it appears possible that a reducing atmosphere (of iridium or carbon) was actually present. This would lead to observation of a higher vapor pressure and, hence, a lower boiling point than the true one. Other container materials tried by Ruff and Konschak⁵ without success included tantalum, tungsten, molybdenum, and zirconium oxide. Ruff and Konschak⁵ further state that their calculated boiling point of 2,590° C is only a minimum value.

-55-

The boiling point of 2,950° C given by Ruft^{6} in 1935 was simply a restatement of his earlier work of 1926. In 1935 he stated that the original 2,590° C boiling point was a misprint and that the measured 11.0 mm pressure at 2,060° C should extrapolate to a boiling point of 2,950° C. However, in repeating his extrapolation we find that the 2,590° C boiling point appears more reasonable. In figure 12, for example, the extrapolation through the ordinate 11.1 at $\frac{1}{T} = 0$, as recommended by Ruff in 1926 leads to \log_{10} 760 mm =

11

•

1

2.88 at 2,590° C as he had reported at that time.

If we plot the three calculated vapor pressure figures as given by Ruff in 1935 and draw the dashed line shown in the graph (figure 12), we obtain an intercept of 8.15 at 1/T = 0.

Since

Pmm = Patm = 760

and

 $\log_{10}P_{mm} = \log_{10}P_{atm} + \log_{10}760$,

the intercepts for the different pressure units are therefore

$$\begin{bmatrix} \log_{10} p_{mm} \end{bmatrix} 1/T = 0 = 11.03$$
$$\begin{bmatrix} \log_{10} p_{atm} \end{bmatrix} 1/T = 0 = 8.15$$

A value of 8.15 for the intercept at 1/T = 0 would appear reasonable if the ordinate were given as $\log_{10} p_{atm}$ instead of the $\log_{10} p_{mm}$ actually used.

It thus appears that Ruff may have mistakenly used 8.15 as an intercept when $\log_{10} p_{mm}$ was plotted as the ordinate. Actually, to be correct, it is necessary to plot $\log_{10} p_{atm}$ in conjunction with the 8.15 intercept.

In view of the uncertainties in the analysis just given above, it is desirable to present some independent data supporting Ruff's 1926 extrapolation to an intercept of 11.1 at 1/T = 0. We have already shown in Section II, E that

- 56-

$$P_{e}(atm) = 3/2e^{18.41(1 - \frac{3160}{T})}$$

or

$$P_t(mm) = 3/2 \pm 760 e^{18.41 (1 - \frac{3160}{T})}$$

The second equation can be rearranged to the form

 $\log_{10}P_t$ (mm) = 11.1 - 25,200/T

in which it is obvious that the intercept is 11.1.

We therefore conclude that the boiling point of 2,950°C given by Ruff in 1935 is too high. On the other hand the value of 2,590°C is only a lower limit. This is particularly true since his measurements were performed under reducing conditions.

Information on the very high boiling point of 3,500° C given by $Mott^{51}$ in 1918 indicates that this measurement was a very rough one. SiO₂ was decomposed in an arc, and the temperature measurements were necessarily quite uncertain.

Summarizing then, the recorded boiling points for SiO_2 , in the literature, are spread over a considerable range. The lower values of 2,230° C and 2,590° C must be considered as lower limits. The value of 2,950° C is apparently a mistake and the value of 3,500° C is only an approximation. Thus, our calculated value of 2,800° C appears to be reasonable and is probably more reliable than the values in the literature.

Additional vapor pressure data for the decomposition of SiO₂, under so-called neutral conditions, have been given by Brewer and Mastick², Inuzuka and Ageha³⁸, and Porter, Chupka, and Inghram³. The data of Brewer and Mastick have been shown to agree with the calculations based on the first reaction $SiO_2 \rightarrow SiO_{(g)} + \frac{1}{2}O_{2(g)}$. Inasmuch as we have found that consideration of all the other possible reactions only changed the predicted boiling point from 3,085° K to 3,070° K, it can be seen that the first reaction is of primary importance. Our calculated vapor pressure data at low temperatures

- 57-

are compared with the data of Brewer and Mastick² in figure 5. The agreement is good and, if anything, Brewer and Mastick's² extrapolated data might indicate an even higher boiling point than the one we have calculated.

