The Defense Metals Information Center was established at Battelle Memorial Institute at the request of the Office of the Director of Defense Research and Engineering to provide Government contractors and their suppliers technical assistance and information on titanium, beryllium, magnesium, aluminum, high-strength steels, refractory metals, high-strength alloys for high-temperature service, and corrosion- and oxidation-resistant coatings. Its functions, under the direction of the Office of the Director of Defense Research and Engineering, are as follows:

1. To collect, store, and disseminate technical information on the current status of research and development of the above materials.
2. To supplement established Service activities in providing technical advisory services to producers, melters, and fabricators of the above materials, and to designers and fabricators of military equipment containing these materials.
3. To assist the Government agencies and their contractors in developing technical data required for preparation of specifications for the above materials.
4. On assignment, to conduct surveys, or laboratory research investigations, mainly of a short-range nature, as required, to ascertain causes of troubles encountered by fabricators, or to fill minor gaps in established research programs.

CURRENT AND FUTURE USAGE OF MATERIALS IN AIRCRAFT GAS TURBINE ENGINES

W. F. Simmons and H. J. Wagner*

BACKGROUND

The "Jet Age" in the United States is less than 30 years old. The first U. S. jet aircraft, the Bell P-59 Aerocomet, made its initial flight in October, 1942. Since that time, the gas-turbine-aircraft-engine industry has grown to vigorous maturity. A dramatic illustration of this growth is shown in Figure 1 by the size of the new McDonnell Douglas tri-jet, DC-10, compared with the DC-3. The 21-passenger DC-3, of 1936 vintage, is only slightly longer than the rear engine nacelle of the DC-10 Series 10. The new tri-jet is 179 ft. 8 in. long, nearly 20 ft. in diameter, and the height to the top of the tail is 57 ft. 3 in.

Most of the aircraft gas-turbine engines currently produced in the United States are made by the following manufacturers:

AiResearch Manufacturing Division, The Garrett Corporation
Allison Division, General Motors Corporation
Continental Aviation and Engineering Corporation
General Electric Company
Lycoming Division, Avco Corporation
Pratt & Whitney Aircraft Division, United Aircraft Corporation

Some brief background information relating to the engine manufacturers is given in the following paragraphs. Additional manufacturer information is given in the Appendix which contains material applications in current aircraft gas-turbine engines and, as a matter of general interest, listings of engine designation, type, size, and the aircraft in which the engines are used.

AiResearch Manufacturing Division, The Garrett Corporation

AiResearch is the largest manufacturer of small gas-turbine engines. It makes the TPE 331 (military version T-76), a 500 to 840 hp turboprop engine used in a dozen commercial aircraft and in the North American-Rockwell OV-10A, Bronco. New facilities are being completed in Torrance, Califor-

nia, for the manufacture of a new high-bypass turbofan engine for corporate and commuter aircraft. Designated the ATF-3, it will be a 4000- to 5000-lb-thrust engine. Another new high-bypass engine, in the 2700- to 3000-lb-thrust class, is the TFE-731 to be built in Phoenix, Arizona. It is slated for certification in August, 1971, and will power the Swearingen SA-28T delta-wing business jet and an advanced model of the 10-place Learjet 25.

An experimental model of a hypersonic ram-jet engine has been built by AiResearch for NASA Langley Research Center. This liquid-hydrogen-fueled engine is designed for speeds between Mach 3 and Mach 8. In this speed range, air inlet temperatures exceed 3600 F.

Allison Division, General Motors Corporation

Allison was the first U. S. company to mass produce turbojet engines, having won the production contract for the General Electric developed J33 and J35 engines. Over 90 percent of the jet engines produced in the U. S. up to 1950 were Allison products. In recent years, its most important products have been turboprop engines. The 501, producing about 4000 shaft horsepower (shp) and weighing about 1875 lb, is the powerplant for the Lockheed Electra and the Convair 580. The military version (T56) capable of producing about 4900 shp, is used for various military transports and Navy antisubmarine aircraft. Allison also produces a small turboshaft engine, the Model 250 (military version T63), producing 317 shp and weighing 139 lb. It is used on several commercial and military helicopters.

