13. ABSTRACT Electric and dielectric rock parameters were measured using an analog/digital computer for rapid evolution and data display. In common with many dielectrics, the imaginary part of dielectric constant established a circular arc when plotted against the real part at a series of frequencies. A conformal arc with the same relaxation time was obtained when the reactive component of impedance was plotted as a function of the resistive component. The data were verified on various rock samples of basalt, granite and quartzite in the frequency range 1Hz to 2kHz. Effects of rock pretreatments in water and in sodium hydroxide solutions upon their electric and dielectric parameters were studied. The highest sensitivity for water detection in rocks was realized by extrapolating the circular arc to determine the real dielectric constant at zero frequency limit. Electrode polarization and double layer effects had been explained in terms of an electrical model that also simulated the rock impedance and dielectric relaxation behaviours.

SECTION I

PROJECT OBJECTIVES AND SIGNIFICANT RESULTS

RESEARCH OBJECTIVES

Objectives of this research were to adopt rock impedance and dielectric parameters as indicators as well as predictors of their geophysical characteristics, of presence of water, entrapped gases, and rock fractures. Dielectric relaxation mechanisms were utilized to describe the impedance and dielectric characteristics of representative rocks. Electrical models to simulate rock impedance and dielectric dispersion were used to correlate rock properties with the model parameters. Data taken at low frequencies (<2kHz) yielded information that is pertinent to rock structure and geophysical characteristics, while the high-frequency data would contribute a valuable input to rock fragmentation by dielectric heating. Research covered in this report was confined to the low-frequency range and to the development of relationships between impedance and dielectric permittivity data on rocks.

SIGNIFICANT RESULTS

Rapid measurement and display of the low-frequency impedance parameters of basalt, granite, and quartzite was accomplished by a novel technique in which the rock under investigation was placed in the feedback path of an operational amplifier, and an analog/digital computer was used for rapid evolution and data display. The data obtained adhered closely to the theoretically predicted circular arc diagram when the equivalent series reactance was plotted as a function of the equivalent series resistance at various frequencies from 0.05 Hz to 2 kHz. The photographs in Figures 1-1, 1-2, and 1-3 show the actual output for the impedance parameters of basalt, granite, and quartzite rock samples as displayed in the Argand diagram.

Figure 1-3. Computer Display of the Impedance Circular Arc for a Large Diameter Quartzite Disc Sample. Points (+) represent experimental variation of reactance with resistance at a given frequency. Dotted curve is an arc of the computer data-fitted circle in the least square sense.

A new "bracketing" technique was developed to extract the rock dielectric constants from the corrected and normalized impedance parameters. Details of this novel technique are presented in Sections IV and VII.

An electrical model that describes the observed behavior of rock impedance data has been developed and is reported in Section VII. The model permits quantitative evaluation and correlation of observed rock impedance data and their geophysical characteristics. The model also elucidates for the first time the inherent complications that arise from electrode impedance and rock/electrode double layer polarization effects by defining a polarization parameter, g .

The highest sensitivity for water detection in rocks was obtained by extrapolating the real component of the dielectric constant to the zero frequency limit. The effects of rock pretreatment in water and in sodium hydroxide solutions upon their electric and dielectric parameters are covered in Section VI. Variation of the polarization constant, g , for a basalt rock with its sodium (mobile) ion content is shown in Figure 1-4. Lower polarization constants correspond to more significant electrode double-layer polarization artifacts, because this type of double-layer polarization impedance appears to be in parallel with the rock impedance components. Hence, the presence of larger quantities of sodium ions increases the double-layer polarization effects in addition to increasing the rock ohmic conductivity.

Figure 1-4. Variation of the Polarization Constant g for Basalt Rock with the Percentage of Sodium Hydroxide in the Pretreating Solution. Pretreatment Time = 23 hours.

SECTION II

EXPERIMENTAL TECHNIQUE

The most common methods of determining the electric and dielectric properties of rocks involve bridge, resonance, and heterodyne techniques. A comprehensive description of these and similar techniques is given in References 1 and 2.

During this program a new direct-comparison method was developed that involved placing the rock sample in the feedback loop of an operational amplifier. This method has the advantage that data can be taken at extremely low frequencies where conventional methods become too unstable. Furthermore, the data were processed by a computer and displayed directly. In this technique, impedance data processing involved time-domain sampling and a discrete Fourier transform to the frequency domain.

EXPERIMENTAL SETUP

The basic approach to the experimental determination of the rock impedance is the use of the rock as a feedback impedance in an operational amplifier. Thus, for a known input signal and resistance, the rock impedance can be determined from the amplifier output signal. This technique lends itself to convenient, on-line signal analysis through the use of analog-to-digital conversion equipment.

Figure 2-1 illustrates the experimental setup in simplified form. Basically, a sinusoid at known frequency drives the amplifier containing the rock, while an in-phase square wave generated simultaneously with the sinusoid is used to clearly define the period of the waveform.

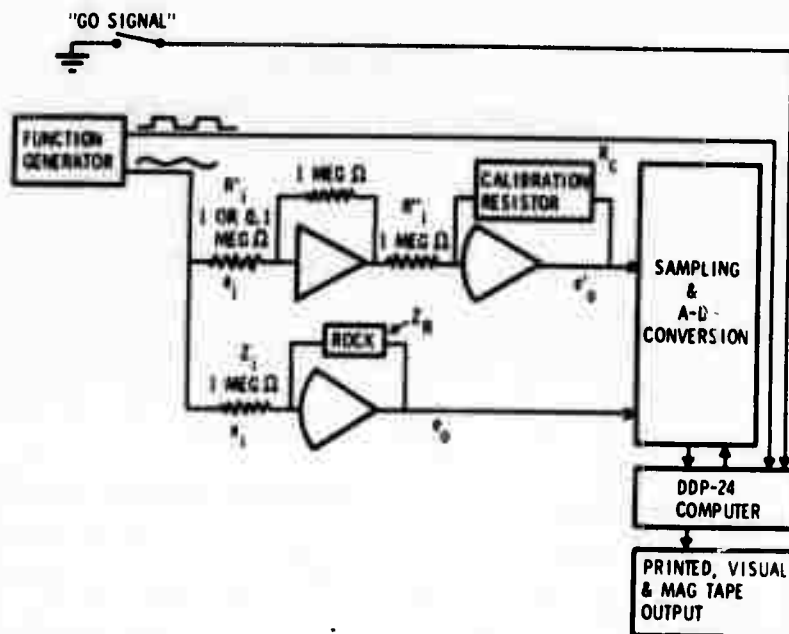

Figure 2-1. Schematic of Experimental Setup

The output from the rock amplifier is sampled over some interval consistent with the signal frequency and converted to digital form. At this stage a DDP-24 computer performs a discrete Fourier transform and computes the equivalent series resistance and reactance for the signal.

Included within the analog circuitry is an amplifier having a known fixed (calibration) resistor in its feedback loop. The signal from this amplifier is analyzed simultaneously with the rock signal and provides a reference signal of known amplitude and phase.

Another amplifier is provided just ahead of the calibration amplifier to provide a means of easily changing the gain through the calibration branch without changing the calibration resistor itself.

The voltage output, e_o (Figure 2-1), from the amplifier having the rock as its feedback impedance is given by

$$e_o = -\frac{Z_R}{Z_i} e_i, \quad e_o = -Z_R e_i \quad (2-1)$$

because $Z_i = 1$ megohm and Z_R is in megohms.

Similarly, the output e_o' from the calibration amplifier is given by

$$e_o' = -\frac{R_c}{R_i' R_i''} e_i \quad (2-2)$$

The amplitude of the complex impedance Z_R is thus given by

$$|Z_R| = \frac{|e_o|}{|e_o'|} \left(\frac{R_c}{R_i' R_i''} \right) \quad (2-3)$$

where e_o and e_o' are determined from a Fourier analysis of the output voltages e_o and e_o' .

The Fourier analysis also provides the phase angle ϕ between output voltage and current. Thus, the series resistance and reactance are calculated from

$$R_s = |Z_R| \cos \phi, \quad \text{and} \quad X_s = |Z_R| \sin \phi \quad (2-4)$$

A least-squares circle fit is also automatically made for the R_s and X_s data and displayed along with the R_s and X_s data on a CRT screen. In addition, all data are permanently stored on magnetic tape for future call back.

PROCEDURE

Sinusoidal signals from the function generator of a discrete frequency from 10 Hz to 1 MHz were used to drive the current electrodes. In addition, an in-phase square wave generated simultaneously with the sinusoid served to clearly delineate the period of the waveform so that its frequency could be easily measured. The excitation current, output voltage, square wave, and "go" signal were led directly to the computer for on-line processing, or else stored intermediately on FM magnetic tapes for subsequent playback when off-line processing becomes necessary. The results were printed, punched on paper tape, and digitally recorded on magnetic tape.

All computations were performed in the laboratory on a DDP-24 computer, which has an 8000-core storage memory bank of 24-bit words. Because this computer is oriented in design for process control, it is ideally suited for on-line measurements of the sort described here. Peripheral equipment contained sample and hold circuitry, a multiplexer, and an analog-to-digital converter as input channels, and a typewriter and paper tape punch for hard copy output.

The operation of the program is outlined in Figure 2-2. After the program was loaded and started, it awaited a "go" signal from the operator. Because complete freedom was desired in selecting frequency as an independent variable, it was necessary for the computer to adjust its own sampling rate accordingly every time the "go" signal was given. The excitation period was measured by determining the interval between successive positive sloped zero crossings, using machine cycles as the "yardstick". A minimum-measurement interval of a few milliseconds, measured to the nearest microsecond increment, was set and the number of cycles occurring in it was noted. With the excitation frequency and a sampling period "window" determined, it was possible to specify a sampling rate and the weighting coefficients of a discrete Fourier transform for harmonic analysis of the data. The waveforms across the

2-5

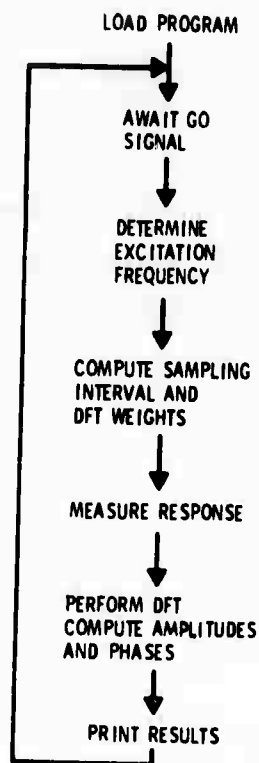

Figure 2-2. Computer Program - Sequence of Events

current source and the rock sample were measured simultaneously and stored internally. From these, the d-c first and second harmonic terms were computed using the above-determined discrete Fourier transform coefficients.