2.1

5

I

T

(18)

The data of Porter <u>et al</u>³ are seen to be too high relative to our vapor pressures infigure 5. However, they were apparently not operating under strictly neutral conditions. Thus, for 1,900° K they gave $P_{Sio} = 3.4 \times 10^{-5}$ and $P_{O_2} = 8.2 \times 10^{-8}$ atm. It follows that $P_{SiO} P_{O_2}^{\frac{1}{2}} = 9.7 \times 10^{-9}$ atm 3/2,

and that

 $\Delta F_{porter, 1,900} = + 69,595$ calorie/mole

As seen in Table VII-A, this free energy value agrees closely with our thermochemical value of 71,000 calories/mole.

The data of Inuzuka and Ageha³⁸ were discussed earlier and it was shown that their reported high vapor pressure data could be accounted for by a reducing reaction involving the molybdenum wire. In fact, the excellent agreement obtained with the thermochemical data for $SiO_{(g)}$ suggests that these data are fairly reliable.

B. OXIDIZING CONDITIONS

Just as in the case of neutral conditions we consider the same two reactions for the case of oxidizing conditions in air. That is, we neglect other possible reactions. It is possible that excess oxygen or nitrogen might lead to new species which are not considered, here, but until experimental data clarify this point we make the assumption that other reactions are negligible.

$$siO_{2(1)} \rightarrow siO_{(a)} + \frac{1}{2}O_{2(a)}$$
 (17)

 $\frac{1}{2}O_{2(g)} \rightarrow O_{(g)}$.

It is assumed that SiO_2 decomposes in the presence of air at various total pressures, p_t . For the present case, nitrogen is assumed to be inert. Then we have the following relations:

-58-

<u>_</u>

$$P_t = P_{N_2} + P_{O_2} + P_{SiO} + P_{O_1}$$
 (19)

$$P_{N_2} = 4(P_{O_2} + \frac{1}{2}P_{O_1} - \frac{1}{2}P_{SiO}),$$
 (20)

$$K_1 = P_{SiO} PO_2^{\frac{1}{2}}$$
, (21)

$$K_2 = P_0 / P_0_2^{\frac{1}{2}}$$
, (22)

We can solve the above set of four equations for the four unknowns PN_2 , PO_2 , PO_3 , and P_{SiO} in terms of P_t , K_1 , and K_2 as known parameters. Combining equations (19) and (20) we get

$$P_{t} = 5 PO_{2} + 3 PO - P_{SiO} , \qquad (23)$$

But from equation (22), $P_0 = K_2 P_0^{\frac{1}{2}}$, and equation (23) becomes

$$P_{t} = 5 PO_{2} + 3K_{2}PO_{2}^{\frac{1}{2}} - P_{SiO}$$
(24)

or

$$P_{SiO} = {}^{5}P_{O_2} + {}^{3}K_2 P_{O_2} - P_t$$
 (25)

Also from equation (21) we have

$$P_{SiO} = \frac{K_1}{\frac{1}{PO_2}}$$
 (26)

Combining this with equation (25), we finally get

$$S PO_2^{3/2} + 3K_2 PO_2 - P_t PO_2^{1/2} - K_1 = 0$$
 (27)

After this cubic equation has been solved for PO_2 , the other unknowns can be evaluated from equations (26), (22) and (20).

Solutions for this set of equations were obtained for values of $p_t = 0.1, 1, 10$, and 50 atm. Calculations were made in the range of 2,000° to 3,750° K. The resulting data have been plotted in figures 13, 14, 15, and 16 which show the partial pressures of SiO, O₂, SiO₂, and N₂ as functions of 1/T.