The new Allison turbofan engine, the TF41, is a joint Allison/Rolls-Royce development. It produces 14,250 lb thrust, weighs 3100 lb and is used on the Air Force LTV A-7D and the Navy LTV A-7E tactical fighter aircraft.

Continental Aviation and Engineering Corporation

Continental produces several turbojet engines in the range of 1025 to 2700 lb thrust. Most of these engines are for unmanned aircraft such as drones and missiles.

FIGURE 1. SIZE COMPARISON OF THE McDONNELL DOUGLAS DC-10 WITH THE DC-3.

* Advisor, Information Operations Division, and Chief, Specialty Alloys Division, respectively, Battelle Memorial Institute, Columbus, Ohio.

General Electric Company

The United States' first jet aircraft, the Bell P-59 Aerocomet, took to the air in October 1942 powered by twin General Electric 1-A jet engines. A total of 30 of these engines were produced. The first large-production General Electric engine was the J47. Between 1947 and 1956, 29,678 J47's were built by General Electric and another 6,154 by Packard and Studebaker. More recently the J79 has been the mainstay of General Electric's production; through the first quarter of 1969, they had produced 10,697 of them.

Currently, General Electric is building the GE4 (68,600 lb thrust) turbojet engine for the Boeing 2707-300, the TF39 (41,100 lb thrust) high-bypass turbofan engine for the Lockheed C-5A, and the CF6-6 (40,000 lb thrust) and the CF6-50 (47,300 lb thrust) for the McDonnell Douglas DC-10 Series 10 and Series 30 "Airbus". G. E. also produces a spectrum of smaller turbojet and turboshaft engines in their Lynn, Massachusetts plant: the J85, T58, T64 and the new TF30, a turbofan engine for the Navy Lockheed S3A airplane.

Lycoming Division, Avco Corporation

About 80 percent of all the helicopters in Vietnam are powered with Lycoming engines. These engines are small compared with the large jet engines used on conventional aircraft, producing between 1200 and 3750 shp and weighing between 540 and 800 lb. The Lycoming T53 and T55 engines have been in such short supply in Vietnam that engines needing overhaul are shipped by air to Corpus Christi, Texas for overhaul at the Army Aeronautical Depot Maintenance Center (ARADMAC) and then flown back to Vietnam. ARADMAC has been overhauling these engines at the rate of 500 per month.

Pratt & Whitney Aircraft Division, United Aircraft Corporation

Pratt & Whitney built their first 400 hp Wasp piston engine for aircraft in 1925, but it was not until after World War II that they entered the jet-engine field and started their rapid rise to their present position. The Pratt & Whitney J57 was the world's first twin-spool, axial-flow gas-turbine engine.

Today, most of the Boeing and McDonnell Douglas jet transports are equipped with Pratt & Whitney engines. The Boeing 747 and the McDonnell Douglas DC-10 Series 20 both will use the Pratt & Whitney JT9D turbofan engine which develops 45,500 lb thrust. The Pratt & Whitney TF30, an afterburning turbofan engine in the 20,000-lb-thrust class, powers the Air Force F-111 and the Navy F-14A. The TF30 is the world's first afterburning turbofan engine.

MATERIALS USAGE -- PAST, PRESENT, AND DEVELOPMENTAL

Compressors and Fans

Until recently, the operating conditions in the compressor section were such that titanium alloys, low-alloy steels, and stainless steels satis-

factorily fulfilled all requirements. Table 1 lists the compositions of some of the current and future compressor-disk alloys and Table 2 lists compositions of some of the current and future compressor-blade and vane alloys.

Low-alloy and martensitic compressor-disk alloys such as "17-22A" and AISI 410 are disappearing in modern engines because higher compression ratios have raised compressor-disk temperatures above the limits for these materials. Superalloys, such as A-286, Incoloy 901, and Inconel 718 are required for disks as well as blades in the high-pressure compressors of advanced engines.