Having determined the frequency, resistance and reactance, a circle was fitted to the data under the condition of minimum deviation (least square calculation). The center of the circle (R_0 , X_0) was found such that the square of the deviations, Δ , was a minimum.

$$\Delta = \sum_{i=1}^n (r_i - \bar{r})^2 \quad (2-5)$$

where n is the number of sampling frequencies at which impedance was measured, \bar{r} is the average circle radius, and r_i is given by

$$r_i = \left[(R_o - R_i)^2 + (X_o - X_i)^2 \right]^{1/2} \quad (2-6)$$

This was accomplished via a gradient descent in two-dimensional R_o , X_o parameter space. For graphical display, the equivalent series resistances and reactances were computed at each of the sampling frequencies.

Sample Preparation

With the exception of the application of electrode material and the pretreatment experiments in Section VI, all measurements have been made on rocks "as received" from the customer.

The electrodes were applied to the flat surfaces of the cylindrical samples. An epoxy-based conductive adhesive* was applied in a thin coat and allowed to dry for at least two days at room temperature.

Copper leads made from thin sheet stock were laid on top of the electrode material and the rock was clamped tightly between two plates of printed circuit board to secure electrical contact with the rock.

The procedures described here for computing rock electric parameters are valid for isotropic specimens only. It was shown by Spinner and Tefft (Ref. 3) that rock elastic moduli equations can be applied to a polycrystalline material if the individual grains of the material are randomly oriented and distributed, and are not larger than one-third of the smallest dimension of the specimen. Such a material may be considered to be isotropic on a macroscopic scale, even though the individual grains themselves are anisotropic.

*Eccobond Solder V-91, Emerson and Cumming, Inc., Dielectric Materials Division, Canton, Massachusetts.

Validation of the Measurement Technique

To check the validity of rock impedance data obtained with the computer technique, some results were compared with those obtained with traditional compensation techniques using a General Radio-type 1650 CRL bridge. Measurements were performed on a basalt sample (I) at a frequency of 1 kHz. With the bridge technique a series capacitance of 28 picofarads and a dissipation factor, D , of 0.36 at 1 kHz were measured. Transformation from a series domain to an isoimpedic system in the parallel domain yields

$$R_s R_p = X_s X_p = R_s^2 + X_s^2 \quad (2-7)$$

The dissipation factor, D , is defined as

$$D = \frac{1}{\omega R_p C_p} = -\frac{X_p}{R_p} = -\frac{R_s}{X_s} \quad (2-8)$$

From Equations (2-7) and (2-8) one obtains

$$\frac{X_p}{X_s} = 1 + D^2 = \frac{C_s}{C_p} \quad (2-9)$$

Hence

$$C_p = \frac{C_s}{1 + D^2} \quad (2-10)$$

From these equations, one calculates a parallel capacitance, C_p , of 25 picofarads and a parallel resistance, R_p , of 17.7 megohms. The series parameters computed at 1 kHz would be -5.72 megohms for the reactance, X_s , and 2.04 megohms for the resistance, R_s .

Measurements with the direct comparison on-line computer technique for the same basaltic rock sample gave the values $R_s = 2.77$, $X_s = -5.28$ megohms and $\phi = -62.3$ degrees, respectively. The series reactances, -5.72 and -5.28 megohms obtained with the bridge and the new techniques, respectively, differ by about 8 percent. However, the series resistance 2.04 megohms measured with the bridge deviates by about 26 percent from the value 2.77 megohms measured with the present technique.

Despite the large deviation in R_s , and considering the lead impedances and stray capacitances which were not taken into account, these results nevertheless lend credence to the general validity of the new measuring technique. It is generally recognized that bridge balancing methods are difficult at very low frequencies, and hence, their data would be susceptible to gross errors at these frequencies. It appears, therefore, that the new direct-comparison technique yields reliable data in the low-frequency range.

On the assumption that rock impedance can be represented by the simple parallel $R_p C_p$ unit measured with the bridge, we constructed a model from the nearest available components in the laboratory of 18 megohms for R_p and 25 picofarads for C_p . A computer run was performed with this $R_p C_p$ unit replacing the rock. This system gave the data in Table 2-1 for the series parameters at four frequencies.

Table 2-1. Frequency Variation of the Impedance Parameters of the $R_p C_p$ Unit ($R_p = 18$ megohms, $C_p = 25$ picofarads)

Frequency (Hz)	R_s (megohms)	$-X_s$ (megohms)	$-\phi$ (degrees)
1000	2.66	4.60	59.9
100	16.22	4.93	16.9
10	17.84	0.61	2.0
1	17.89	0.08	0.2

As predicted, the series resistance approaches the model R_p value of 18 megohms as the frequency approaches zero. The time constant of this unit is equal to $R_p C_p = 45$ milliseconds. This corresponds to a turnover frequency of about 360 Hz. Around this characteristic frequency, the dispersion in R_s assumes rapidly decreasing values, while the dispersion in X_s assumes a flat maximum (see Figure 3-2). Hence, R_s will be subjected to the greatest error at frequencies between 100 and 1000 ohms by slight changes in the frequency of measurement, while X_s will be somewhat insensitive to such changes. Frequencies reported in this work are the nominal ones; for example, the 1000 Hz was actually sampled by the computer as 1007.33 Hz.

When the simple $R_p C_p$ unit was replaced by the basaltic rock sample in the feedback of the operational amplifier, the data in Table 2-2 were obtained.

Table 2-2. Frequency Variation of Basalt (I) Impedance Parameters

Frequency (Hz)	R_s (megohms)	$-X_s$ (megohms)	$-\phi$ (degrees)
1000	2.77	5.28	62.3
100	16.99	32.15	62.1
10	99.88	110.76	48.0
1	355.84	197.30	29.0

As expected, the values obtained at 1 kHz are in good agreement with those measured with the bridge method. The data at the lower frequencies of 100, 10, and 1 Hz deviated markedly. Thus, a simple $R_p C_p$ model cannot describe the impedance behavior of rocks. More complicated models are therefore needed to simulate the electrical behavior of rocks. One such model is described in Section VII of this report.

SECTION III

ROCK IMPEDANCE AND ELECTRODE EFFECTS

Room-temperature measurements were made on several dry samples of basalt, granite, and quartz. The following results show that impedance data on rocks at audiofrequencies adhere to a circular arc, or series of arcs, when displayed in the Argand diagram. Finite rock resistive and reactive dispersions were evident at characteristic frequencies, which permitted evaluation of rock relaxation time(s).

IMPEDANCE PARAMETERS OF DRESSER BASALT

A disc basaltic sample (II) containing SiO_2 , Fe_3O_4 , Al_2O_3 , TiO_2 , CaO , and MgO in the percents* 48.42, 6.6, 15.23, 1.9, 8.35, and 6.4, respectively, and measuring 0.635 cm in length and 6.41 cm^2 in cross-section was supplied to Honeywell by the Thermal Fragmentation Group, Twin Cities Mining Research Center, U. S. Bureau of Mines. Silver electrodes were painted to the circular surfaces of the rock and contact to the electrodes was made with copper wires. Replication of the impedance data at 14 different frequencies and at time intervals ranging from several minutes to three weeks, as well as with repeated electrode applications to the cleaned rock surface gave fairly reproducible results. The standard deviation at the high frequency of 2 kHz was 3.8 percent of the mean in R_s , and 2.6 percent of the mean in X_s . At the low frequency of 0.05 Hz, standard deviations of 3.7 and 8.1 of the mean in R_s and X_s , respectively, were calculated.

*Chemical analysis of the rock samples are taken from a recent report by Lindroth and Kranze (Reference 4).

The reactive component of the measured impedance is plotted in Figure 3-1 against its corresponding resistive component at a series of frequencies. The least-squares circle fit to the data was determined and plotted in the solid arc of Figure 3-1. The experimental points were found to deviate from the fitted arc by a standard deviation of 2.44 percent of the fitted radius. Inspection of the data in Figure 3-1 suggests a value of 16.4 megohm for the d-c resistance, R_0 , of this basalt sample. A rock phase angle, ϕ , of 29 degrees was also measured for this sample.

When the data were displayed in a log frequency plot, Figure 3-2 was obtained. Curves A and B have been drawn through the series reactance and resistance data, respectively. Careful examination of these curves indicates three dielectric relaxation peaks. The main peak appears at a frequency of 21.8 Hz, which corresponds to a turnover frequency, ω_{\max} , of 136.9 radians per second, and to a relaxation time, τ , of 7.3 milliseconds. A second, well-developed relaxation peak appears at a frequency of 1.7 Hz, corresponding to a relaxation time of 93.4 milliseconds. A third relaxation peak appears to be anticipated at frequencies less than 0.01 Hz. In agreement with these observations, the R_s curve shows two definite dispersion regions.

A major emphasis in this work was to represent the process(es) responsible for the impedance or dielectric circular arc by a single time constant, rather than a distribution of time constants. Splitting of the data into 3 overlapping circular arcs will obviously yield three characteristic times, each representing one of the circular arcs, and hence characterize a given relaxation process.

The first dispersion, α_1 , appears at a frequency which coincides with the first and main relaxation peak in the series reactance. A second dispersion, α_2 , occurs at a frequency of 0.05 Hz, somewhat displaced from the second relaxation peak. A third dispersion may be anticipated at frequencies below 0.01 Hz. In conformity with the adopted notations in dielectric dispersion, we will reserve the symbol α for rock dielectric dispersion in the low-frequency range (below 10 kHz). The symbol β will be used for dispersions in the

Figure 3-1. Argand Circular-Arc Plot for Dresser Basalt

Figure 3-2. Dispersion of Impedance Components of Dresser Basalt and the Relaxation Time(s)

medium frequency range; i. e., between 10 kHz and 100 mHz. The symbol γ will be adopted for dispersions at frequencies beyond 100 mHz. Each of these dispersions may split into more than one subdispersion, such as the α_1 , α_2 , . . . etc., of the α -dispersion investigated in this project. Each of the discovered dispersions should correspond to a certain relaxation mechanism of a substructure or "structon" within the rock. Huggins and Huggins (Ref. 5) recommended the use of local structural groupings as the basic structural units. They used the term "structon" to signify a specific type of atom(s), with specific kinds and numbers of close neighbors.

IMPEDANCE PARAMETERS OF GRANITE

A sample of charcoal gray granite from St. Cloud, Minnesota, was supplied to Honeywell by personnel from the Thermal Fragmentation Group of the Twin Cities Mining Research Center. The sample analyzed (Ref. 4) 63.5 percent SiO_2 , 15.6 percent alumina, 4.1 percent CaO, 3.6 percent Na_2O , 3.6 percent K_2O , 4.2 percent CaO, 2.7 percent FeO, 1.8 percent Fe_2O_3 , and smaller quantities of manganese and titanium.