It is seen that at temperatures well below the boiling point, the $SiO_{(g)}$ formation is markedly repressed. Thus from figure 13 at $p_t = 0.1$ atm and $T = 2,000^{\circ}$ K, the SiO partial pressure is essentially equal to the SiO₂ partial pressure. However, in this case a boiling point is not reached until about 2,700° K. At all higher temperatures, $SiO_{(g)}$ formation becomes more important than $SiO_{2(g)}$

formation. For reference purposes in figures 13 through 16, the vaporization curve for SiO under neutral conditions is also given. The curves given in each of the figures extend up to the boiling point. At higher temperatures, total pressures are obtained in excess of the postulated pressure. At the boiling point and higher temperatures the N₂ pressure is zero. Also at the higher temperatures, the SiO, O₂ and O partial pressures are the same as for the neutral conditions already discussed. However, these data are not repeated in figures 13 through 16. The rapid variation in partial pressure of N₂ has not been indicated with much precision but an approximate indication is given in the figures.

The data presented in figures 13 through 16 show that under some conditions the oxygen present in air is sufficient to repress SiO formation significantly. Although the effect decreases near the boiling point it becomes very pronounced at lower temperatures.

Consequently, in any proposed application of fused silica, the conditions of the high-temperature exposure must be known before the equilibrium gas species can be estimated.

The author wishes to thank Dr. W. Bade who offered numerous helpful suggestions during the present study. Dr. M. S. Klamkin and the Mathematics Section solved the cubic equation listed in the text. Drs. R. Barriault and M. Malin provided helpful guidance. Several people participated in discussions of the topics covered including Drs. B. Kivel, M. Panish, and S. Ruby.

APPENDIX A

SUMMARY OF PHYSICAL AND CHEMICAL PROPERTIES OF SILICA

Because of the great current interest in silica as a possible consumable reentry vehicle material, there is a need for a convenient summary of the best available data on its properties. The following summary presents these data in a concise systematic form. It contains not only the material from the literature, reviewed in the main body of the report plus the results of calculations with the literature data, but it also includes other data on mechanical and heat transfer properties, thermal shock resistance, crystal structure, electrical and magnetic properties, availability, and cost.

A. DECOMPOSITION REACTIONS AND HEAT OF VAPORIZATION

The two processes below have been considered but under equilibrium conditions (Eq. 1) decomposition to form SiO and O_2 has been shown to be the most important reaction.

$$SiO_{2(1)} \rightarrow SiO_{(g)} + \frac{1}{2}O_{2(g)}$$

 $SiO_{2(1)} \rightarrow SiO_{2(g)}$
 $SiO_{2(1)} \rightarrow SiO_{2(g)}$
 $\Delta H_{vaporization, 3,000^{\circ}K} = 171,000 calorie/mole$ (1)
 $= 5,130 BTU/lb$
 $\Delta H_{vaporization, 3,000^{\circ}K} = 127,000 calorie/mole$ (2)
 $= 3,810 BTU/lb.$

B. VAPOR PRESSURE

The vapor pressure of SiO_2 is not a unique function of temperature but is also very sensitive to the presence of oxidizing or reducing agents in the atmosphere. The total vapor pressure (p_t) versus temperature (T) for silica under neutral conditions, where the decomposition is essentially

$$SiO_{2(1)} \rightarrow SiO_{(g)} + \frac{1}{2}O_{2(g)}$$

is.

$$P_t = 3/2_e^{18.41 \left(1 - \frac{3160}{T}\right)} = 3/2_e^{18.41(1 - 5680/T_R)},$$

 $P_{t} = P_{SiO} + P_{O_{2}},$ $P_{SiO} = 2/3 P_{t},$ $P_{O_{2}} = 1/3 P_{t},$ $P_{t}, P_{SiO}, \text{ and } P_{O_{2}} \text{ are in atmospheres,}$ $T = {}^{O}Kelvin ({}^{O}K)$ $T_{R} = {}^{O}Rankine ({}^{O}R)$