Incoloy 901 is regarded by Pratt & Whitney^{(1)*} as a logical choice for service in a high-pressure compressor. It was originally developed for use in turbine disks operating in the 1200-to-1300 F temperature range. Since the turbine disks are creep-strength limited, the processing parameters were established to maximize the creep strength of disk forgings. However, service for compressor disks in the 800-to-1100 F temperature range is fatigue-strength rather than creep-strength limited. Therefore, it was necessary to modify the processing of Incoloy 901 disks to raise the fatigue strength for compressor applications. This was done at Pratt & Whitney by reducing the solution temperature from 2000 to 1800 F. The lower solution temperature resulted in an average grain size of ASTM 5-6, with no grain larger than ASTM 4. The 2000-F solution temperature had given an average grain size of 0 with some grains as large as 0.050-in. diameter. The finer and more uniform grain size resulted in a significant improvement in fatigue properties without significantly affecting the creep strength.

Advanced engines such as the GE4 will have a compressor inlet temperature of 500 F, a midpoint compressor temperature of about 800 F, and an exit temperature of 1000 to 1100 F. These operating conditions have led to the selection of Alloy 718, a nickel-base superalloy, for the last stages in the compressor.

It has been said that the advanced high-bypass engine could not be built without titanium alloys. This is true today, but in the near future composites will be used in the fan parts and at the cold end of the compressor. Glass-reinforced plastics (already in use in the TF39) and graphite or boron-reinforced aluminum and epoxy are expected to be among the first composites to see service in gas-turbine engines.

The TF39 develops 80 percent of its thrust in the 1-1/2-stage fan which is 93 in. in diameter. The fan and the compressor spool are made of Ti-6Al-4V. The fan stator and casing are Ti-5Al-2.5Sn. For the spacers between the fan-stator vanes, glass-reinforced plastic stiffened with aluminum honeycomb has already replaced metal fabrications, yielding both a weight and cost advantage.

There are many low-stress low-temperature parts in the front end of subsonic engines that can be made of composite materials to save both weight and dollars. Some of these parts are being made

(b) Under consideration for application in advanced engines

using today's materials and processing technology. The next generation of engines will contain a significant increase in the use of composite parts. However, composite materials have not yet been proven ready to meet commercial-airline reliability requirements as far as erosion resistance and foreign-object damage (FOD) are concerned, and are therefore not yet used in rotating components of U. S. built engines.

Hollow construction of titanium-alloy fan and compressor blades may permit substantial weight reductions without sacrificing resistance to erosion and FOD, and is being considered for blades in advanced engines.

A reduction in engine sound level is desirable, and engine manufacturers are working on this problem. Steps being taken are based on these ideas:

- (1) A high-bypass ratio can cut the exhaust velocity in half and thus reduce the jet noise.
- (2) Elimination of inlet guide vanes helps reduce noise.
- (3) Low fan tip speeds help reduce noise.
- (4) A wider clearance between the fan and subsequent compressor stages reduces the sound level. Both Boeing and McDonnell Douglas, under NASA contracts, are investigating nacelle modifications that would reduce fan-compressor noise. They appear to have been successful, but the cost to modify existing aircraft will be high. (See Aviation Week and Space Technology, Oct. 27, 1969, page 31.) The McDonnell Douglas modification includes a lengthened fan discharge duct and a single-ring inlet. Both sides of the concentric inlet ring were treated with sound absorbing honeycomb sandwich material.
- (5) Plastic sound-absorbing material for fan duct surfaces and the fan frame flow path might cut the sound level.

Aviation Week, June 16, 1969, has this comment regarding the General Electric CF6 engine for the McDonnell Douglas DC-10, "General Electric has developed a glass-fiber sandwich structure which has emerged as the favored sound attenuation material. It is a 1-inch thick sandwich consisting of a perforated glass-fiber face sheet, a double-diamond truss core, and a solid glass-fiber face sheet, which acts as a backstop for the sound energy. This material will be installed from the inlet lip downstream to the trailing edge of the outer fan air duct wall."