The impedance data of granite followed the same pattern as that of basalt, except that the semicircular arc was not easy to close at the low-frequency side. Resistive and reactive components for a cylindrical granite sample 0.148 cm in length and 3.67 cm^2 in cross-sectional area described a segment of a circular arc when plotted in an Argand diagram. Computer extrapolation of this arc to its point of intersection with the resistive axis yielded a value of 4.8×10^9 ohm (about 5 gigaohm) for R_0 . The preceding basaltic sample has an R_0 value of 16.4 megohm. If a basalt sample of the same dimension of granite had been used, its R_0 value would be

$$16.4 \left(\frac{0.148}{0.635} \right) \left(\frac{6.41}{3.67} \right) = 6.68 \text{ megohm}$$

The d-c resistance value, R_0 , as determined by extrapolation of the impedance vector to zero frequency, is therefore about seven hundred times higher for granite than for basalt of similar shape and dimension. This result is consistent with the fact that granite contains 30 percent more of the covalently coordinated, and hence nonconductive, silica tetrahedra. Basalt has more iron, calcium, and titanium, although somewhat less sodium and potassium than granite.

IMPEDANCE PARAMETERS OF QUARTZITE

Sioux quartzite, with a bulk density of $2.64 \text{ gram cm}^{-3}$, was used in the following experiments. The source location of this type of quartzite was Jasper, Minnesota. Its chemical analysis (Ref. 4) indicated 97.84 percent silica, 0.87 percent Al_2O_3 , 0.81 percent CaO , 0.25 percent FeO , and 0.27 percent Fe_2O_3 . As with granite, the impedance parameters of quartzite were very large, in the gigaohm range, at low frequencies. A quartzite disc sample of length 0.61 cm and cross-sectional area 18.8 cm^2 gave an extrapolated R_0 value of 4.5×10^9 ohms. When corrected to the same dimensions of granite, this value should be modified to

$$4.5 \times 10^9 \left(\frac{0.148}{0.61} \right) \left(\frac{18.8}{3.67} \right) = 5.6 \times 10^9 \text{ ohms}$$

Hence, the quartz d-c resistance is about 20 percent higher than that of granite, and about three orders of magnitude higher than that of basalt. Thus, it appears that the rock's impedance parameters are not only affected by the quantity of silica that it contains, but also by the quantities of volatile oxides within the rock.

Under given environmental conditions, impedance results changed markedly by changes in the rock humidity, despite the reasonable repeatability of impedance data obtained with a given rock sample. In particular, impedance measurements on quartzite were found to be extremely sensitive to ambient air moisture, which contributed a great deal to d-c drifts. With basalt and granite, the data were not as sensitive to room moisture as quartz, and it was possible to study the effect of humidity on their impedance parameters.

EFFECT OF HUMIDITY ON ROCK IMPEDANCE

The effect of moisture content has been examined with a basaltic sample (II) and the data are shown in Figure 3-3. Curve A in this figure was obtained with the rock sample as received from the customer; no attempt was made to control the rock environment. Curve B in Figure 3-3 was obtained when the basalt sample was baked with electrodes attached in a 110°C oven for 19 hours. After baking, the sample was immediately placed in an airtight desiccator and allowed to cool to room temperature for the following 24 hours. The resulting measurements indicated a significant increase in impedance at frequencies up to 500 Hz. Above 500 Hz, the humidity effect on impedance parameters is not very pronounced. While the R_0 value for the unbaked basalt was 16.4 megohm, the value determined when the rock was baked is about 45 megohm.

Chemical analysis of Dresser basalt (Ref. 4) indicated the presence of 0.14 percent water in the rock and a loss of ignition (LOI) of 2.26 percent. By contrast, the granite sample and the quartzite sample contained 0.11 and 0.08 percent water, respectively, and showed a loss on ignition of 0.59 and 0.32 percent, respectively. Upon ignition, not only water is lost, but some of the volatile oxides such as Na_2O and K_2O which are not bound in the silicate structure may also sublime. When these volatile oxides are attached to the nonvolatile silica tetrahedron, they are in the form of a solid solution of alkali silicate,

A - Rock at ambient room environment

B - Dry baked rock in desiccator

Figure 3-3. Effect of Moisture on the Impedance Semicircle of Basalt (II)

and the alkali will thereby be prevented from sublimation. A free alkali metal oxide unit in the rock will show a higher LOI ; will also be easily leachable with water, and thus will contribute significantly to the rock conductivity. Thus, the alkali content of a rock as shown by chemical analysis will not be the decisive factor in determining the rock conductivity; rather, the mode by which the alkali oxide enters the rock structure appears to play the predominant role. Because of its higher LOI, Dresser basalt appears to have more of the mobile sodium and potassium ions, which contributes greatly to its higher conductivity relative to granite and quartzite.

ELECTRODE EFFECTS IN IMPEDANCE MEASUREMENT

Measurement of electrical impedance by conventional, two-electrode techniques involves passage of a working current through the sample. At frequencies below 1 kHz, passage of current in the electrode-through-sample junction produces an interfacial phenomenon, which manifests itself as an additional frequency dependent electrode polarization impedance (Ref. 6).

The magnitude of electrode polarization impedance is generally inversely proportional to frequency or some power of frequency. Warburg electrochemical law (Ref. 7) is a special case in which this power is 0.5. In the four-electrode configuration, the current through the measuring electrodes can be minimized when they are properly designed with sufficiently large output impedance, and hence the electrode polarization artifacts can be minimized.

Shedlovsky (Ref. 8) attempted to eliminate electrode polarization by selecting different pairs of electrodes at different separations. Assuming constant polarization effects at each electrode, difference measurements can be made to determine the true sample impedance. At very low frequencies where electrode polarizations are severe, Shedlovsky's method may require finding differences of large numbers with resultant loss of accuracy.

ELECTRODE IMPEDANCE IN CYLINDRICAL ROCKS

Thin slices were cut from a long cylindrical rock sample. The same electrode material was applied to both sides of the rock sample (with the longer length d , and for the thinner rock sample whose length was d'). The total impedance measured with either rock sample is

$$Z_m = Z + Z_e \quad (3-1)$$

where Z_m is the measured impedance, Z is the true impedance of the rock, and Z_e is the electrode impedance. For the long example,

$$Z = \rho \left(\frac{d}{A} \right) \quad (3-2)$$

and for the thin sample,

$$Z' = \xi \left(\frac{d'}{A} \right) \quad (3-3)$$

where ξ is the rock impedivity and A is the electrode area. Impedivity ξ is the vector summation of resistivity ρ and specific reactance χ , thus

$$\xi = \rho + j\chi \quad (3-4)$$

By separating the real from the imaginary variables, identical relationships to those derived for Z_e will result for electrode resistance R_e and reactance X_e . Substituting from Equation (3-2) and (3-3) into (3-1), one obtains for the long sample

$$Z_m = \xi \left(\frac{d}{A} \right) + Z_e \quad (3-5)$$

and for the thin sample

$$Z_m' = \xi \left(\frac{d'}{A} \right) + Z_e \quad (3-6)$$

therefore,

$$\frac{Z_m - Z_e}{Z_m' - Z_e} = \frac{d}{d'} = \beta \quad (3-7)$$

where β is the ratio of the lengths of the two rock samples. Solving Equation (3-7) for Z_e , one obtains:

$$Z_e = \frac{\beta Z_m' - Z_m}{(\beta - 1)} \quad (3-8)$$

Separating Equation (3-8) into its real and imaginary parts gives

$$R_e = \frac{\beta R'_m - R_m}{(\beta - 1)} \quad (3-9)$$

and

$$X_e = \frac{\beta X'_m - X_m}{(\beta - 1)} \quad (3-10)$$

A thin slice of height 0.152 cm was cut from a basalt cylinder. The length of the remaining long cylinder was 4.08 cm. Hence, $\beta = 26.8$. Circular silver paste electrodes, each of area 3.75 cm^2 , were fastened to each side of the two cylinders. The impedance data measured on these two rock specimens are shown in columns 2, 3, 4, and 5 of Table 3-1. R_e and X_e calculated from these data with the aid of Equations (3-9) and (3-10) are given in columns 6 and 7 of Table 3-1.

By subtracting the data in columns 6 and 7 point by point from the corresponding measured impedance data, and multiplying each resulting number into (A/d) , the basaltic specific resistance, ρ , and reactance, χ , were calculated and recorded in columns 12 and 13 of Table 3-1.

A check on the validity of this technique was made by cutting a third section of the basalt sample with length 0.150 cm. Repeated measurements on this third sample gave data which agreed closely with those just reported. The specific impedance data for this third sample were calculated and found to be within a 1-percent error from those recorded in Table 3-1. This agreement supports the technique of correcting for the electrode-impedance artifacts and lends credence to the validity of our impedance measurements.

In nearly all the measurement in this report each rock sample was cut into two unequal lengths and the ratio β of the two lengths was accurately determined. The computer program was modified to automatically correct for electrodes by Equations (3-9) and (3-10) before the final data of ρ and χ were displayed.

In a similar manner, the electrode corrections for granite were applied and the data in Table 3-2 were obtained. The plots of the specific reactance χ against the specific resistance ρ at a series of frequencies for basalt, granite, and quartzite are shown in Figure 3-4. The impedivity of each of these three rocks expressed in (ohms x meter) is thus determined at frequencies between 1 and 2000 Hz.

Figure 3-4. Specific Impedance Parameters for: (A) Basalt; (B) Granite; and (C) Quartzite

SECTION IV
TRANSFORMATION OF COMPLEX IMPEDANCE DATA
TO COMPLEX PERMITTIVITY DATA

An important phase of this research has been concerned with the development of techniques for the extraction of the real and imaginary parts of the complex permittivity, ϵ^* , from their impedance counterparts, namely the imaginary and real parts of the electric impedance, Z .

The admittance vector, \vec{Y} , is defined as

$$\vec{Y} = G + j\omega C_p \quad (4-1)$$

where G is the conductance, ω is the angular frequency, and C_p is the parallel capacitance of the medium. Hence, admittance is conceptually related to parallel circuit components. In terms of this vector, one can define the admittivity, \vec{y} , of the medium by

$$\vec{I} = \vec{y} E = (\sigma + j\omega\epsilon') E \quad (4-2)$$

Admittivity, therefore, relates the current density vector, \vec{I} , to the scalar potential difference, E . If the medium is simulated by a simple parallel $R_p C_p$ combination, then the parallel resistance, R_p , would be inversely related to the rock conductance, G , and per unit volume to the rock conductivity, σ . The parallel capacitance, C_p , is similarly related to the dielectric permittivity (its real component ϵ'). In this report the dielectric constant, K , of the rock is defined as the ratio of its dielectric permittivity, ϵ , to the dielectric permittivity of free space, ϵ_r .

