13. ABSTRACT

For the past 3 years, studies were designed to investigate: 1. the distribution of oncomelanid snails in Taiwan, 2. the susceptibility of oncomelanid snails from various areas to infection with human and zoophilic strains of Schistosoma japonicum, 3. the nature of definitive host for Ilan strain of S. japonicum, and 4. adaptation of S. japonicum in Oncomelania hupensis chiui. In addition, gel-diffusion studies on sera from animals infected with S. japonicum were also made.

ABSTRACT

Studies were designed to investigate: 1. the distribution of oncomelanid snails in Taiwan, 2. the susceptibility of oncomelanid snails from various areas to infection with human and zoophilic strains of *Schistosoma japonicum*, 3. the nature of definitive host for Ilan strain of *S. japonicum*, and 4. adaptation of *S. japonicum* in *Oncomelania hupensis chiui* in the past 3 years. During the last one year, efforts have been made to complete the studies. In addition, gel-diffusion studies on sera from animals infected with *S. japonicum* were also made. Results obtained are as following.

1. Parasitological studies at Jui-Ping area, a new habitat for *O. h. chiui*, demonstrated that none of the 2,682 snails examined was found to be infected with *S. japonicum*. Susceptibility studies, however, showed that similarly to the snail from Alilao, the snail from the new habitat is also highly susceptible to all geographic strains of *S. japonicum*. The snail is found on a hill side along the coast, at least 4 km long in distance from Jui-Ping to the west.

Intradermal tests for *S. japonicum* were performed among 736 people, and 19 (2.6%) showed positive reactions. Significantly higher rate was found in males (3.3%) than in females (1.8%). Stool examinations of 605 people including 19 positive skin test reactors were all negative for *S. japonicum* eggs. The infection rates for intestinal helminths were: *Ascaris lumbricoides* 36.5%, hookworm 53.6%, and *Trichuris trichiura* 14.4%. Of the 499 school children examined by single Scotch-tape technique, 278 (55.7%) were found to be infected with *Enterobius vermicularis*.

2. Studies of the egg distribution of *S. japonicum* in various organs of mice and hamsters indicated that there are three types of egg distribution in mice. The Ilan and Changhua strains of *S. japonicum* belong to the first type in which the eggs deposited in the liver are greatest in number and proportion at 40 days of infection, and then decrease while the infection is longer. In contrary, the proportion of eggs deposited in the small intestine is going up from 40 days to 70 days after infection. The Chinese parasite shows the second type of egg distribution. Similar egg distribution is observed in the liver and small intestine in the first and second types. But significantly higher proportion of egg deposition in the large intestine is found. The Japanese and Philippine parasites are the third type in which the egg deposited in the small intestine are the greatest in number and proportion usually through the period from 40 to 60 days after infection.

The Ilan and Changhua *S. japonicum* demonstrated similar pattern of egg distribution. More eggs were quantitated in the liver at the early stage than the later stage of infection. In the large intestine, however, more eggs were quantitated in the later stage than in the early stage of infection. The characteristics of egg distribution in the Japanese *S. japonicum* was the lowest proportion of eggs deposited in the liver, and exceedingly high proportion of egg distribution in the small intestine at the early stage of infection. On the other hand, the characteristic egg distribution of

the Chinese parasite was observed in the large intestine in which the highest number of eggs were always quantitated and significantly less involvement in the small intestine.

3. Gel-diffusion studies on sera from animals such as rabbits, dogs, monkeys and rats which were infected with S. japonicum were made. Results obtained indicated that no distinct relationship between the precipitating antibody production and the degree of susceptibility of animal to the infection with S. japonicum was observed. The best antibody production was demonstrated in the rabbit, and the lines demonstrated in the tests were also more distinct in rabbits than in other species of animals.

It seems that, in general, the Ilan strain of S. japonicum possesses higher precipitating antibody production than the Changhua strain of S. japonicum.