Developmental Titanium Usage

The large high-bypass turbofan engines could not have been developed without strong lightweight titanium alloys. The percentage of titanium alloy in the TF39 engine for the CSA has reached 32 percent of the total metals weight in the engine. This may be the high point for titanium usage in jet

engines, because two factors will work to reduce the application of titanium. The first is the use of composites, which is just beginning. Large fan parts that now account for most of the titanium alloy usage can probably be made largely of composites. The second factor is the increased temperature in the compressors of supersonic engines, which has already necessitated the replacement of several titanium stages in the hot end by parts made of a nickel-base alloy. However, new manufacturing techniques may result in lighter hollow titanium fan and compressor blades which could make it quite difficult for composites to replace titanium.

Ti-6Al-4V alloy has been the high-volume alloy in gas-turbine engine applications, with some Ti-8Al-1Mo-1V and Ti-5Al-2.5Sn alloys being used. It is expected that Ti-6Al-2Sn-4Zr-2Mo and Ti-6Al-6V-2Sn alloys will reach high-volume usage in advanced engines. Table 3 lists the titanium parts in a typical modern fan-jet engine along with alternate titanium alloys and competing materials for the parts.

Figure 2 shows the relationship between the design stress/density ratio and temperature for composites, titanium alloys, and superalloys. This figure shows how the titanium range is being compressed to between about 400 and 800 F by the composites and the superalloys. (2)

On the other hand, new titanium alloys are being developed and, if most of the manufacturing and application problems can be solved, titanium will continue to hold its own in jet-engine usage. The total mill products for aircraft engines is expected to increase as shown in Figure 3. Some of the problems and handicaps that are unique to (or accentuated in) titanium have been listed by L. P. Jahnke, of General Electric Company as follows: (2)

Problems in manufacturing:

- (1) Segregation
- (2) Production of large precision forgings
- (3) Production of precision castings
- (4) Material cost.

Problems in applications:

- (1) Erosion
- (2) Foreign object damage
- (3) Fretting
- (4) Surface sensitivity
- (5) Salt stress corrosion
- (6) Oxidation embrittlement
- (7) Structural stability
- (8) Fire.

Table 4, prepared for DMIC by R. A. Wood in April, 1969, shows the estimated fly weight of titanium in aircraft engines.

Combustors

The alloys used for combustors and their liners and for the transition ducts connecting the combustors to the turbine inlet nozzles, must be formable, weldable sheet alloys capable of 8000 to 10,000 hours of operation in an oxidizing environment at average metal temperatures of about 1650 F or more. These sheet alloys must be stable for this long-time high-temperature service and have optimum

6Al-4V	Bar and forging	223.8	1544.0	14.5
8Al-1Mo-1V	Bar	2.0	15.3	13.1
	Forging	238.0	1152.8	20.6
Total Titanium Alloy		944.3	5909.4	16.0

(a) Depending on temperature, stress, corrosive resistance, cost, and weight requirements.

(b) Commercially pure titanium A-55 or A-70 grade.

(c) Such as graphite fiber-reinforced epoxy, boron-reinforced aluminum, etc.

erosion-corrosion, thermal fatigue (cracking), and distortion resistance. Most manufacturers now use annular combustors, which give a more even temperature distribution at the turbine nozzle. Liners are always air-film cooled and are often coated for additional protection. Coatings improve the resistance to erosion-corrosion damage and may assist in distributing the heat flux more evenly.

Currently Hastelloy X is by far the most commonly used alloy for combustor liner applications. L-605 and N-155 alloys have also been used, and AISI Type 321 and 310 alloys may be used at lower temperatures, as in stationary gas turbines. Haynes Developmental Alloy No. 188, which is superior to Hastelloy X in

high-temperature strength, ductility, and oxidation resistance, is receiving much attention from engine builders for combustor applications. Table 5 lists some typical combustor alloys.