By contrast, the impedance vector, \vec{Z} , is related to the series resistance, R_s , and series reactance, X_s , of the medium; thus,

$$\vec{Z} = R_s + jX_s \quad (4-3)$$

Ohm's law may be written in terms of an impedivity vector, $\vec{\xi}$; thus,

$$\vec{I} \cdot \vec{\xi} = E \quad (4-4)$$

where $\vec{\xi} = \rho + j\chi$, ρ being the rock resistivity, and χ its specific reactance. Impedance is, therefore, defined as that vector whose dot product into the current vector yields the potential difference, a scalar quantity. Comparing Equations (4-1) and (4-3), and remembering that impedance is the inverse vector of admittance, it becomes apparent that both R_s and X_s are necessarily frequency dependent.

Rock impedance data are presented in terms of the series equivalent circuit parameters because these are the parameters that are easy to measure without previous commitment to an exact electrical analog or model to simulate the medium. In addition, the series parameters can elegantly display a circular arc in the Argand diagram when X_s is plotted as a function of R_s , both measured at the same frequency.

The parallel-to-series transformation with frequency-independent components of an R-C network provides the proof of the determined semicircular arc in the Argand diagram. This is explained in detail in Appendix A.

In the transformation of complex impedance to complex permittivity data for an ideal system (Debye case), the impedance vector for the system is given by Equation (4-3).

Assuming that the rock system can be represented by the simple $R_p C_p$ unit, one can use Equation (A4) in Appendix A and (4-3) to obtain

$$\begin{aligned}\bar{Z} &= \frac{R_s^2 + X_s^2}{R_p} + j \frac{R_s^2 + X_s^2}{X_p} \\ &= (R_s^2 + X_s^2) \left[\frac{1}{R_p} + j \frac{1}{X_p} \right]\end{aligned}$$

$$\therefore \bar{Z} = |Z|^2 [G_p + j\omega C_p] \quad (4-5)$$

For normalization purposes, one must use specific quantities for the rock system. This is achieved by multiplying both sides of Equation (4-5) into A/d , where A is the area of the electrodes attached to the rock and d is their distance apart. This will transform impedance to impedivity ξ ; thus,

$$\begin{aligned}\bar{\xi} &= |\xi|^2 \left[G_p \left(\frac{d}{A} \right) + j\omega C_p \left(\frac{d}{A} \right) \right] \\ &= |\xi|^2 [\sigma + j\omega \epsilon'] \\ &= j\omega |\xi|^2 [-j\kappa'' \epsilon_r + \kappa' \epsilon_r] \\ &= j\omega |\xi|^2 [\epsilon' - j\epsilon''] \\ &= j\omega |\xi|^2 \epsilon_r [\kappa'' - j\kappa']\end{aligned} \quad (4-6)$$

Here ϵ_r is the permittivity of free space (8.85×10^{-12} farad per meter), and the rock conductivity σ defines (Ref. 9) the imaginary part of the dielectric permittivity, ϵ'' , according to

$$\sigma = \omega \epsilon'' = \omega \kappa'' \epsilon_r \quad (4-7)$$

Using the complex dielectric permittivity, ϵ^* , as

$$\epsilon^* = \epsilon' - j\epsilon'' \quad (4-8)$$

and complex dielectric constant, κ^* , as

$$\kappa^* = \kappa' - j\kappa'' \quad (4-9)$$

Equation (4-6) becomes

$$\begin{aligned} \vec{\xi} &= j\omega |\xi|^2 (\epsilon' - j\epsilon'') \\ &= j\omega |\xi|^2 \epsilon^* \end{aligned}$$

Equation (4-10) gives the relation between the impedivity vector and the dielectric permittivity vector. Using the vectorial notation

$$\vec{\xi} = |\xi| e^{j\theta} \quad (4-10)$$

Into Equation (4-10) one obtains

$$\begin{aligned} \epsilon^* &= \frac{\xi}{j\omega |\xi|^2} = -\frac{j e^{j\theta}}{\omega |\xi|} \\ &= \frac{j^3 e^{j\theta}}{\omega |\xi|} \end{aligned} \quad (4-11)$$

Equation (4-11) signifies that the permittivity vector can be obtained from the impedivity vector by rotating the latter through $(3\pi/2)$ and dividing through $\omega |\xi|^2$. These operations are diagrammatically illustrated in Figure 4-1.

Figure 4-1. A. Transformation of parallel circuit with frequency independent parameters to isoimpedic series circuit gives a semicircle in the Argand diagram.
 B. Diagram to show rotation of impedance vector to give dielectric permittivity vector.

The conversion of impedivity data to complex permittivity data in a real system will be described in Section VII where a workable model for dielectric relaxation will be developed.

SECTION V
RESISTIVITY AND DIELECTRIC CONSTANT OF ROCKS

The principles presented in Section IV and implemented in Section VII to include real systems, were used to compute values for the dielectric constant of two basaltic rock samples and one quartzite rock from the experimentally measured impedance parameters.

Basaltic sample (III) was obtained in the form of a cylinder with diameter 2.17 cm. Thin slices that measured 0.30 and 0.61 cm in length were cut from this sample. The ratio A/d for the thinner slice was 0.1232 meter and for the thicker slice 0.0618 meter. The electrode impedances were calculated with the aid of Equations (3-9) and (3-10) for the two slices. The electrode impedances were subtracted point by point from the corresponding measured impedance values. The resulting data were then multiplied into (A/d) to give the specific resistance and reactance of basalt. Photostatic copies of the computer output for the two basaltic slices are shown in Tables 5-1 and 5-2.

Dielectric permittivity at each frequency was calculated by the procedure described in Section VII. The Cole-Cole plots resulting from these data are shown in Figures 5-1 and 5-3 for the 0.30- and 0.61-cm slices of basalt, respectively. These figures can be considered to be in satisfactory agreement within experimental error. The dielectric dispersion curves for basalt are shown in Figures 5-2 and 5-4 for the 0.30- and 0.61-cm slices of basalt. The relaxation times calculated from either the maximum in the loss factor, ϵ'' , or the inflection point in the ϵ' curve were found to be 16.6 and 13.4 milliseconds for the two basalt slices. Since the experimental measurements on both slices were completely independent of each other, the derived values of relaxation time are considered to be in reasonable agreement.

Table 5-1. Impedance and Dielectric Data on Basalt (III).

Figure 5-2. Dielectric Constant of Dresser Basalt as a Function of Frequency [(a) Real Part of Dielectric Constant, ϵ' ; (b) Imaginary Part, ϵ'']. Data on the 0.30-cm Slice; Relaxation Time, $\tau = 16.6$ msec.

Figure 5-3. Cole-Cole Plot of Dresser Basalt Data on 0.61-cm Slice

Figure 5-4. Dielectric Constant of Dresser Basalt as a Function of Frequency [(a) Real Part of Dielectric Constant, κ' ; (b) Imaginary Part, κ'']. Data on the 0.61-cm Slice; Relaxation Time, $\tau = 13.4$ msec.

Table 5-3 summarizes the impedivity and dielectric permittivity data on the two basalt slices. The d-c resistivity of basalt, ρ_o , is estimated as 1.27×10^8 and 1.00×10^8 ohmmeter for the thin and thick slices, respectively. These resistivity data appear to be internally consistent with each other and are in agreement with the value 1.26×10^8 ohmmeter reported in Parkhomenko (Ref. 10) monograph for dry basalt. The agreement is surprising in view of the anticipated differences between the Dresser basalt and Parkhomenko's most probably Russian basalt (origin not given). Table 5-3 also shows that the zero frequency dielectric constant of basalt is 1.77×10^3 and 1.50×10^3 for the thin and thick slices. The internal agreement in this case is also acceptable. Parkhomenko (Ref. 10) reports that at low frequencies of 10^2 to 10^4 Hz the dielectric constant may assume very large values (10^3 to 10^5).

Keller (Ref. 11) observed that the product of the dielectric permittivity at low frequency, ϵ_o , into the resistivity at low frequency, ρ_o , is nearly a constant characteristic of a particular type of rock. For rhyolite and basalt, the average value of $\rho_o \epsilon_o$ is 0.63 sec with the range of 19 values from 0.25 to 26 sec. Average values of this product varied from 1.4×10^{-3} for basic igneous rocks such as gabbro and chromite to 10.8 for the hematite ore from Minnesota, which contains appreciable quantities of electronically conducting materials. The data in Table 5-3 also show that the products $\rho_o \kappa'_\infty \epsilon_r$ and $\rho_\infty \kappa_o \epsilon_r$ are equal to the relaxation time for both the thin and thick samples of basalt.

Similar experiments to those performed on basalt were run on a cylindrical quartzite sample (II) of 2.22 cm diameter, 0.955 cm length, and an (A/d) ratio of 0.0406 meter. The computer output data on this sample are shown in Table 5-4. From the present data, one can calculate the d-c resistivity of quartzite, ρ_o , from the observed value R_o of 31737.9 megohm, thus

$$\rho_o = R_o \left(\frac{A}{d} \right) = 3.17 \times 0.041 \times 10^{10} = 1.29 \times 10^9 \text{ ohm-meter}$$

The relaxation time of this quartzite sample is also calculated to be 60.3 milliseconds. The real component of the dielectric constant at infinite frequency, κ'_{∞} , is determined as 5.29. Also, the real component of the quartzite dielectric constant at the time of zero frequency, κ'_0 , is found to be 3.95×10^3 .

Table 5-3. Electric and Dielectric Parameters of Dresser Basalt (III)

Parameter	0.30 cm Slice	0.61 cm Slice
dc resistivity, ρ_0 , ohm meter	1.27×10^8	1.00×10^8
infinite frequency resistivity, ρ_{∞} , ohm meter	1.06×10^6	1.01×10^6
model parallel resistance, R_p , ohm/(meter) ³	3.89×10^{14}	6.87×10^{14}
model capacitance, C_p , farad	1.3×10^{-5}	6.8×10^{-6}
relaxation time, τ , second	16.6×10^{-3}	13.4×10^{-3}
zero frequency dielectric constant, κ_0	1.77×10^3	1.50×10^3
infinite frequency dielectric constant, κ_{∞}	14.8	14.8
maximum dielectric constant, κ''_{\max}	4.6×10^2	4.2×10^2
$\rho_0 \kappa'_{\infty} \epsilon_r$, second	16.4×10^{-3}	13.1×10^{-3}
$\rho_{\infty} \kappa'_0 \epsilon_r$, second	16.6×10^{-3}	13.2×10^{-3}

SECTION VI
EFFECT OF WATER AND SODIUM HYDROXIDE PRETREATMENT
ON ROCK ELECTRIC AND DIELECTRIC PARAMETERS

The presence of underground water ahead of excavation can be detected in principal by electrical resistivity probes. A major emphasis of Honeywell's rock impedance research is to determine the impedance or dielectric parameter that exhibits the largest change in value by the presence of small quantities of entrapped water. To define these parameters, basaltic rock samples were subjected to planned water treatments. Their impedance and dielectric parameters were measured before and after these pretreatments, so that each sample acted as its own control standard.

