DATA ON THE COMPARATIVE BIOCHEMISTRY OF HELANS

-ND SIJIANS*)

Ukrainian Biochemical Journal No 3, Kiev, 1958, pp 392-401

}_>

:0

V. S. sentiani, **) State Medical Institute, Ttilimi

The biclogical provides sufficient ground for the study of their bicchemistry. However, the chemical statics and dynamics of simians have not beeninvestigated very extensively, while other laboratory animals, such as the dog, rabbit, rat, etc., have been studied in much greater detail.

The comparative biochamical value of the scattered and meagre data on the biochamicstry of similars is further reduced by the fact that corresponding data are rarely obtained as a result of simultaneous investigations and use of the sume methods on both humans and similars.

Presented below are our laboratory data on the biochemical composition of the blood of similars, in comparison with corresponding data obtained from a blood enalysis of bealthy humans.

The investigation of invertible was conducted on the species Macaca-razus (two makes and two factors, 2g to 3g years old, weighing 2.7 to 4.1 kilograms). The blood was taken from the aural vein, after the animals had been subjected to a 16-hour starvation period.

In the comparative investigation of humans, venous blood was analyzed by the sume investigation methods from a group of 10 healthy men and woman, 10 to 25 years old.

*) Article received by editors office 10 June 1957.

**) Assisted by A. K. Agayeva, O. V. Kekelidze, T. P. Pichkhaya and T. V. Pruidze.

In both cases, the blood was analyzed in order to determine the porcentage of albumen fructions in blood (for this purpose, the method of electrophoresis on puper was used), quantities of glucoproteids, non-albuminous nitrogen compounds, lipides, mineral substances, the action of some ferments, and the quantities of various forms of adrenaline.(1)

٦

and a second second second and the second second

. . . .

The results obtained are shown in tables.

Table 1, shows the correlation of albumen fractions in the blood serum of simians and humans. For comparative purposes, data are also presented from Deutsch and Goodloe, ⁽²⁾ who employed the classical Tiselius method of electrophoresis.

In analyzing the data on the detormination of protein fractions as shown in Table 1, we must realize that for obvious reasons we can not expect an exact coincidence between the results obtained by the method of electrophoresis on paper and the results obtained by the Tiselius method. Therefore, the comparison of the results of the two methods can not be complete. In spite of this some comparison of the data is possible. As seen from the table, both methods of analysis yield comparable results. The electrophoresis on paper gives higher values for results on the quantity of albumon and comparatively low values for results on the quantity of globulins. This is even more clearly reflected in the results of the analysis of blood sorum in simians. T.

We were interested in the question whether the albumen fractions in the blood of simians possess characteristics which could be considered specific to their species. A cortain amount of evidence for such a conclusion can be found in our data. It may suffice to point out that the percentage content of the alpha and alpha - globulins is considerably lower in the blood of simians than in the blood of humans, while the content of gamma-globulins is slightly higher in the blood of simians than in human blood. It must also be noted that in respect to gamma-globulins, these differences are loss pronounced. As it is known, the number of gamma-globulins which basically carry different anti-bodies sharply in creases in immunized animals. At the present time gamma-globulins are widely used as preventive and curative means in combating many infec tious diseases (the protection of monkeys from experimental poliumyelitis by the use of gamma-globulins of human blood can be cited as an example).

According to the data of Deutsch and Goodloe, the percentage content of gamma-globulin in the blood plasma of both humans and simians (Macacorozus) is the same. These authors found the difference between the blood plasma of humans and simians in the quantity of the first electrophoreous fraction (f) which precedes the albunins (origin of this fraction has not been determined), and also in the presence of alpha-globulin fractions, which are also found in the blood of cats and guinea pigs. As can be seen from the data of these authors, the quantitative differences are of a less pronounced nature.

On the basis of the above-mentioned differences, we can conclude that the electropheretic characteristics of the blood of lower menkeys provide us with sufficient avidence for the determination of specific distinctions between these animals and man.

Quantities of glucoproteids in milligram percentage in the blood serum of healthy humans and simians

[milligram percent, henceforth referred to as mg \$]

In relation to simians, the data are only of a tentative character. Nevertheless, they give us reasons to suppose that the deeper study of glucoproteids in the blood of simians (not only in locor monkoys, but also in anthropoid ages) can be of substantial interest to comparative biochemistry.

_s far as non-albuminous nitrous substances are concorned, comparative data are presented in Table 3.