Section I

General Introduction

Schistosoma japonicum was first discovered in Taiwan by Takegami (1914)[1] in Changhua County, in the central part of the western coastal plain of the island. This parasite is defined as a zoophilic or non-human strain of *S. japonicum*. Experimentally the snail host, *Oncomelania hupensis formosana*, in Changhua, although susceptible to the local strain of *S. japonicum*, was found to be refractory to any human strains of the parasite from Japan, the Philippines and mainland China (DeWitt, 1954[2]; Hsu and Hsu, 1960[3]). Therefore, it was stated that no oncomelanid snails on the island was susceptible to the infection with the human strain of *S. japonicum*, and because of this no indigenous human schistosomiasis has been established in Taiwan. In 1962, Kuntz[4] found a new endemic area for *S. japonicum* in Ilan County, in the northeastern part of Taiwan. Subsequently a considerable amount of effort has been made to determine whether the parasite prevalent in Ilan is the human strain or not. So, far, no human case has been discovered, and three rodents were the only natural hosts that have been found in this area. Therefore, it is considered that the Ilan *S. japonicum* may also be a non-human strain. Susceptibility studies on *O. h. formosana* from this area to infection with *S. japonicum*, however, revealed that they were slightly susceptible to the human strain of *S. japonicum* from Japan and the Philippines (Moose and Williams, 1964)[5]. In the meantime, in the course of a study on *Paragonimus* in the northern tip of Taiwan, a new species of snail, *O. h. chiui*, was incriminated as the snail host for *P. iloktsuenensis* at Alilao village, Taipei County (Chiu, 1961)[6]. Subsequent studies on the susceptibility of this species of snail to infection with the geographic strains of *S. japonicum* demonstrated that *O. h. chiui* is highly susceptible not only to the two zoophilic strains from Taiwan, but also to the three human strains of *S. japonicum* from Japan, the Philippines and mainland China (Chiu, 1965[7], 1966[8], 1967[9], 1968[10]). As a result of these studies, it is essential that further investigations be carried out to further establish the possibility of human schistosomiasis becoming established in Taiwan. Therefore, studies on host-parasite relationships of *S. japonicum* and its host have been initiated and designed to investigate:

1. The distribution of oncomelanid snails in Taiwan, as well as searching for new foci of *Oncomelania hupensis chiui*.

2. The susceptibility of oncomelanid snails from known sites or from new focus to infection with both the human and non-human strains of *S. japonicum*.

3. The nature of the definitive host for the Ilan strain of *S. japonicum*.

4. Adaptation of *S. japonicum* in *O. h. chiui* snails.

Main findings of the first two years of studies were as follows:

1. A new habitat for O. h. chiui was found at Jui-Ping village, on the north coast of Taiwan, approximately 10 km west of the mouth of the Tamsui River.

2. O. h. formosana from , villages in Ilan have been demonstrated to be susceptible only to the Ilan strain of S. japonicum and resistant to the Changhua, Japanese, Philippine and Chinese strains of the parasite.

O. h. formosana from 17 villages in Changhua were tested with two Formosan strains of S. japonicum. The infection rates varied from 21.3 to 73.8% for Changhua parasite, and 0-11.4% for the Ilan parasite. O. h. formosana from Kaohsiung, on the other hand, have been demonstrated to be resistant to Ilan, Changhua and Japanese parasite.

3. Fourteen species of animals have been exposed to the Ilan strain of S. japonicum to study the nature of the definitive host of this strain of parasite. Some species of animals have been exposed to the Changhua, Japanese, Philippine and Chinese strains of S. japonicum. Results obtained from the studies on the prepatent period, relative amount of egg passage in stools, duration of egg passage in the feces, worm recovery rate, and egg distribution in various organs of mice and hamsters indicate that the Ilan strain is more closely related to the Changhua strain than to the other strains. The dog, goat and squirrel have been found to be excellent host for the Ilan S. japonicum.

4. The Ilan strain of S. japonicum has been passed in O. h. chiui for 5 generations using the mouse as the definitive host. The infectivity of the parasite was tested in O. h. formosana and mice. A few differences were observed between the parasite maintained in O. h. chiui and O. h. formosana.