Previous workers (Refs. 12 and 15) have shown that the resistivity of a rock completely saturated with saline is determined by the rock porosity to a first approximation. However, the pore spaces in a rock may not always be saturated with aqueous electrolytes. In oil reservoirs, for example, oil may partially replace water in the pore spaces. The presence of oil, natural gas, or air in the pore structure of a rock may increase the resistivity significantly over what it would be in a completely water-saturated rock.

Rock resistivity is greatly affected by the quantity of water present. Letting ρ be the bulk resistivity of the rock, ρ_w the resistivity of water as it actually exists in the pore space of the rock, and θ the rock porosity, then

$$\rho = \rho_w / \theta^n \quad (6-1)$$

This relationship is commonly known as Archie's law (Ref. 12). The exponent n is an empirically derived parameter characteristic of the texture of the rock. Its value varies from about 1.3 in loosely packed granular material to about 2.2 in well-cemented granular rocks (Refs. 13 and 14).

Pirson (Ref. 15) modified Archie's relationship by introducing a second empirical parameter, m , which multiplies the porosity term; thus,

$$\rho/\rho_w = m \theta^{-n} \quad (6-2)$$

The value of m varies from 0.6 to 1.3 in marine sedimentary rocks, and appears to be related to the texture of the rock. For rocks with less than 4 percent porosity, including dense igneous rocks and metamorphosed sedimentary rocks, $m = 1.4$ and $n = 1.6$. These expressions apply only when a rock is completely saturated with water. Keller (Ref. 16) observed that the resistivity of a rock increases proportionately to the inverse square of the fraction, S , of the pore space filled with water, provided the water which remains coats the grains uniformly. Accordingly, Archie's relationship becomes

$$\rho = \rho_w \theta^{-n} S^{-2} \quad (6-3)$$

Scott et al. (Ref. 17) used this relationship in the form

$$\sigma = \sigma_w \theta^n S^m \quad (6-4)$$

where σ is the rock conductivity, σ_w is the conductivity of the pore fluid at the same frequency, and the constants m and n are approximately equal to 2. The product of the fractional saturation of the rock, S , into the fractional porosity, θ , should yield the fractional water content of the rock, w . Under these conditions, Archie's law becomes

$$\sigma \approx \sigma_w \times w^2 \quad (6-5)$$

It should also be remembered that σ_w is approximately proportional to the salinity of the pore fluid.

WATER TREATMENT OF BASALT

To investigate the effect of rock water content on its electric properties, a series of experiments were performed with three slices of basalt. The slices were cut from the one long cylinder of basalt (III), hence they possessed the same diameter of 2.18 cm, but were of different lengths. Slices K_1 , K_2 , and K_4 were of lengths 0.956, 0.605, and 0.304 cm, respectively. The rock samples were pretreated simultaneously in distilled water for periods of 23 and 77 hours. After each soak, the rocks were dried in an 80°C oven for two hours, then cooled in a dessicator before the impedance circular arcs were determined.

Typical results on samples K_1 , K_2 , and K_4 before and after the water pretreatment are shown in Tables 6-1 to 6-9. These results show that R_0 decreased, after soaking the sample in water for 23 hours, to about one third of its value before soaking. Further soaking to 77 hours increased R_0 slightly, but it still remained smaller than the baseline value before water pretreatment. Typical values of R_0 for sample K_1 before water pretreatment, after 23 hours, and after 77 hours of pretreatment were 1031, 328, and 447 megohms, respectively. This same trend can be noticed in the results obtained with the rest of the basaltic rock samples.

By contrast, the dielectric constant at zero frequency, κ_0 , increased monotonally with increase in water soak time. Typical values of κ_0 were 1770, 60200, and 146000 before water soak, after 23 hours, and after 77 hours of water pretreatment, respectively. The infinite frequency parameters R_∞ and κ_∞ did not change significantly with the water pretreatments. Furthermore, the impedance arc plots were very close and actually tangential to each other down to a frequency of 300 Hz. Below that frequency, the arcs began to separate from each other following each water soak. Typical data on sample

K1 are given in Table 6-10. The significant conclusion indicated by these results is that the highest sensitivity for water detection in rocks can only be achieved by data extrapolation to the static or zero frequency dielectric constant.

Table 6-10. Effect of Water Pretreatment on Selected Electric and Dielectric Parameters of Basalt

Parameter ↓ \ Soak Time (Hours) →	0 (Baseline)	23	77
R_o , megohm	1,031.0	328.0	447.0
τ , millisecond	16.6	24.4	29.6
$\epsilon_o \epsilon_r = \kappa_o$	1,770.0	60200.0	146000.0
$\epsilon_\infty \epsilon_r = \kappa_\infty$	14.8	68.2	60.7

The highest selectivity for water detection is obtained by choosing the real component of the dielectric constant at the limit of zero frequency from among the impedance and the dielectric parameters.

The variations of the impedivity vectors for three basalt samples with frequency are shown in Figure 6-1. After the three rocks were soaked for 23 hours in distilled water, their impedivity variation with frequency are shown by the curves in Figure 6-2. Figure 6-3 gives the same relationships for the rocks following a 77-hour soak period.

Here again, the impedivity vectors are the most separated at low frequencies, and approach each other as the frequency increases.

The variation of rock impedivity at 1 Hz with the duration of water pretreatment is shown in Table 6-11 and Figure 6-4 for the three basalt rocks.

Figure 6-1. Variation of Impedivity with Frequency for an Untreated Basalt Sample

Figure 6-2. Variation of Impedivity with Frequency for Basalt Samples Following a 23-hour Water Soak

Figure 6-3. Variation of Impedivity with Frequency for Basalt Samples Following a 77-hour Water Soak

Figure 6-4. Variation of Rock Impedivity with the Duration Time of Water Treatment for Three Samples of Basalt

Generally speaking, the impedance versus time-of-soaking decreases initially, goes through a minimum, and increases again with longer soak times. This behavior is explainable by the assumption that the first portions of water that diffuse through the rock pores leach the adjacent sodium and potassium ions, and thus decrease the rock impedance. Further introduction of water into the pores will begin to leach out the dissolved alkali ions, thus resulting in an increase in rock impedance.

Table 6-11. Effect of Water Soaking on Impedivity of Basalt at 1 Hz

Time of Soaking (hours)	Impedivity at 1 Hz, megohm x cm		
	K ₁	K ₂	K ₄
0	58	48	39
23	11	19	27
77	50	41	32

PRETREATMENT OF BASALT IN SODIUM HYDROXIDE

To further investigate the effects of environmental conditions on rock impedivity, other series of tests were conducted on basalt that had been pretreated in solutions of sodium hydroxide. The three samples K₁, K₂, and K₄ of basalt were soaked for 23 hours in 1, 5, and 10 percent solutions of sodium hydroxide in water. The impedance data of these experiments were grouped with those obtained while soaking the same rock samples in distilled water (zero percent NaOH) for 23 hours. Computer output data of these experiments are given in Tables 6-12 to 6-20. Variations of the magnitude of impedivity vector with frequency as a result of the various soaking solutions are shown in Figures 6-5, 6-6, and 6-7. Here again, the impedance arcs for various NaOH concentrations seem to overlap and become indistinguishable at frequencies greater than 100 Hz.

Table 6-12. Computer Output for Electric and Dielectric Data of Basalt Sample K₁ Pretreated in 1% NaOH for 23 Hours

Figure 6-5. Variation of Impedivity with Frequency for the Basalt Samples after 23-hour Pretreatment in 1% NaOH

Figure 6-6. Variation of Impedivity with Frequency for Basalt Samples Following a 23-hour Pretreatment in 5% NaOH

Figure 6-7. Variation of Impedivity with Frequency for Basalt Samples Following a 23-hour Pre-treatment in 10% NaOH

The effect of sodium hydroxide concentration on the impeditivity at 1 Hz for the three basaltic rocks is shown by the data in Table 6-21.

The plot of impeditivity against the concentration, c , of sodium hydroxide in the pretreating solution is shown in Figure 6-8. Apparently, impeditivity decreases exponentially with the electrolyte concentration following an equation of the form

$$\xi = \xi_0 e^{-\lambda c}$$

Table 6-21. Effect of Pretreatment in NaOH for 23 Hours

Conc. of NaOH	Impeditivity at 1 Hz, Megohm cm		
	K_1	K_2	K_4
0	11.0	19.0	27.0
1	7.0	9.0	16.5
5	7.4	5.0	3.5
10	2.4	0.9	1.8

The plots of $\log \xi$ against c for the three basalt cylindrical rocks are shown in Figure 6-9. The slopes of the lines in this figure allow a determination of the constant λ for each cylindrical rock. Table 6-22 gives these straight-line parameters.

It is interesting to note from these limited number of data points that the coefficient λ decreases linearly with increasing rock length, providing that the rocks are of the same cross sectional area. The variation of λ with d is shown in Figure 6-10 and indicates a significant dependence of the rock impeditivity decay constant due to electrolyte impregnation with the length of the rock samples.

EFFECT OF WATER SOAKING ON QUARTZ ELECTRIC PARAMETERS

Three quartz (II) disc samples were cut from one cylinder with lengths 0.31, 0.61, and 0.92 cm and are designated M1, M2, and M3, respectively. These samples had a cross sectional area over length (A/d) ratio of 0.122, 0.061, and 0.041 meter, respectively. The samples were pretreated in distilled water, once for 24 hours and another time for 75 hours. After each pretreatment, the rock was dried in an 80°C oven for two hours before the electrodes were applied and measurements were taken. Computer output data pertaining to the untreated and water-treated quartz are shown in Tables 6-23 to 6-31.

The variation of the untreated quartz impedivity with frequency is shown in Figure 6-11. Following a 24-hour soak, the same quartz samples gave the impedivity frequency relationships shown in Figure 6-12. When the soaking time was prolonged to 75 hours, the quartz impedivity changed with frequency according to the curves of Figure 6-13.

Figure 6-11. Variation of Impedivity with Frequency for the Untreated Quartz Samples

Figure 6-12. Variation of Impedivity with Frequency for the Quartz Following 24-hour Soak

Figure 6-13. Variation of Impedivity with Frequency for the Quartz (II) Following 75-Hour Soak

The electric and dielectric parameters that exhibit the most significant change with water treatment are chosen and given in Table 6-32. It is noted that the resistivity at zero frequency (dc resistivity), ρ_0 , decreases by about three orders of magnitude by mere soaking in water. This explains the frequent difficulties experienced in working with quartz where the output was often very unstable and exhibited considerable d-c drift, apparently due to slight changes in environmental humidity. The decrease in quartz resistivity with duration of soaking time is illustrated by the curves in Figure 6-14. The d-c resistivity of dry quartz was 8.36×10^{10} , 7.55×10^{10} , and 7.13×10^{10} ohm·cm for the three samples, with an average of 7.68×10^{10} ohm·cm. The water-treated samples exhibited larger variability in resistivity. In addition, prolongation of water treatment beyond 24 hours produced little variation in ρ_0 , except for the thinnest sample M1 where a slight increase in ρ_0 occurred at larger soaking times. This is suggestive of the leaching out of the conductive ions by prolonged soaking, a phenomena which should occur more readily with thinner rock samples.