In the future, coated TD-Nickel or TD-NiCr may be used in combustor applications. Thoria dispersions in nickel produce a material that is stronger than conventional superalloys in the 1800 to 2300 F temperature range. These dispersion strengthened materials also are superior in thermal fatigue and thermal distortion resistance. A drawback to the use of TD-Ni is its poorer oxidation-corrosion-erosion resistance, requiring that protective coatings be used. TD-NiCr has better surface properties,

(a) Under consideration for application in advanced engines

and may be used at 2200 F without coating, however, it is still an experimental material and has not been produced in commercial quantities. Both dispersion strengthened materials are difficult to fusion-weld without gross loss in strength because of agglomeration of the dispersoids. Because of this agglomeration problem, processes such as resistance spot and seam welding, diffusion bonding, and mechanical joining are used.

Smoke reduction of jet engines has been receiving considerable attention from engine builders. However, this is more a design problem than a material problem. Component tests of combustors having advanced dome and nozzle design have given virtually smoke-free operation.

Turbines

The turbine section of the gas turbine engine is probably more demanding of the materials engineer than any other part of the engine. Here the highest temperatures and stresses are encountered. Turbine inlet temperatures (gas temperature) in advanced engines will approach 3000 F within the next decade. The use of increasingly more cooling is the only alternative to the use of refractory metals or ceramics.

Disks

Materials for turbine disks in the past have been low-alloy steels and iron-base alloys such as 16-25-6, A-286, V-57, and Incoloy 901. The disks in production engines are alloys such as A-286, Incoloy 901, D-979, and Waspaloy. The trend to higher operating temperatures will require the use of superior alloys. Among the disk alloys selected for advanced engines are Waspaloy, Alloy 718, René 95, and Astroloy.

For some of the smaller engines such as the Allison 250 and the AirResearch 331 and T76, the wheels (disks) are precision cast integrally with the blades. For this purpose, alloys such as Alloy 713LC (coated), IN 100, and MAR-M-211 have been used.

Research is underway to improve the casting techniques so that larger wheels and blades can be integrally cast from the stronger nickel- and cobalt-base casting alloys.

Some typical turbine disk alloys are listed in Table 6.

Blades

In the past, turbine blades have been made from iron-, nickel-, or cobalt-base alloys, both cast and forged. Currently, however, practically all of the turbine blades are made from either cast or forged nickel-base alloys, and the trend is toward increased use of castings. There are several reasons for this trend:

- (1) Through variation in composition, casting alloys can be made that are inherently stronger than the workable alloys.
- (2) At high temperatures, cast alloys are usually stronger than wrought alloys of the same composition.

(3) The relative ease with which complex air-cooled precision cast blades and vanes can now be made is an advantage in engine design. This advance in the state of the art of casting is largely due to the development of high quality core materials and improved temperature and solidification control.

(4) Complex precision castings are now reliably producible.

(5) The economics now favor castings for complex parts such as air-cooled blades and vanes.

(6) Cast blades are less susceptible to thermal fatigue cracking than are forged blades.

(7) Special structures, such as directionally solidified grains, can be obtained.

Turbine blades are subjected to a severe combination of high temperature and high stress. Current materials have sufficient creep-rupture resistance to minimize failure by creep for extended time periods at rated speeds and temperatures. Blades are inspected and measured during engine overhaul and those that have increased in length or changed shape because of creep are replaced. Thermal fatigue cracking appears to be the predominant blade failure process today. Engine starts and stops and even the heating and cooling during engine acceleration and deceleration contribute to the nonuniform stresses that cause thermal fatigue cracking of the leading or trailing edges.

Hot corrosion (sulfidation) has been a problem for some military and commercial aircraft operating in marine atmospheres. Particularly susceptible are low-chromium (less than 12 percent) nickel-base alloy blades operating at higher than average metal temperatures. Protective coatings have given relief, and the trend now appears to be toward the use of coatings wherever they can increase the service life, whether the problem is sulfidation, corrosion, oxidation or erosion.