5. Intradermal tests among inhabitant of the Ilan endemic area indicated that 28 (2.6%) of 1,088 people examined showed positive reactions. However, the stool examinations of 727 people including 28 positive reactors were all negative for the ova of S. japonicum.

Continuous efforts have been made in the last one year to complete the present studies. In addition, gel-diffusion studies on sera from animals infected with S. japonicum have been made to utilize the blood of infected animals used in the study and the new immunology laboratory which has just been set up in our department. Results obtained are reported as followings:

Section II

Parasitological Studies at Jui-Ping Area: a New Habitat for Oncomelania hupensis chiui in Taiwan

1. Introduction

Intensive surveys for oncomelanid snails revealed a new habitat for O. h. chiui at Jui-Ping village, Linkou District, Taipei County, in the second year of the present project. Subsequently, parasitological studies were carried out to determine the distribution of O. h. chiui at this area, the susceptibility of the snail to the infection with geographic strains of S. japonicum, and the presence of S. japonicum at this area.

2. Materials and Methods

O. h. chiui was searched around the area to determine the distribution of the snail. The snails were collected from each place where O. h. chiui was found, and were examined for natural infection with S. japonicum by crush preparations.

The susceptibility of O. h. chiui from this area to infection with geographic strains of S. japonicum including the Changhua, Ilan, Japanese, Philippine and Chinese S. japonicum was studied. Each strain of the parasite was tested on 50 snails along with a control. Each snail was exposed individually to 5-7 miracidia. Ninty-eight to 157 days after infection, the surviving snails were examined by means of crush preparations.

A total of 736, 399 males and 337 females, received the intradermal test for S. japonicum. The antigen was obtained from the U. S. Army 406th Medical Laboratory in Japan. Fecal containers were given out to people who received skin testings, and they were asked to submit stool specimens for examination in 2 days. As a result, 605 people, 337 males and 268 females, submitted stools. Stools were examined by direct smear and the AMS III concentration technique.

The Scotch-tape technique was performed among primary school children in the morning to determine the pinworm infection rate in this area. A total of 499 school children (264 males and 235 females), consisting of 152 from Jui-Ping and 347 from Chia-Pao primary schools, were examined.

3. Results and Discussion

A total of 2,682 O. h. chiui snails were collected and examined for natural infection with S. japonicum. Not a single snail was found to be infected with schistosome. O. h. chiui is found on a hill side along the coast, at least 4 km long in distance from Jui-Ping to the west. An average size of the 100 snails from Jui-Ping (4.7 mm lorg by 2.5 mm wide) is larger than those from the type locality, Alilao (3.8 mm long by 2.0 mm wide). The apex of the shell is eroded in 15 of the 100 snails from Jui-Ping, and 88 of the 100 snails from Alilao.

Susceptibility studies of the snail to the infection with geographic strains of S. japonicum indicated that similarly to the snail from Alilao, the snails from the new habitat have been demonstrated to be highly susceptible to all geographic strains of S. japonicum from Changhua, Ilan, Japan, the Philippines and mainland China (Table 1). The infection rates ranged from 44.7% to 93.8%. Not a single snail was infected in the control group.

Results obtained from the intradermal tests are shown in Table 2 according to age and sex of the examinees. Of the 736 people who received intradermal tests, 19 (2.6%) showed positive reactions with S. japonicum antigen. It was the same positive rate as we obtained in Ilan. In Ilan 28 (2.6%) of the 1,088 people examined showed positive reactions with S. japonicum antigen. When the rates were observed among four age groups, the highest positive rate was observed in the age group of from 41 to 60 years (4.6%). No positive reactor was detected in the age group of from 21 to 40, and it is not known why the rate for the 1-20 years group was as high as 2.4%. On the other hand, significantly higher rate was seen in males (3.3%) than in females (1.8%). Stool examinations of 605 people including 19 positive skin test reactors were all negative for S. japonicum eggs.