The above presented data allow us to see considerable differences in the distribution of non-albuminous nitrous substances in the blood of humans and lower monkeys (a higher concentration of creatinine, a lower concentration of uric acid and glutathions, and the absence of ergotioneine is found in the blood of monkeys).

It is necessary to point out that lower monkeys secrete very little uric acid as such. They transmute the uric acid into allantoin, which is characteristic of a majority of mammals, with the exception of anthropoid apes and man himself. This fact can be compared to the above-cited data on the low level of uric acid in the blood of lower monkeys. In spite of the fact that allantoin may be found in small quantities in the urine of humans (urine of newborn babies contains a considerable amount of allantoin), this blochemical peculiarity of the urine of lower monkeys is of interest.

It is possible that anthropoid apes (as well as humans) are deprived of the ferment of unicase, under whose influence unic acid turns into allentoin.

In as far as the quantity of non-albuminous nitrous substances in the whole blood of lower monkeys is concerned, only those data are available (3) which show that the quantity of uses varies within the limits of 5.8 - 6.4 mgS, the quantity of usic acid, within the limits of 0.3 - 0.4mgS; and the quantity of creatinine is 1.4 mgS (all data are given in mgS of nitrogen). (See Table 3).

The content of lipides in the fluids and tissues of simians is very little known. According to the data of N. I. Tavastsherma (4), the thols-blood of monkey-regue contains 167 mgS of common chloresterine, and that of monkey-lapunder contains from 120 - 149 mgS. In the blood serum of a young female (three years eld), N. I. Tavastsherma found 105-118 mgS of common chloresterine, in the blood of a young male, 118 mgS, and in the blood of an old male and female, 100 and 177 mgS, respectively. According to other data (5) the blood serum of a monkey contains 118 mgS of common chloresterine.

Our laboratory has obtained only a few results from the blood analyses of lower monkeys (regus). These results offer some idea on the distribution of frue chlorestering and its ethers in the blood of simians. According to these results, the whole-blood of a monkey contains 115-132 agis of common chlorestering, 22-31 mg; of ether-related chlorestering.

As we know, numerous investigators give contrudictory data on the quantity of chloresterin in the blood (serum, plasma) of humans. Espocially contradictory are the data on the extreme content ranges of chlorestering. 150-200 mgs of common chlorestering are accepted as the stundard rate for whole-blood. (6)

In spite of the magre data, it appears that the blood of simians contains a alightly smaller amount of common chloresterine than the blood of humans. The low percentage of free chorosterine (about 20 percent of the total amount, instead of 30 - 40 percent usual for the blood of mature mon in the blood of simians, resembles a picture often observed in the blood of children.

The data on the quantity of chlorestering in the blood of similars also resembles the blood of humans under starvation. In the blood of humans under starvation, together with the reduced quantity of chloresterine, a reduced level of albuman is also observed.

In the blood of both similars and humans, the quantities of calcium, iron, copper, sine, silicium, iedine, and various forms of sulphur vers determined.

Data oburactorizing the quantities of these minoral substances in the blood of humans and similars are shown in Table 4.

L

.

The table also includes data obtained by various investigators at different times but employing the same method of blood analysis on both bumans and simians.

As can be seen from Table 4, data on the mineral composition of blood show no special distinctions between the blood of lower monkeys and humans. Hence we can reach the conclusion that the formulae of liquids which can compensate the loss of blood when they are injected into blood vessels can be first determined on lower monkeys and later applied to human beings.

Unfortunately, data on the individual components of the salt-composition of the blood of simians were obtained by different investigators (including authors of this article) during various seasons of the year. It is therefore impossible to determine the presence of probable seasonal fluctuations in the data.

At the sume time, in spite of all the similarity of mineral compositions, the erythrocytos /red blood corpuscles/ of humans are slightly richer in zinc content.

This does not completely correspond to the degree of activity of carbonic anhydrosis (ugol'naya angidraza) (of which zinc is a constituent part), which is the same in the blood of humans and simians.

The somewhat higher quantity of mignesium found in the whole-blood of simians is probably due to the fact that the investigations were conducted on young monkeys (the erythrocytes of young animals are usually richer in magnesium). The slightly lower quantity of iron and copper found in the whole-blood of simians, corresponds to the lower concentrution of common albumen (particularly bemoglobin) in the blood of simians, which was mentioned carlier.