Table 7 shows some representative turbine-blade alloys.

Vaness

The first-stage nozzle vanes are the hottest part in the engine and are subject to tremendous thermal shock stresses. They take the first impact of the hot gas from the combustors as they direct it into the turbine inlet. These vanes are usually coated for improved oxidation resistance and may be air cooled. Since they are stationary they are not highly stressed. Cast nickel- and cobalt-base alloys are usually used for the first- and second-stage vanes. Hollow blades are less subject to thermal stresses that result in thermal fatigue and both sheet metal and cast hollow blades are used. As an example of hollow sheet-metal vanes, the GE J79 engine has stator vanes in the first two stages that are fabricated from René 41 alloy and third-stage vanes that are fabricated from A-286. Both of these alloys are relatively easy to form and weld, with proper precautions.

(a) Cast alloys.

(b) Under consideration for application in advanced engines.

(c) British

Table 8 lists the best known cast nickel- and cobalt-base vane alloys.

Developmental Superalloys

Research programs are being conducted by both industry and government for the purpose of developing alloys with improved hot strength, better microstructural stability after long-time exposure at elevated temperature, and improved resistance to attack by combustion products containing sulfur and sea salt (hot corrosion/sulfidation). Some of the new experimental superalloys are given in Table 9.

Refractory Metals

During the past decade there has been extensive government-supported research on the refractory metals -- columbium, tantalum, molybdenum, and tungsten. At present, columbium base alloys containing additions of tungsten, tantalum, and/or hafnium appear to be of potential importance in the design of future gas-turbine engines. However, all of the refractory alloys, because of their lack of oxidation resistance, must be coated, and to date a coating has not been found that would be fail-proof in creep, thermal fatigue, erosion, oxidation, and corrosion, except for very short times. The engine builders are in agreement that they will not use materials that are dependent upon coatings for their service life, although they will use coatings to extend an already acceptable service life. Specialists in the field of refractory metals are of the opinion that a revolutionary break-through in coating technology will be required before there is any significant use of refractory-metal alloys in gas-turbine engines.

Static Structures and Miscellaneous Components

Alloys that engine manufacturers have identified as being used for casings, shafts, and sheet components applications are listed in Tables 10, 11, and 12.

OTHER FUTURE MATERIALS AND PROCESSES TRENDS

The aircraft-engine industry has been the leader in the development of new materials and processes promoting increased efficiency and thrust-to-weight ratios in gas turbine engines. Since increased engine efficiency and operating temperature go hand in hand, the turbine inlet temperature of aircraft engines has been increased from about 1300 F in 1942 to the current level of 2300 F, or over. Figure 4 illustrates the effect of increased turbine inlet temperature on the performance of a typical turboshaft engine sized for about 4 lb/sec airflow and 8.0:1 compression ratio using either a regenerative or a nonregenerative engine cycle. For either cycle, increasing the turbine inlet temperature produces a substantial increase in specific horsepower and a modest decrease in specific fuel consumption. Experimental engines have been operated at temperatures up to about 3000 F. The increase in operating temperature already attained has depended primarily upon the development of advanced techniques for air cooling of vanes, blades, and associated engine parts made possible by refinements in casting and machining of the intricate cooling passages needed. At the same time, the use of new higher temperature nickel- and cobalt-base alloys in the turbine sections of the engine, and the use of titanium alloys, and, in advanced engines, composites and superalloys, in the compressor and fan sections, have contributed significantly to the advance in engine performance. Four cooling methods for blades and vanes have been classified as follows:

- (1) Convection Cooling
- (2) Impingement Cooling
- (3) Film Cooling
- (4) Transpiration Cooling.

The first three methods, shown schematically in Figure 5, are currently being used. Transpiration cooling is still experimental, but it shows enough promise so that manufacturers are looking for

FIGURE 4. INFLUENCE OF TURBINE INLET TEMPERATURE ON ENGINE PERFORMANCE (REFERENCE 2, CURTISS-WRIGHT CORP.)