Results obtained from both direct smear and AMS III concentration technique of fecal examinations are shown in Table 3 according to the sex of the examinees. Of the 605 people examined, 444 (73.4%) were found to be infected with one or more helminths. Only the common parasites, Ascaris lumbricoides, hookworm and Trichuris trichiura, were found. The highest rate of infection was found for hookworm in which 324 (53.6%) of the 605 people examined were found infected. Most of the examinees were farmers who used nightsoil in the cultivation of vegetables. A little higher rate was observed in males (55.8%) than in females (52.2%). The infection rates for Ascaris lumbricoides and Trichuris trichiura were 36.5% and 14.4%, respectively. The rates between sex for these two species of parasites were close.

Of the 499 school children examined by single Scotch-tape technique, 278 (55.7%) were found to be infected with Enterobius vermicularis (Table 4). The infection rates for the two primary schools were similar. But a significantly higher infection rate was observed in males (60.2%) than in females (50.6%).

Section III

Egg Distribution of Human Strains of Schistosoma japonicum in Various Organs of Mice and Hamsters

1. Introduction

Very little is known about the definitive host for the Ilan strain of S. japonicum. The only report dealing with the finding of reservoir host was made by Kuntz (1965)[4]. He examined 300 wild and domestic animals, and found 2 Rattus rattus and 1 Bandicota indica nemorivaga naturally infected with S. japonicum. In later studies, Khaw and Fan (1966)[11] after examining 1,361 stools, organs and tissues of 356 pigs, 188 buffaloes, 20 dogs, 247 poultry and 550 rodents were unable to find either the adult worms or ova.

In the last two years, the susceptibility of various species of mammals to the infection with the Ilan strain of S. japonicum has been studied to understand the nature of the definitive host for this parasite. Some species of animals have also been exposed to the other geographic strains of S. japonicum for the comparison. The degree of susceptibility of each species of animal is based upon the following information: a) length of the prepatent period, b) quantitation of eggs in stools, c) duration of egg passage in the feces, d) worm recovery rate, e) location of worms in the host, f) distribution of eggs in various organs of mice and hamsters, g) egg hatching ability, and h) growth and development of the parasite.

The first four items have been studied, and the last two items are still under study. Results obtained from the study on egg distribution of the Ilan and Changhua strains of S. japonicum invarious organs of mice and hamsters have been reported in the previous annual reports. In order to complete the study, egg distribution of the three human strains of S. japonicum in various organs of mice and hamsters was studied for the comparison.

2. Materials and Methods

The laboratory mouse (Swiss Webster) and hamster (Golden Syrian) have been subjected to quantitative percutaneous infections of cercariae obtained from pools of infected snails The Japanese strain was obtained from O. h. nosophora, the Philippine strain from O. h. quadrasi and the Chinese strain from O. h. chiui. Animals were sacrificed at intervals of 40, 50, 60 and 70 days after infection. Following the recovery of worms, the liver, small intestine, large intestine, stomach, spleen, mesentery, lungs and brain were removed and assayed for eggs by trypsin digestion. Eggs quantitated were pooled together and tabulated in Tables 5-9 according to the days of infection. Most eggs were found in the liver, small intestine and large intestine. The eggs found in other organs were low in number and were therefore pooled.

3. Results and Discussion

In mice infected with the Japanese parasite (Table 5), the greatest number of eggs were quantitated in the small intestine (62.7%) 40 days after infection, followed by the liver (26.8%), large intestine (10.1%) and others (0.4%). Eggs deposited in the small intestine increased in number and proportion (87%) 50 days, but decreased rapidly in number and proportion (17.3%) 70 days after infection. The number in the liver, on the other hand, decreased at 50 days (9%), and increased suddenly at 70 days (79.9%). Decrease of the eggs in proportion was observed in the large intestine through 70 days after infection, and there was no significant change in the other organs throughout the study period. It was significant that most eggs deposited in the small intestine and liver regardless of the days of infection.