It is a known fact (10) that the average quantity of hemoglobin is slightly lower in the whole-blood of similars than in the whole-blood of humans.

It is of interest to comparative blochumistry that the simians and humans belong to the same group of mummals, i. e. if we judge them on the character of the selective concentration of potassium ions by erythrocytes. In the second group of mammals, we would then have the dog and the cat, which have a prodominonce of sodium in the crythrocytes in their blood.

In respect to specific albuman-formants, corresponding data are rather scanty. A. S. Konikova and A V. Vodova (11) discovered that the catalytic activity in the blood of the baboon-hamadril / gamadril/ con-

The table also includes data obtained by various investigators at different times but employing the same method of blood analysis on both humans and simians.

As can be men from Table 4, data on the mineral composition of blood show no special distinctions between the blood of lower monkeys and humans. Hence we can reach the conclusion that the formulae of liquids which can compensate the loss of blood when they are injected into blood vossels can be first determined on lower monkeys and later applied to human beings.

Unfortunately, data on the individual components of the salt-composition of the blood of simians were obtained by different investigators (including authors of this article) during various seasons of the year. It is therefore impossible to determine the presence of probable seasonal fluctuations in the data.

at the sume time, in spite of all the similarity of mineral compositions, the erythrocytes /red blood corpuscles/ of humans are slightly richer in zinc content.

This does not completely correspond to the degree of activity of carbonic anhydrosis (ugol'maya angidraza) (of which zinc is a constituent part), which is the same in the blood of humans and simians.

The somewhat higher quantity of mignetium found in the whole-blood of simians is probably due to the fact that the investigations were conducted on young monkeys (the erythrocytes of young animals are usually richer in magnetium). The slightly lower quantity of iron and copper found in the whole-blood of simians, corresponds to the lower concentration of common albumen (particularly hemoglobin) in the blood of simians, which was mentioned earlier.

It is a known fact (10) that the average quantity of hemoglobin is slightly lower in the whole-blood of similans than in the whole-blood of humans.

It is of interest to comparative biochemistry that the simians and humans belong to the same group of mummals, i. 9. if we judge them on the character of the selective concentration of potassium ions by erythrocytes. In the second group of mammals, we would then have the dog and the cat, which have a prodominance of sodium in the crythrocytes in their blood.

In respect to specific albuman-forments, corresponding data are rather scanty. A. S. Konikova and A V. Vodova (11) discovered that the catalytic activity in the blood of the baboon-hamadril / gamadril/ con-

10

and in the second

stitues 6.75 equivalent units (according to the method of A. N. Baon abd Zubkova), while the proteclytic activity in the blood of three baboonhamadrils, equalled 20, 23, and 29 mgs of residual nitrogen. This figure is noticeably higher than the figures obtained from the analyses of normal blood.

According to the data of these investigators, the amylase activity in the blood of three lower monkeys equalled 12.0, 22.6 and 41.1 mgs of sugar . Corresponding analyses of human blood were not performed.

Finally, the review of H. Gibian (12), mentions the presence of a considerable quantity of carbonic anhydrosis in the cerebellum and cortex of a monkey (type not indicated).coording to C. Kochakian and others (13), the blood of lower monkeys, unlike the blood of man, does not contain any arginases. The lower monkeys also differ from humans and anthropoid apes in the fact that their blood contains ferments of uricase. In the available literature, we did not find any other information pertaining to the blood ferments (enzymes?) of simians.

Data which were obtained in our laboratory are presented in Table 5.

Table V

The activity of various ferments in the blood of burnens and similans:

Objuct of	: No. of	:]	Ferments (in eq	uivalent unit	ta)
		: Amyln so : oftr King : :	: Aldolase : after Brun : :		: Carbonic : anhydrase : arter :Brinkman- : Krops
Man .	: 10	: 85-195	: : 3,3-8,0	: : 1.6-4.8	i : 2.3-2.8
Mozkey (Macaoa- rezus)	: : : 4	: : 65–220	: : 2.6-14.5	: : 2.5-16.5 :	: : : 2.4-2.9 :

An analysis of this data shows an extensive range of variations of the anylase activity in the blood serve of simians. These variations in the titre of anylase were observed not only in different monkays. For instance during a period of 15 days we found that the variations in the anylase activity of the blood serve of the very same monkey ranged from 80 to 170 equivalent units.