Figure 6-15 shows the variation of the dielectric constant at the limit of zero frequency, K_0 , with soaking time. For quartz the decrease in dielectric constant with soaking time is much smaller than the decrease in resistivity. The decrease was nearly linear except for the thinner sample M1, where K_0 appeared to increase with increased soaking time after reaching a minimum at about 40 hours.

The foregoing experiments were planned to illustrate the effects of rock water content and alkali (mobile) ion content on the rock electric and dielectric properties. The experiments suggest a choice of certain electric or dielectric parameters that respond the most by change in water or alkali content. Further experiment should be done with shorter pretreatment times to show whether the chosen parameters can indeed be used to measure the quantity of water retained in the rock. The experiments described in this section are, therefore, illustrative in nature and by no means quantitative. Developments

of procedures to measure the water content in rocks, while not the intent of this research, can nevertheless be improved by choice of the optimum electric or dielectric parameter; i. e., the one that exhibits the highest sensitivity to the presence of water or sodium ions. This research shows beyond doubt that the zero-frequency parameters (dc or those extrapolated from measurements at low frequencies) are the most sensitive ones, while the high-frequency parameters show little or no variation by presence of water or mobile sodium ions.

SECTION VII
MODELS TO SIMULATE THE ELECTRIC
AND DIELECTRIC ROCK BEHAVIOR

This section is concerned with the mathematical description of physical models selected to describe the experimentally obtained electric and dielectric data on rocks.

Conventional models, such as the one by Debye (Ref. 18) and K. W. Wagner et al (Ref. 19), have been able to explain many fundamental characteristics of molecular behavior. They do, however, fail to explain the dielectric characteristics of complex systems such as rocks. For the interpretation of data obtained during this study, a mathematical model will be introduced that is able to explain many of the rock impedance characteristics. A method of converting the impedance data into the complex permittivity data is also treated in detail.

In principle, it is always possible to simulate the impedance and dielectric behavior of many real systems, rocks included, by circuits composed of frequency-independent parameter components. An impedance whose frequency dependence is given by

$$Z = r_2 + \sum_i \frac{R_{p(i)}}{1 + j(\omega\tau_i)^{1-\alpha}} \quad (7-1)$$

establishes a circular arc in the complex impedance plane (Argand diagram). In this equation, r_2 is the impedance at infinite frequency (equal to the resistance then, since any capacitive reactance will vanish and the presence of inductive reactance is not anticipated), $R_{p(i)}$ is the i^{th} component representing a difference between the zero and infinite frequency resistances, τ_i is a

constant with the dimensions of time (relaxation time for the i^{th} component or subprocess), and α is a constant between 0 and 1, but less than 1.

The impedance circular arc subtends an angle, 2φ at the center, such that $\varphi = \frac{\pi}{2}(1-\alpha)$. For a rock system, the angle φ is called the rock phase angle.

From Equations (7-1) and (4-1), and with the assumption of an α of zero, we can separate the real and imaginary parts of the impedance to:

$$R_s = r_2 + \sum_i \frac{R_{pi}}{1 + (\omega\tau_i)^2}, \quad X_s = \sum_i \frac{\omega\tau_i R_{pi}}{1 + (\omega\tau_i)^2} \quad (7-2)$$

The relationship between X_s and R_s can be shown to describe a semicircle.

These equations can also be represented by a plot of X versus $\log \omega$ or $\log f$. This representation is of particular value in determining the magnitude and frequency of the maximum value of X (turnover frequency). Equation (7-2) predicts that the maximum value of X is $R_p/2$, while the relaxation-time is found from the frequency of the maximum, ω_{max} , thus

$$\tau = \frac{1}{\omega_{\text{max}}} = \frac{1}{2\pi f_{\text{max}}} \quad (7-3)$$

Impedance data for rocks have been found to describe a circular-arc plot when displayed in an Argand diagram with the series reactance as ordinate and the series resistance as abscissa. The display is never a full semicircle, but is a part of a circle whose center does not lie on the real axis (resistance), and is substantially below it. The phase angle is defined as half of the angle, subtended by the circular-arc at the center of the circle, i. e., between the two radii of the circle defining the two points of intersection of the arc with the resistive axis.

An ideal dielectric dispersion model (Debye Model) is easily simulated by a parallel RC unit, and can be shown to give a full semicircular plot upon transformation to an isoimpedic series RC unit.

Sinbel (Khalafalla) (Ref. 20) derived various analytical proofs of the semicircular arc in an attempt to describe the relationship of the equivalent series reactance to the corresponding resistance. The derivations were based on a parallel-to-series transformation of electrical models with a single time-constant. In the simplest case, it was shown that the transformation from a parallel RC unit (with frequency independent components) to an adjustable series RC unit (with the same total impedance) results in a full arc plot in the Argand diagram. The locus of the series reactance, X_s , when plotted against the series resistance, R_s , follows the analytical equation of a circle of radius, $\frac{1}{2} R_p$, where R_p is the parallel resistance assumed to be a constant quantity characteristic of the system, thus

$$X_s^2 + [R_s - \frac{1}{2} R_p]^2 = \frac{1}{4} R_p^2 \quad (7-4)$$

The center of the semicircular plot should then have the coordinates $(0, \frac{1}{2} R_p)$ and hence is located on the real or resistive axis. This seems to represent a very idealized situation. In real systems the semicircular arc observed experimentally is usually translated vertically downwards so that its center has the coordinates $(n$ and $-m)$ and accordingly follows an equation of the form

$$[X_s + m]^2 + [R_s - n]^2 = a^2 \quad (7-5)$$

where m , n , and a are constants related to X_p and C_p .

An electrical model with a single time constant will be developed to account for the experimentally observed electrical data of rocks. The model will also permit a determination of the dielectric data of rocks. In addition, the introduced model allows one to select the parameters that are strongly

influenced by rock conditions, such as the inclusion of water, mobile ions, entrapped gases, pores, and cracks; etc.

ELECTRICAL ANALOG WITH ONE FREQUENCY DEPENDENT RESISTANCE

An electrical model, Figure 7-1, in which a frequency dependent resistance, r_1 , is shunted across the condenser, C_p , is capable of describing a circular arc in the series domain with a vertically displaced center (Figure 7-2). A condition to be imposed on the resistor, r_1 , is that its value changes inversely with the frequency such that $r_1 = \frac{g}{f}$, where g is a constant and f is the frequency. The total impedance of this model is given by

$$\begin{aligned}
 Z_p &= \frac{R_p \frac{jr_1 X_p}{r_1 + jX_p}}{R_p + r_1 + jX_p} + r_2 \\
 &= \frac{r_1 R_p X_p^2 (r_1 + R_p)}{r_1^2 R_p^2 + X_p^2 (r_1 + R_p)^2} + j \frac{r_1^2 R_p^2 X_p}{r_1^2 R_p^2 + X_p^2 (r_1 + R_p)^2} + r_2 \quad (7-6) \\
 &= R_s + jX_s.
 \end{aligned}$$

From which one obtains

$$R_s = r_2 + \frac{r_1 R_p X_p^2 (r_1 + R_p)}{r_1^2 R_p^2 + X_p^2 (r_1 + R_p)^2} \quad (7-7)$$

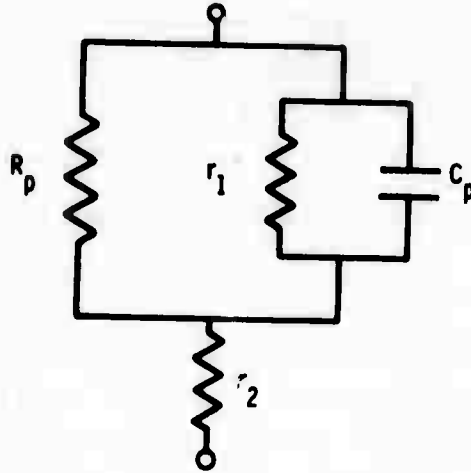

Figure 7-1. Electrical Model That Produces a Circular Arc Plot

Figure 7-2. Circular Arc Plot Between Equivalent X_s and R_s of the Model

and

$$X_s = \frac{r_1^2 R_p^2 X_p}{r_1^2 R_p^2 + X_p^2 (r_1 + R_p)^2} \quad (7-8)$$

Taking the following representative values for the electrical parameters,

$$R_p = r_2 = 300 \text{ ohm}$$

$$C_p = 1 \text{ microfarad}$$

$g = 150,000 \text{ ohm per second}$, such that $r_1 = \frac{g}{f} = 300 \text{ ohm}$ at a frequency of 500 Hz, one is able to calculate values for R_s and X_s at various frequencies. These calculations are given in Table 7-1.

Table 7-1. Equivalent Series Resistance and Reactance for Electrical Model of Figure 7-1

f (Hz)	r_1 (ohm)	X_p (ohm)	R_s (ohm)	X_s (ohm)
0	150,000	159,000	599	0.6
10	15,000	15,924	594	5.4
100	1,500	1,592	544	38.3
300	500	531	467	58.9
500	300	318	423	57.8
700	214	227	396	52.8
1,000	150	159	372	45.1
10,000	15	16	308	7.1

The plot of X_s against R_s as shown in Figure 7-2 is found to describe a circular-arc with a depressed center and whose boundary values satisfy the limiting values required by the electrical model of the circuit in Figure 7-1. Thus, at infinite frequency, both r_1 and X_p become zero, and the total impedance of the network equals r_2 ; i. e., 300 ohm. The first intersection point of the circular-arc with the R_s axis is also found to be 300 ohm. At zero frequency, the limiting impedance of the network becomes $(R_p + r_2) = 600$ ohm.

It appears, therefore, that the electrical model of Figure 7-1 gives a realistic analog to a system displaying a circular-arc plot in the Argand diagram. The limits of the rock impedance at zero frequency would be given by $(r_2 + R_p)$ and, at infinite frequency, by r_2 . A direct estimation of r_2 and R_p is thus possible by extrapolating the circular-arc to intersect the real axis. The unusual resistor in this model is $r_1 = \frac{g}{f}$, where g is a constant given by

$$g = \frac{1}{2\pi K C_p} \quad (7-9)$$

where K is a constant related to the phase-angle, and C_p is the frequency independent rock capacitance which can be taken as a constant.