This formula is estimated to be accurate to \pm 50 percent near 3,000° K and applies to the temperature range above 2,000° K. It predicts a total vapor pressure of 2.17 x 10⁻³ atm. (1.65 mm Hg) at 2,060° C (2,330° K). This is much lower than the value of 11 mm reported at this temperature by Ruff et al.⁵ However, their measurement was performed only once and they stated that reducing conditions made their vapor pressure determination give high values. For approximate estimates of P_{SiO} under neutral conditions see Fig. 4.

Small contributions to the vapor pressure are made by other equilibrium products. (See Fig.11). The following is a typical expected neutral equilibrium mixture at a temperature of 3,000° K (2,727° C, 4,940° F, 5,400° R):

| Species | Partial Pressure (atm.) |
|------------------|-------------------------|
| SiO | 0.43 |
| 0 ₂ | 0.18 |
| 0 | 0.05 |
| si0 ₂ | 0.04 |
| Si202 | 5×10^{-5} |
| Si | 1.3×10^{-6} |
| Pt | = 0.70 atm |

r.

For the effects of an oxidizing atmosphere under different total pressures, see Figures 13-16.

-68-

C. MOLECULAR WEIGHT

The molecular weight is 60.06.

D. MELTING POINT

Fused silica, being a supercooled liquid, has no recognized melting point. It softens (viscosity $\cong 10^{7.6}$ poises) at 1,500° C⁵². The various crystalline forms of SiO₂ do melt, however.

| Form | Melting point | |
|--------------|---------------|------------|
| | • F | <u>• C</u> |
| cristobalite | 3,140 | 1,728 |
| tridymite | 3,056 | 1,680 |
| quartz | 2,930 | 1,610 |

E. BOILING POINT

As indicated in (A) and (B) of this appendix, vaporization of SiO_2 yields predominantly a mixture of SiO and O₂. Lesser amounts of SiO₂ gas and O atoms are formed. The calculated normal boiling point (vapor pressure = 1 atm) is 5,072° F (2,800° C, 3,070° K).

F. VISCOSITY

A viscosity relation which is valid for the temperature range of 2,197°K to 2,333°K (1,924°C to 2,060°C) is

 $\log_{10}\eta = 28,200/T_{(^{\circ}K)} - 7.73$ 53, 54

G. SPECIFIC HEAT

For vitreous or fused silica the molar heat capacity relation given by Kelley 13 covers the range of 298° K to 2,000° K. Its accuracy is \pm 2 percent.

 $C_p = 13.38 + 3.68 \times 10^{-3}T - 3.45 \times 10^5 T - 2$

C_p = calorie/mole - degree K

T = ^oKelvin

H. SENSIBLE HEAT PLUS HEAT OF VAPORIZATION

The sensible heat required to bring fused silica from 298° K to $3,000^{\circ}$ K is found to be 1,524 Btu/lb (or 50,670 calorie/mole). Going from 298° K to 3,070° K requires 1,570 Btu/lb (or 52,190 calorie/mole). Assuming that the heat of vaporization at 3,070° K does not differ appreciably from that at 3,000° K, one can obtain the following total heat absorptions for the principal decomposition equations (A-1) and (A-2) of this appendix.

| Temperature | Process | Btu/lb | Calorie/mole |
|------------------|-------------------------------------|--------|--------------|
| 3,000° K | Reaction (1) | 6,650 | 222, 183 |
| 3,000 | (2) | 5,336 | 177, 877 |
| 3,070 | (1) | 6,700 | |
| 3,070 | (2) | 5,386 | |
| 3,070 for normal | 0.915 moles SiO by (1) | 6,790 | |
| equilibriur | n 0.11 moles O by 1/2 O | ~~~0 | |
| mixture: | 0.085 moles SiO ₂ by (2) | | |

These data show that the total heat of decomposition is essentially controlled by reaction (1).