Similar results were obtained for the Philippine parasite in mice (Table 6). The greatest number and proportion of egg deposition were observed in the small intestine throughout the study from 40 to 60 days after infection. The eggs deposited in the liver (9.7%) was less than that of in the large intestine (16%) at 40 days. But later 50-60 days after infection, eggs quantitated in these two organs were very close. High proportion of egg count was observed in the other organs (10.2%) 60 days after infection.

The egg distribution of Chinese parasite in mice demonstrated different type from other strains of the parasite (Table.7) The egg distribution in the liver and small intestine was very similar to the Ilan and Changhua strains of <u>S</u> <u>japonicum</u>. The proportion of eggs deposited in the liver decreased while the infection was getting longer. On the other hand, the increase of the propotion of eggs deposited in the small intestine was observed. Involvement of the large intestine was characteristic in the Chinese strain of S. <u>japonicum</u>. Eggs deposited in the large intestine were from 29.1% to 36.1% in proportion through 40-60 days after infection, and it was higher than any other strain of the parasite.

On the whole, there are three types of egg distribution in mice. The Ilan and Changhua strains belong to the first type in which the eggs deposited in the liver are greatest in number and proportion at 40 days of infection, and then decrease while the infection is going longer. In contrary, the proportion of eggs deposited in the small intestine is going up from 40 days to 70 days after infection. The Chinese strain of <u>S</u>. <u>japonicum</u> shows the second type of egg distribution. Similar egg distribution is observed in the liver and small intestine in the first and second types. But significantly higher proportion of egg deposition in the large intestine is found, usually around 30% from 40 to 60 days after infection. The Japanese and Philippine parasites are the third type in which the eggs deposited in the small intestine are the greatest in number and proportion usually through the period from 40 to 60 days after infection.

The egg distribution of the Japanese and Chinese strains of S. japonicum in various organs of hamsters was studied to compare with the Ilan and Changhua strains of the parasite. As seen in Table 8, the proportion of eggs deposited in the liver was very low (3.9-9.9%) in the Japanese S. japonicum regardless of the days of infection as compared with the two Formosan strains of the parasite which are usually more than 20% (Annual Report, 1970). On the other hand, the highest proportion was observed in the small intestine (74.9%) at 40 days. It, however, decreased at 50 days (56.7%) and 60 days (37.4%). The increase of egg distribution was observed in the large intestine from 18.7% (40 days) to 32.5% (50 days) and 58.4% (60 days).

In the Chinese strain of S. japonicum (Table 9), the proportion of eggs deposited in the liver was 28.7% at 40 days, then increased to 36.7% at 50 days and remained approximately the same rate, 37.9% at 60 days. The fewest number of eggs were quantitated in the small intestine through the period of from 40 to 60 days after infection (4.1-12.7%). The eggs deposited in the large intestine were greatest and remained almost the same proportion from 40 to 60 days after infection (57.0-28.9%).

Results obtained indicated that egg distribution of geographic strains of S. japonicum in various organs of hamsters was quite characteristic. The Ilan and Changhua S. japonicum demonstrated similar pattern of egg distribution. More eggs were quantitated in the liver at the early stage than the later stage of infection. In the large intestine, however, more eggs were quantitated in the later stage than in the early stage of infection. The characteristics of egg distribution in the Japanese S. japonicum was the lowest proportion of eggs deposited in the liver, and exceedingly high proportion of egg distribution in the small intestine at the early stage of infection. On the other hand, the characteristic egg distribution of the Chinese S. japonicum was observed in the large intestine in which the highest number of eggs were always quantitated and significantly less involvement in the small intestine.