The rock phase-angle, ϕ , would only be dependent on the values of C_p and r_1 and, since these two components are in parallel, then

$$\phi = \tan^{-1} \left(\frac{r_1}{X_p} \right) = \tan^{-1} \left(\frac{1}{K\omega C_p} \bigg/ \frac{1}{\omega C_p} \right) = \tan^{-1} \left(\frac{1}{K} \right) \quad (7-10)$$

and, hence,

$$K = \cotan \phi, \text{ or } \phi = \cotan^{-1} K. \quad (7-11)$$

The angle, ϕ would also be identical with the experimentally measured phase-angle between the vertical through the semicircular-arc center and the line joining it to either of its intercepts with the real axis. Thus, experimentally determining the rock phase-angle, ϕ , in each individual case would enable a determination of the constant K required to calculate r_1 .

To calculate the turnover-frequency, one can make use of the fact that it is the characteristic frequency which maximizes X_s . Upon differentiating Equation (7-8) for X_s with respect to ω , it is possible to derive (see Appendix B) that the turnover frequency is given by

$$f_{\max} = \frac{1}{2\pi R_p C_p \sqrt{1 + K^2}} \quad (7-12)$$

Despite its unusualness for being "electrically unrealizable," the suggested model of Figure 7-1 provides a mechanism for explaining the observed results; i. e., a circular arc with a depressed center in the Argand diagram relating X_s to R_s . Previous literature on electrode polarization had often revealed many such unusual electrical components, similar to r_1 , in the model. Warburg (Ref. 7) stated that the electrochemical polarization resistance is inversely proportional to the square root of frequency; thus

$$R_m = R + \frac{g}{\sqrt{f}} \quad (7-13)$$

where R_m is the measured resistance, R is the true electrolytic resistance, and g is the polarization resistance at a frequency, f , of 1 Hz. Fricke (Ref. 21) had also proposed a capacitance for cell membranes that changes as a power function of frequency.

CONVERSION OF IMPEDITIVITY DATA TO COMPLEX PERMITTIVITY IN A REAL SYSTEM

This subsection is concerned with a method of transforming the experimentally obtained electrical data (Argand diagram) into complex permittivity (Cole-Cole diagram). The technique used here invokes a single relaxation for both the circular arc plots in the Argand and Cole-Cole diagrams, and will be denoted as a "bracketing" technique. This method relates the boundary points for both the impedance and dielectric circular arcs with one characteristic relaxation time. Previous investigators (Refs. 19, 22, 23, and 24) used a distribution of relaxation times to account for dispersion in a real system. Unlike our electrical model, a mathematical distribution of time constants cannot provide a one-to-one correspondence between rock characteristics and their electrical parameters.

The relaxation time for a dielectric dispersion process following the Maxwell-Wagner mechanism is related to the volume resistivity by the following equation given in Vera Daniel's monograph (Ref. 25).

$$\tau = K \epsilon_r \rho \quad (7-14)$$

where ρ is the volume resistivity defined by

$$R = \rho \left(\frac{d}{A} \right), \quad \text{or } \rho = R \left(\frac{A}{d} \right) \quad (7-15)$$

At the two boundary points of infinite and zero frequency, respectively, the application of Equation (7-14) with the provision that the value of ϵ decreases with increasing frequency, leads to

$$\tau = \epsilon_{\infty} \rho_0 = \epsilon_{\infty} R_0 \left(\frac{A}{d} \right) \quad (7-16)$$

Also,

$$\tau = \epsilon_0 \rho_\infty = \epsilon_0 R_\infty \left(\frac{A}{d} \right) \quad (7-17)$$

This is justified under the assumption of a single relaxation time.

The dielectric permittivity at infinite and zero frequency can therefore be calculated from

$$\epsilon_\infty = \left(\frac{\tau}{R_0} \right) \left(\frac{d}{A} \right) \quad (7-18)$$

and

$$\epsilon_0 = \left(\frac{\tau}{R_\infty} \right) \left(\frac{d}{A} \right) \quad (7-19)$$

Both R_0 and R_∞ can be determined from the experimental impedance circular arc as the points of furthest and nearest intersection with the real axis. The relaxation time, τ , can be determined from the experimental impedance data by the maximization of X_g with $\log f$. The maximum reactance appears at a frequency, f_{\max} , such that

$$\omega_{\max} \tau = 1, \text{ or } \tau = \frac{1}{\omega_{\max}} = \frac{1}{2\pi f_{\max}} \quad (7-3)$$

The relaxation time can also be estimated in terms of the model parameters. A detailed derivation (given in Appendix B) leads to

$$\tau = (R_0 - R_\infty) C_p \sqrt{1 + \cotan^2 \varphi} \quad (7-20)$$

where φ is the rock phase angle derived from the impedance diagram as follows:

$$\varphi = \sin^{-1} \left[\frac{R_0 - R_\infty}{2r} \right] \quad (7-21)$$

where r is the radius of the circle whose arc represents the Argand diagram.

The Cole-Cole parameter (Ref. 24), α , is related to the phase angle, φ , as follows:

$$\varphi = \frac{\pi}{2} (1 - \alpha) \quad (7-22)$$

In the ideal case of a Debye dielectric, $\varphi = \frac{\pi}{2}$ and $\alpha = 0$. In general, α is a fraction, usually close to 0.5.

The capacitance, C_p , needed in Equation (7-20) for calculating the relaxation time can be obtained from the impedance data combining Equations (7-7) and (7-8) leads to the result:

$$C_p = \frac{-X_\omega}{\omega \left[(R_\omega - R_\infty)^2 + X_\omega^2 \right]} \quad (7-23)$$

In practice, the plot of C_p as a function of frequency shows a sharp decrease between 0.01 and 100 Hz, which is followed by a plateau between 100 Hz to 2000 Hz. The average value of this plateau is considered to represent C_p .

The capacitance C_p can also be determined from Equation (7-20) by using the model-independent value of relaxation time, τ , from Equation (7-3), and R_0 , R_∞ , and ω from the experimental data. It was noted that τ determined by the maximization of X_g (7-3) was in close agreement with that determined from the model equations (7-20).

Using the phenomenological equations of the complex dielectric permittivity given by Cole and Cole (Ref. 22) and in V. Daniel monograph (Ref. 25) as

$$\epsilon^* = \epsilon_\infty + \frac{\epsilon_0 - \epsilon_\infty}{1 + (j\omega\tau)^{1-\alpha}} = \epsilon' - j\epsilon'' \quad (7-24)$$

Equation (7-24) is separable into its real and imaginary parts using the identity:

$$j^\alpha = e^{\frac{j\pi}{2}\alpha} \quad (7-25)$$

to give

$$\epsilon' = \epsilon_\infty + \frac{\epsilon_0 - \epsilon_\infty}{2} \left[1 - \frac{\sinh(1-\alpha)s}{\cosh(1-\alpha)s + \cos\left(\frac{\alpha\pi}{2}\right)} \right] \quad (7-26)$$

and

$$\epsilon'' = \frac{\frac{1}{2}(\epsilon_0 - \epsilon_\infty) \cos\left(\frac{\alpha\pi}{2}\right)}{\cosh(1-\alpha)s + \sin\left(\frac{\alpha\pi}{2}\right)} \quad (7-27)$$

where s is given by

$$s = \log_e(\omega\tau) \quad (7-28)$$

The plot of $\epsilon''(\omega)$ (or $\kappa'' = \epsilon''/\epsilon_r$) as a function of $\epsilon'(\omega)$ (or $\kappa' = \epsilon'/\epsilon_r$) as calculated from Equations (7-26) and (7-27) gives the Cole-Cole diagram.

The necessary operational steps in accordance with the foregoing equations were, therefore, added to the computer algorithm to extract the dielectric permittivity data from the specific impedance parameters. Provision for correcting the measured impedance parameters for electrode effects was also included in the program. Note that the calculations of dielectric parameters according to this procedure can be made independently of any assumed model. All the needed quantities R_0 , R_∞ , ρ , and τ are obtained experimentally. The proposed model in this section can, however, be used to calculate τ according to Equation (7-20).

EVALUATION OF THE MODEL PARAMETER,
 r_1 , FOR BASALT

The model transformation equations from the parallel to the series domain were used to solve for r_1 of Figure 7-1 (with no condition imposed on its frequency dependence). At each frequency, r_1 was calculated from the measured values of X_s and R_s at that frequency.

Combining Equations (7-7) and (7-8), one obtains

$$\frac{R_s - r_2}{X_s} = \frac{X_p (r_1 + R_p)}{r_1 R_p} = \frac{X_p}{(r_1 // R_p)} \quad (7-29)$$

$$\begin{aligned} X_s X_p &= (R_s - r_2) (r_1 // R_p) \\ &= \frac{(R_s - r_2) (r_1 R_p)}{(r_1 + R_p)} \end{aligned} \quad (7-30)$$

$$\text{and } X_p = \frac{(R_s - r_2) (r_1 R_p)}{X_s (r_1 + R_p)}$$

Substituting the value of X_p from (7-30) into (7-8), one obtains

$$X_s = \frac{r_1 R_p X_s (R_s - r_2)}{(r_1 + R_p) [X_s^2 + (R_s - r_2)^2]} \quad (7-31)$$

Hence,

$$r_1 R_p (R_s - r_2) = (r_1 + R_p) X_s^2 + (R_s - r_2)^2 \quad (7-32)$$

Solving (7-32) for r_1 , one obtains

$$r_1 = \frac{R_p [X_s^2 + (R_s - r_2)^2]}{R_p (R_s - r_2) - X_s^2 - (R_s - r_2)^2} \quad (7-33)$$

One can also calculate X_p at all frequencies by combining Equations (7-31) and (7-30), thus

$$X_p = \frac{X_s^2 + (R_s - r_2)^2}{X_s} = -\frac{1}{\omega C_p}$$

and hence

$$C_p = \frac{-X_s}{\omega [X_s^2 + (R_s - r_2)^2]} \quad (7-23)$$

Equations (7-23) and (7-33) were used to calculate r_1 and C_p for all the rocks studied in the pretreatment experiments of Section VI. An equation of the form

$$r_1 = g/f^n \quad (7-34)$$

was assumed for each of the basalt samples. At each frequency, f , the resistance r_1 was calculated from the X_s and R_s values measured at that frequency. A least-squares fit using Equation (7-34) was performed on these data points. Table 7-2 presents a summary of the values of g and n computed for each basalt sample in the dry state and after being subjected for various pretreatment conditions.

Table 7-2. Basalt Parameters of the Equation $r_1 = g/f^n$

Sample → Basalt Rock State ↓	K ₁		K ₂		K ₄	
	g	n	g	n	g	n
Basalt (dry)	3626	0.474	2375	0.634	2048	0.704
Following 23 hour soak in water	5016	0.778	2331	0.554	2018	0.635
Following 77 hour soak in water	4775	0.782	2404	0.745	1517	0.741
Following treatment in 1% NaOH	4817	0.778	3333	0.772	2422	0.794
Following treatment in 5% NaOH	4022	0.735	2933	0.735	2159	0.779
Following treatment in 10% NaOH	3222	0.734	2344	0.670	1831	0.745
Average n	0.713		0.685		0.733	
Standard deviation in n	0.109		0.075		0.052	

Examination of the r_1 values in Equation (7-34) for the obtained data shows a systematic variation in the value of g with both the basaltic rock sample and its pretreatment history. Except for dry basalt, the constant n appears to be independent of the rock size or the presence of water or mobile sodium ions. For basalt, an average n value of (0.71 ± 0.08) may be concluded from the present data.