-

10.00

...

1.1.00

That is even when the equilibrium mixture at 3,070° K is considered the extra energy required to dissc~iate O_2 is partially offset by the reduced heat required to evaporate gaseous SiO₂. It can also be seen that the uncertainty in the heat of reaction (1) at 3,000° K was of the order of 5,000 calorie/mole or 150 Btu/lb. Thus, for most purposes, it is sufficient to use only the data from reaction (1).

I. DENSITY

The density of pure fused silica is 137.3 lb/ft^3 or 2.20 gm/cm³. ⁵²

J. THERMAL CONDUCTIVITY

At O[•]C, fused silica has a thermal conductivity of 0.795 Btu/hr ft[•]F or 33 x 10^{-4} calorie - cm/sec - cm² - [•]C. ⁵⁵

-70-

K. COEFFICIENT OF THERMAL EXPANSION

The coefficient of thermal expansion for clear, fused silica from $20^{\circ} - 320^{\circ}$ C is reported to be 3.05×10^{-7} /° F or 0.55×10^{-6} /° C by G.E.⁵⁵, and from $0^{\circ} - 300^{\circ}$ C it is reported to be 3.1×10^{-7} /° F or 0.56×10^{-6} /° C by Corning.

L. YOUNG'S MODULUS

Clear, fused silica, at room-temperature is reported to have a Young's Modulus of $10.1 \times 10^6 \text{ lb/in}^2$ or 7,138 kg/mm² by G.E.⁵⁵

M. TENSILE STRENGTH

In 1/4 inch rods, fused silica has a strength of 7,100 lb/in² or 5 kg/mm²; whereas in fibres, it has a strength of 43,500 to 116,000 lb/in² or 30.6 - 81.6 kg/mm^2 .

N. THERMAL SHOCK RESISTANCE

Fused silica has excellent thermal shock resistance.

Other forms of silica have poor resistance at certain temperatures because of volume changes which occur at inversion points.

A 6 x 6 x 1/4-inch annealed plate of fused silica can withstand a 1,000° C^{52} differential from being plunged into cold water after oven heating.

O. HARDNESS

The hardness of fused silica is 4.9 on the Mohs Scale⁵⁵ whereas cristobalite, quartz, tridymite have a value of 7.0 on the Mohs Scale.⁴⁵

P. CRYSTALLINE STRUCTURE

Pure SiO_2 is a polymorphic material. The vitreous or glassy form of SiO_2 is a metastable, undercooled liquid at all temperatures below 1,728° C (2,000° K). The rate of transformation of vitreous SiO_2 into the other forms may become measurable above 1,000° C. Impurities also affect the rate of transformation. Listed below are the stability ranges for the various forms of SiO_2 :

| Form | Temperature range of stability |
|------------------------|--|
| Silica glass | T > 1,728° C |
| β - Cristobalite | $1,728^{\circ} - 1,470^{\circ} C^{12}$ |
| β - Tridymite | 1,470° - 870° C ¹¹ |
| β - Quartz | 870° - 573° C |
| a - Quartz | 573° - |

T

r -

In fused silica glass, the Warren model is generally accepted ⁵⁶ to represent the short range order. Being a liquid-like material ⁵⁷ there is no long-range order greater than about 4 or 5 interatomic distances. According to the Warren view each silicon atom is surrounded tetrahedrally by four oxygen atoms. Each oxygen atom is shared by two silicon atoms. The SiO distance is about 1.6 Å, the O-O distance is 2.65 Å, and the Si-Si distance is 3.2 Å.