FIGURE 5. SCHEMATIC OF VANE AND BLADE COOLING METHODS (MODIFIED FROM GENERAL ELECTRIC COMPANY INFORMATION)

practical methods of overcoming its deficiencies. Experimental transpiration cooled blades have been tested for only relatively short times, of the order of 100-200 hours; therefore, their resistance to foreign object damage, blocking of pores by dirt, and oxidation damage has not been determined. Figure 6 shows an experimental turbine blade in which the porous mesh has been EB welded to a precision cast spar by Curtiss-Wright Corporation.

Materials trends in turbojet and turbofan engines built by General Electric Company indicate some interesting progressions in materials usage for aluminum/magnesium alloys, titanium alloys, steels, superalloys, and composites, as shown in Table 13.

Superalloys

The selection of new materials for use in aircraft gas-turbine engines is becoming increasingly sophisticated. In addition to long-time strength, ductility, and corrosion resistance considerations, the engine designers are increasingly concerned with such factors as low-cycle fatigue, fracture toughness and crack propagation characteristics, surface and structural stability, fabricability, repairability, and cost. In general, the operating life is now of the order of 15,000 to 30,000 hours in the hot section and up to 50,000 hours in the cold section.

During the next 6-8 years it is expected that the temperature capability of blade and vane materials will be increased by about 100 F over current alloys, with no loss of stability. This development will arise largely from processing innovations rather than modifications in chemistry. Contributing may be directional solidification of eutectics and intermetallics in cast superalloys, and dispersion strengthening of powder metallurgy products by particles or fibers. At the present time, cast alloys appear to have a cost advantage in blades and vanes because the intricate cooling passages can usually be cast more easily than they can be machined.

If cost and production problems can be solved, Pratt & Whitney's directionally solidified or single-crystal turbine blade (Monocrystalloy) process may result in a significant step forward. Many types of elevated temperature failure, including thermal-fatigue cracking and creep-rupture, originate as grain-boundary cracks. Therefore, the absence of grain boundaries normal to the direction of maximum stress in the directionally solidified blades and the absence of all grain boundaries in the single-crystal structure significantly retard the onset of such failures. Pratt & Whitney⁽¹⁾ reports that directionally solidified turbine airfoils have been shown to exhibit up to a ten-fold advantage in rupture and thermal fatigue life over conventional castings of identical composition in certain applications.

Titanium

Although composites will make inroads into the applications of titanium alloys in the fan and front end of the compressor and austenitic alloys will replace some titanium in the hot aft end, there will still be a place for titanium alloys in fan-compressor applications if titanium-alloy development continues. New alloys and new processing methods must improve the properties and lower the

FIGURE 6. EXPERIMENTAL TRANSPIRATION AIR-COOLED TURBINE BLADE
(Courtesy Curtiss-Wright Corporation)

cost of titanium-alloy parts. M. J. Donachie et al of Pratt & Whitney⁽⁴⁾ have listed the 1973 and 1978 goals for new titanium alloys (Table 14).

Composites

As shown in Table 13, General Electric Company is predicting that the next generation of jet engines will contain 5 to 10 percent composites. An extensive research and development effort on composites is underway in the U.S., and significant progress is being made. However, fabricability and reliability of composite materials still present problems that are causing U. S. designers to approach the use of composites in stressed parts with caution.

Pratt & Whitney engineers⁽⁴⁾ have listed the temperature capability of some current and future composite materials (Table 15) and have plotted the effective strength-density ratios (Figure 7).

13. ABSTRACT This memorandum discusses the applications of heat-resistant metallic materials in aircraft gas turbine engines. Brief background information on the engines of each of the manufacturers is followed by a detailed discussion of the materials used in various components of the engines. Some current trends in turbine-engine materials applications are pointed out. An extensive appendix arranged according to manufacturer, lists materials used in recent and current engines and presents some brief data on size, weight, and application of each of the engines.