The search in the second se

If We supplement these facts by the findings of S. D. Balakhovskiy (14), who points out that the variations in the titre of amilase in the blood of healthy humans, are not extensive, we can speak about specific distinctions of lower monkeys. However, observations of healthy humans show (see Table 5) that similar variations in the titre of amilase are also possible in the human blood.

We were also unable to find any special differences between the aldolace activity in the blood serum of lower monkeys and that of healthy humans. More evident are the differences in the phosphatase activity. The quantity of alkaline phosphatase in the blood serum of the rhesus monkey considerably differs from the quantity of the same agent in the blood serum of grown men and somewhat resembles the variations of the titre of alkaline phosphates in the blood of younger children. However, we can not entirely exclude the possible presence of obliterated, beginning stages of rachitis, in the captive monkeys under investigation. As it is known, rachitis is followed by an increase in the titre of the phosphatase in the blood.

It was also indicated that the amount of carbonic anydrase in the blood of the rhesus monkey and in the blood of humans are almost the same.

Data on the quantity of hormones in the blood of simians, particularly hormones which are socreted by the adrenal glands, are also of considerable interest to comparative biochemistry.

The quantity of corticosterons / "Kortikosteron" / and hydrocortizons / "Gidrokortizon" / (that is, 17-oxicorticosterons / "17-oksikortikosteron" /) in the blood flowing from the adrenal glands gives us a basic idea about the secretory activity of these glands. The activity of the glands in simians, is of a different character from that in humans and other kinds of animals. We have some data which show that the quantity of 17-corticosterone in simians is 20 times higher than the quantity of corticosterone. As far as cortizone is concerned, it can be found in the peripheral blood and urine of humans but not in the blood flowing from the adrenal glands.

The quantity of 17-oxisteroids /"oksisteroid"/ in the blood of 1cmer monkeys was recently determined in reliable investigations (16). The investigations were carried out on 50 monkeys of the Macaca-rhesus and Cinomelgus /"tsinomolgus"/ spacies. In respect to the quantity of steroids in the plasma of peripheral blood, the authors found no differences between the kinds /species/ and serves.

The average level of 17-oxisteroids was 37.7 mgs (standard deviation of 7.8). By comparing this data with corresponding data on human blood (6), we find that the blood of the rhesus monkey contains almost three

18

··· • • • • • •

times more storoids than the blood of humans. This picture of adrenal steroids gives us a busis for the assumption of specific distinctions in the biochemistry of lower monkeys.

We found no data in the literature about another hormone of the adronal glands - the adrenalize - nor did we find anything about adrenalinemia in simiane. The activity of the cerebral layer of adrenal glands is of interest, even if only because of the fact that during the deficiency of adrenals, the biochemical peculiarity of the carbo-hydrate metabolism in monkeys is characterized by an appreciable low level of sugar in the blood, and glycogen in the liver. This fact stands in a contrast to the comparatively high values of the conclusive data (17). The chief symptom of this deficiency in simians, are hypoglycamic convulsions. As far as the level of glycogen in the muscles and in the heart is concorned, lower monkeys hardly differ from humans.

Our laboratory has at its disposal a number of results from the analyses of whole-blood of the rhesus monkey. The quantity of adrenaline varies between 0-35 mkgs and the quantity of dehydrenaline, between 0-18 mkgs.

as it is known, data on the quantity of adrenaline in the blood of humans are quite contradictory, as they vary with the methods of analysis used by the various researchers. For this reason, we shall compare only the results of those researchers who used the same methods of analysis. T. P. Pichkhaya (18), found that the fluctuations of adrenaline in the blood of humans remain within the limits of 8-28 mkg%, and the fluctuations of dehydroadrenaline, within the limits of 2-25 mkg%.

A comparison of the titres of physiological adrenalinemia and hyperadrenalinemia shows a close similarity in this aspect between the blochemistry of humans and similars.

Conclusion

On the basis of the above-presented information, we can conclude that the intensified study of biochemical indices of the organisms of lower and higher monkeys is of considerable interest and should, undoubtedly, yield materials for a further differentiation of biochemistry (possibly, not only between species but within species as well). The application of the methods of biochemical analysis, as used in the study of the biochemistry of humans, to the systematic study of simians, should produce information which can be of considerable interest for the understanding of the evolution of biochemical processes. The application of the biochemical analysis will also enable us to use monkeys as objects for the experimental reproduction and study of those diseases which are common to man.