Q. ELECTRICAL RESISTIVITY¹¹

The electrical resis...vities of various forms of silica are:

| Form | Temperature | Resistivity (ohm-cm) |
|-------------------------|--------------------|--|
| Vitreous | 20° C | 1×10^{15} |
| | 600° C | 7×10^6 |
| | 1,300° C | 4×10^{5} |
| Crystalline (quartz) | 20° C 1, 300° C | l x 10 ¹⁴ to prin- 5 x 10 ³ cipal axis |
| | 20° C 1, 300° C | 2 x 10 ¹⁶ _to prin- l x 10 ⁴ cipal axis |
| | 11 | |

R. DIELECTRIC CONSTANT

The dielectric constants of silica are:

| Form | Temperature Dielectric C | | stant |
|----------------------|--------------------------|-----------------------------|----------|
| Vitreous | 20• C | 3.75 | |
| Crystalline (quartz) | 20° C | 4.6 to dire field | ction of |
| | | 4.5 <u>to dire</u> field | ction of |

S. MAGNETIC SUSCEPTIBILITY¹¹

The magnetic susceptibilities of silica are:

| Form | Susceptibility | |
|----------------------|------------------------|-------------------|
| Vitreous | -0.45×10^{-6} | magnetic units/gm |
| Crystalline (quartz) | -0.45×10^{-6} | magnetic units/gm |

T. PURITY

Fused silica can be obtained as one of the purest chemicals known. For example, Corning's commercial grade is 99.9 percent pure. It is possible to obtain a grade of 99.99 percent purity for use in delay lines, and a grade of 99.999 percent purity is available for use in spectroscopy. The cost climbs rapidly with purity.

Some analyses for the Corning grades are presented below. It should be emphasized that the impurities given need not be unavoidable since precautions can be taken to remove certain impurities if necessary. The type 7943 grade (99.99 percent purity) is a desirable optical grade for infrared work because of the absence of the OH group. As of March 1958 it was not available in sizes over 1/8-inch thick. Type 7940 can be obtained in flat sheets to 20 inches in diameter and up to 3 inches thick. ⁵⁸

| Impurity | Type 7940 (percent) | Type 7943 (percent) |
|----------|------------------------|------------------------|
| он | 0.1 | 0.00 |
| Li | < 0.0001 | |
| Na | 0.00003 | 0.001 |

| Impurity | Type 7940 (percent) | Type 7943 (percent) |
|--------------------|------------------------|---|
| к | 0.0001 | 0.0003 |
| Fe | 0.002 | 0.001 |
| Cu | 0.00001 | 0.00001 |
| ті | 0.0005 | 0.0005 |
| Ві | | 0.000047 |
| P | | 0.000010 |
| As | | 0.0000057 |
| Sb | | 0.0000051 |
| Zr, V, Pb, Sn, G | ie, Mo, Ca | not detected, and less than \sim 10 ppm = 0.001 percent |
| A12 ⁰ 3 | 0.001 59 | |

A typical analysis of some G.E. fused silica is presented below. The source is a Brazilian quartz sand. The data were given to D. Walker by K. Field of General Electric. 60

| Impurity | Percent | |
|--------------------|------------------|--|
| Fe2 ⁰ 3 | 0.0017 | |
| A1203 | 0.014 | |
| TiO2 | nil | |
| Zr02 | nil | |
| к | 0.0003 | |
| CeO | < 0.0003 | |
| MgO | < 0.0007 | |
| C B | none < 0.0001 | |
| | B 4 | |

-74-

U. AVAILABILITY

Fused or vitreous silica is produced by at least three manufacturers in this country:

- a. Corning Glass Works, Corning, New York.
- b. General Electric Company, Lamp Glass Department, Nela Park, Cleveland 12, Ohio.
- c. Amersil Division of Engelhard Industries.

V. COST

The cost of fused silica is very dependent on the purity, finished form, etc. Some typical prices for G.E. products are shown below:

| Form | Clear, Fused Quartz (Cost/lb.) | Translucent (Cost/lb.) |
|-------------------------------------|-----------------------------------|---------------------------|
| rod, 1/16-inch diameter | \$50.00 | |
| rod, 3/16-inch diameter | 30.00 | \$12.00 |
| ingot, to 18 1/2 inches diameter | 15.00 | |