Section IV

Gel-Diffusion Studies on Sera from Animals Infected with *Schistosoma japonicum*

1. Introduction

Gel-diffusion studies on sera from animals infected with *S. japonicum* were made to utilize the blood of infected animals used in the present project, and also to utilize the new immunology laboratory which has just been set up in our department. The purposes of this study are 1) to investigate the difference of the precipitating antibody production in suitable and unsuitable hosts, and 2) to compare the precipitating antibody production between the Ilan and the Changhua strains of *S. japonicum*

2. Materials and Methods

The dog and rabbit were used as suitable host, and the monkey and rat as unsuitable host. Two groups of animals were designed for the Ilan and Changhua strains of *S. japonicum*. Each group contained 5 each of the dog, rabbit and monkey, and 18 rats. The number of cercariae exposed were: 312-523 for monkey, 326-563 for dog, 228-282 for rabbit and 121-361 for rat. Sera were collected from the monkey, dog and rabbit before the infection, and every 10 days from 20 days of infection till 60 days of infection, and then every 30 days thereafter. Sera of rats were obtained from the heart directly after sacrificing the animal. Three rats were sacrificed each time according to the same time schedule of the other animal species including 3 non-infected rats as control. The preparation of antigen described by Damian (1966)[12] was followed. The gel-diffusion tests performed were of the double diffusion plate technique of Ouchterlony. The agar used was 1% Noble agar (Difco) in 0.02M Phosphate buffered 0.9% NaCl at pH 7.0.

3. Results and Discussion

Results obtained indicated that no distinct relationship between the precipitating antibody production and the degree of susceptibility of animal to the infection with *S. japonicum* was observed (Tables 10-17). All 10 rabbits began to show one line 40 days after infection regardless of the strain of the parasite. The rabbit numbered C-Rb-1 which was infected with the Changhua parasite demonstrated the second line at 50 days of infection. This line also appeared in two rabbits, I-Rb-23 and I-Rb-24, which were infected with the Ilan parasite 120 and 150 days after infection, respectively. The third line was found in serum of I-Rb-24 40 days after the infection.

One of the 5 dogs and 3 of the 5 dogs infected with the Changhua and

Ilan strains of S. japonicum, respectively, showed one line 40 days after infection, and another dog with the Ilan parasite showed the corresponding line 90 days after infection. One dog, C-C-12, infected with the Changhua parasite demonstrated the second line 50 days after infection.

Not a single monkey showed one line after the first infection. Two monkeys infected with the Ilan S. japonicum, however, showed one line 30 days after the challenge infection at the 136th day of the first infection. No line was observed in monkeys infected with the Changhua S. japonicum even after the challenge infection.

Two and three rats infected with the Changhua and Ilan S. japonicum, respectively, gave one line either 50 or 60 days after infection. The rest of rats showed no lines. It was not possible to follow the precipitating antibody in the rat, as the animals were sacrificed in order to collect the sera from the heart.

Results obtained seem to indicate, in general, that the Ilan strain of S. japonicum possesses higher precipitating antibody production than the Changhua strain of S. japonicum. The lines demonstrated in the tests were more distinct in rabbits than in other species of animals.

Table 1. Results of examinations on Jui-Ping *Oncomelania hupensis chiui* exposed to geographic strains of *Schistosoma japonicum* miracidia.

Strain of parasite	No. snails exposed*	No. snails examined	No. snails infected	Percent infected
Changhua	50	48	45	93.8
Ilan	50	23	20	87.0
Japanese	50	38	17	44.7
Philippine	50	22	20	90.9
Chinese	50	10	8	80.0
Control	50	39	0	0

* Each snail was exposed to 5-7 miracidia individually.

Table 2. Results of intradermal test for *Schistosoma japonicum* among inhabitants of Jui-Ping area, by age and sex.

Age or Sex	Number examined	Number positive	Percent positive
Age			
1 - 20	531	13	2.4
21 - 40	55	0	0
41 - 60	109	5	4.6
61 - 80	41	1	2.4
Sex			
Male	399	13	3.3
Female	337	6	1.8
Total	736	19	2.6

Table 3 Prevalence of intestinal helminthic infections among inhabitants of Jui-Ping, by sex.

Sex	Number examined	No. with helminth		Species of Helminth					
				Ascaris		Hookworm		Trichuris	
		No.	%	No.	%	No.	%	No.	%
Male	337	247	73.3	120	35.6	188	55.8	51	15.1