INSTRUCTIONS

1. **ORIGINATING ACTIVITY:** Enter the name and address of the contractor, subcontractor, grantee, Department of Defense activity or other organization (corporate author) issuing the report.

2a. **REPORT SECURITY CLASSIFICATION:** Enter the overall security classification of the report. Indicate whether "Restricted Data" is included. Marking is to be in accordance with appropriate security regulations.

2b. **GROUP:** Automatic downgrading is specified in DoD Directive S200.10 and Armed Forces Industrial Manual. Enter the group number. Also, when applicable, show that optional markings have been used for Group 3 and Group 4 as authorized.

3. **REPORT TITLE:** Enter the complete report title in all capital letters. Titles in all cases should be unclassified. If a meaningful title cannot be selected without classification, show title classification in all capitals in parenthesis immediately following the title.

4. **DESCRIPTIVE NOTES:** If appropriate, enter the type of report, e.g., interim, progress, summary, annual, or final. Give the inclusive dates when a specific reporting period is covered.

5. **AUTHOR(S):** Enter the name(s) of author(s) as shown on or in the report. Enter last name, first name, middle initial. If military, show rank and branch of service. The name of the principal author is an absolute minimum requirement.

6. **REPORT DATE:** Enter the date of the report as day, month, year, or month, year. If more than one date appears on the report, use date of publication.

7a. **TOTAL NUMBER OF PAGES:** The total page count should follow normal pagination procedures, i.e., enter the number of pages containing information.

7b. **NUMBER OF REFERENCES:** Enter the total number of references cited in the report.

8a. **CONTRACT OR GRANT NUMBER:** If appropriate, enter the applicable number of the contract or grant under which the report was written.

8b, 8c, & 8d. **PROJECT NUMBER:** Enter the appropriate military department identification, such as project number, subproject number, system numbers, task number, etc.

9a. **ORIGINATOR'S REPORT NUMBER(S):** Enter the official report number by which the document will be identified and controlled by the originating activity. This number must be unique to this report.

9b. **OTHER REPORT NUMBER(S):** If the report has been assigned any other report numbers (either by the originator or by the sponsor), also enter this number(s).

10. **AVAILABILITY/LIMITATION NOTICES:** Enter any limitations on further dissemination of the report, other than those imposed by security classification, using standard statements such as:

- (1) "Qualified requesters may obtain copies of this report from DDC."
- (2) "Foreign announcement and dissemination of this report by DDC is not authorized."
- (3) "U. S. Government agencies may obtain copies of this report directly from DDC. Other qualified DDC users shall request through _____."
- (4) "U. S. military agencies may obtain copies of this report directly from DDC. Other qualified users shall request through _____."
- (5) "All distribution of this report is controlled. Qualified DDC users shall request through _____."

If the report has been furnished to the Office of Technical Services, Department of Commerce, for sale to the public, indicate this fact and enter the price, if known.

11. **SUPPLEMENTARY NOTES:** Use for additional explanatory notes.

12. **SPONSORING MILITARY ACTIVITY:** Enter the name of the departmental project office or laboratory sponsoring (paying for) the research and development. Include address.

13. **ABSTRACT:** Enter an abstract giving a brief and factual summary of the document indicative of the report, even though it may also appear elsewhere in the body of the technical report. If additional space is required, a continuation sheet shall be attached.

It is highly desirable that the abstract of classified reports be unclassified. Each paragraph of the abstract shall end with an indication of the military security classification of the information in the paragraph, represented as (TS), (S), (C), or (U).

There is no limitation on the length of the abstract. However, the suggested length is from 150 to 225 words.

14. **KEY WORDS:** Key words are technically meaningful terms or short phrases that characterize a report and may be used as index entries for cataloging the report. Key words must be selected so that no security classification is required. Identifiers, such as equipment model designation, trade name, military project code name, geographic location, may be used as key words but will be followed by an indication of technical context. The assignment of links, rules, and weights is optional.