Variation of the parameter g for basalt with the percentage of sodium hydroxide, c , in the pretreating solution is illustrated by the curves in Figure 7-3. The pretreatment time was 23 hours, and pretreatment in distilled water for the same period was taken to represent zero percent sodium hydroxide. In

Figure 7-3. Variation of the Basalt Constant g with the Percentage of Sodium Hydroxide in the Pretreating Solution. Pretreatment Time = 23 Hours

Figure 7-4. Effect of Length of Rock Cylinder on the Parameter g

general, g decreases linearly with increasing sodium content, except for the thinner rock samples K_2 and K_4 where a slight increase in g is observed between 0 and 1 percent sodium hydroxide. Linear least-square fitting of the data gives the following relationships:

For basalt sample K_1

$$g = 4989 - 180C \quad (7-35)$$

For basalt sample K_2

$$g = 2885 - 37.5C \quad (7-36)$$

For basalt sample K_4

$$g = 2249 - 35.4C \quad (7-37)$$

Systematic variations of the parameter g with the rock dimension are also evident from the data in Table 7-2. The variation of g with thickness of the basaltic rock cylinders is shown in Figure 7-4. The data indicate a systematic increase in g with increasing rock thickness.

CORRELATION OF IMPEDANCE POLARIZATION ARTIFACTS WITH THE MODEL

Electrode polarization effects have been found to constitute an integral part in impedance measurements. Polarization effects are simulated by the model resistor $r_1 = g/f^n$, which is parallel with the $R_p C_p$ unit that represents the dielectric in Figure 7-1. The presence of r_1 in the model accounts for the observed deviation from the ideal or Debye dielectric behavior, and hence for the observance of a circular arc with a depressed center, rather than the Debye full semicircle in the Argand diagram.

When various basalt samples were pretreated in solutions of sodium hydroxide of various concentrations for a period of 23 hours, the polarization parameter, g , was found to decrease nearly linearly with increasing concentration of the sodium ion. It also decreases systematically with decreasing rock thickness. The exponent, n , on the other hand appears to be independent of the rock condition, dimension, or pretreatment history.

The foregoing findings suggest that most of the polarization effects reside in the electrical double layer at the rock/electrode interfacial contact. The mobile sodium ions are expected to influence the structure, and hence the relaxation properties of this double layer. Remembering that r_1 is in parallel with the dielectric model of Figure 7-1, it can be appreciated that polarization will be stronger at smaller values of r_1 (or g); i. e., in the presence of larger sodium ion contents.

CORRELATION OF r_1 WITH THE WARBURG POLARIZATION

The suggested model of Figure 7-1, with its unusual resistor r_1 , provides a useful mechanism for explaining the observed results; i. e., the appearance of a circular arc with a depressed center in the Argand diagram relating the series reactance, X_s , to the series resistance, R_s (both measured at the same frequency). Electrochemical literature had often revealed many such unusual electrical components to account for electrode polarization effect. The Warburg electrochemical formula (Equation 7-13) suggests that the electrolytic polarization resistance is inversely proportional to the square root of frequency.

To explore the polarization significance of r_1 , the data on dry basalt (Table 6-1) were examined in some detail. The variation of r_1 for dry basalt with $1/\sqrt{f}$ yielded a curvilinear plot, as shown in curve "a" of Figure 7-5. The points at frequencies larger than 100 Hz (the initial segments of curve "a" at $1/\sqrt{f}$ less

than 0.1) appear to represent a straight line. This tangential line (curve "b" of Figure 7-5) has a slope of 2509 and is taken to represent the Warburg resistance for dry basalt.

$$r_w = \frac{g_1}{\sqrt{f}} = \frac{2509}{\sqrt{f}} \quad (7-38)$$

The Warburg line (curve "b") was extrapolated to very low frequencies and subtracted point by point from curve "a". The resulting "difference curve" was concave as shown in curve "c" of Figure 7-5. When the data on curve "c" were plotted as a function of $1/f$, straight line "d" in Figure 7-5 resulted. A new resistance, $r_k = g_2/f$, is therefore assumed to describe the polarization at very low frequencies. The slope of line "d" for the variation of this new resistance with $1/f$ gives a value of 4032 megohm Hz for g_2 of dry basalt.

The unusual resistor, r_1 , appears to be analytically composed of two polarization terms, one of which is the Warburg resistance; thus,

$$\begin{aligned} r_1 &= r_w + r_k \\ &= \frac{g_1}{\sqrt{f}} + \frac{g_2}{f} = \frac{g}{f^n} \end{aligned} \quad (7-39)$$

For dry basalt

$$r_1 \text{ (megohms)} = \frac{2509}{\sqrt{f}} + \frac{4032}{f} = \frac{3626}{f^{0.71}} \quad (7-40)$$

Table 7-3 gives the parameters g_1 and g_2 for the rest of the basalt rock samples in the dry state as well as those following water soaking and pretreatment in sodium hydroxide. Except in a few instances, both g_1 and g_2 decrease

Table 7-3. Basalt Parameters of the Equation $r_1 = \frac{g_1}{\sqrt{f}} + \frac{g_2}{f}$

Sample → Basalt Rock State ↓	K ₁		K ₂		K ₄	
	g ₁	g ₂	g ₁	g ₂	g ₁	g ₂
Basalt (dry)	2509	4032	881	1021	500	1000
Following 23 hour soak in water	2164	1625	1152	2187	1022	1302
Following 77 hour soak in water	1713	2256	1067	905	674	606
Following treatment in 1% NaOH	1796	2166	1389	1252	899	1035
Following treatment in 5% NaOH	2904	-382	1885	325	992	664
Following treatment in 10% NaOH	1414	1309	3607	-248	1102	233

with increasing sodium content in the pretreating solution as well as with decreasing rock thickness. Linear least-square fit of the data with the percentage, c , of sodium hydroxide gave the following relations:

- For rock sample K₁

$$g_1 = 2241 - 43C$$

and

$$g_2 = 1536 - 89C$$

- For rock sample K₂

$$g_1 = 1057 + 238C$$

and

$$g_2 = 1761 - 220C$$

- For rock sample K₄

$$g_1 = 951 + 13C$$

and

$$g_2 = 1212 - 101C$$

The increase in the Warburg coefficient g_1 for rock samples K₂ and K₄ with increasing sodium content is difficult to explain. Of the preceding six equations, two have a positive coefficient of g with c and the remaining have a negative coefficient. It may be suspected that the Warburg coefficient g_1 increases while the very low frequency polarization coefficient, g_2 decreases with increasing sodium content.

PHYSICAL SIGNIFICANCE OF r_1

The preceding data reveal the interesting finding that r_1 is indeed a polarization resistance. It, therefore, represents the term in which electrode polarization artifacts reside. An equally important conclusion is that electrode impedance is not in series with the sample impedance as has been universally accepted, but appears to be for the most part in parallel with it.

The inherent polarization represented by r_1 , and which constitutes an integral part of the measurement, is evidently responsible for the deviation of the

dielectric from the ideal or Debye behavior. The model has, therefore, permitted for the first time a clarification of the complex polarization term in rock impedance. R_p is directly determinable from the point of farthest intersection of the experimental circular arc with the R_s axis. If one corrects for the polarization effects, the time constant or relaxation time, τ , for the ideal system is given by the product $R_p C_p$. For the real system, the model Equation 7-12 gives a time constant of

$$\tau = R_p C_p \sqrt{1 + K^2} \quad (7-20)$$

where $K = \cotan \varphi$ and φ is the rock phase angle. The relaxation time, τ , can be determined independently of the model assumptions by plotting $-X_s$ as a function of $\log f$. The maximum in reactance will determine the turnover frequency, f_{\max} , from which τ can be calculated as

$$\tau = \frac{1}{\omega_{\max}} = \frac{1}{2\pi f_{\max}} \quad (7-3)$$

The capacitance of the condenser, C_p , can thus be calculated from experimental data by Equations (7-3) and (7-20). The model, therefore, permits complete analysis of the rock impedance parameters for estimating its complex dielectric constant, $\kappa^* = \kappa' - j\kappa''$. Here κ' will be related to the condenser C_p , and κ'' is related to the rock conductivity as given by the reciprocal of R_p .

SECTION VIII
TECHNICAL REPORT SUMMARY AND RECOMMENDATIONS
FOR FUTURE WORK

TECHNICAL REPORT SUMMARY

This research program was initiated to determine the electric and dielectric properties of rocks with the objective of finding a correlation between these properties and the rock geophysical characteristics and structure. Low-frequency data will eventually be useful to determine the presence of underground water and entrapped oil and gases ahead of excavation, and for underground tunneling. Accurate knowledge of the rock impedance and dielectric properties enables us to determine the attenuation of electromagnetic fields and thus predict the range and frequency for underground communication systems.

For this study program a novel technique of determining the electrical properties of rocks has been used that allows us to directly display complex impedance as a function of frequency. Three characteristic rock samples have been investigated in the frequency range from 0.05 Hz to 2 kHz. The data obtained were displayed in an Argand diagram and could be fitted very closely by an arc of circle with a depressed center.

An equivalent circuit with an RC network was used to determine from the resistivity values at zero and infinite frequencies the dielectric constant at the corresponding frequencies. The method depends on "bracketting" the circular arc in both the Argand and the Cole-Cole plot and on the assumption that a single relaxation time must be the same for both the impedance and the dielectric dispersions. The computer algorithm has been extended to derive the dielectric loss, ϵ'' , or imaginary part of the dielectric constant, κ'' , and the real part of the dielectric constant, κ' , at the frequencies at which

the specific impedance parameters are measured. The conversion technique by rotating the impedance vector from the Argand plane and transforming it to the permittivity vector in the dielectric plane is novel and reported here for the first time. Application of this technique to the impedance data of basalt and quartzite gave dielectric constants that agree reasonably well with those reported in the literature.

The hypothetical electrical model used in this investigation consists of a resistor, which is frequency dependent, in parallel to a capacity. Both are shunted by a resistor. This model successfully describes the detailed experimental results. The polarization effect can be described by a resistor whose value is inversely proportional to frequency with a power between 0.5 and unity.

The electrode impedance effects have been determined from a series of measurements with slices of various thicknesses cut from the same cylindrical sample. The electrode effects are significant for thin rock samples where they may represent a substantial portion of the measured impedance. For long rock samples the electrode correction may be negligible. However, in this case the sample impedance may be comparable or larger than the amplifier impedance preventing a stable measurement.

RECOMMENDATIONS FOR FUTURE WORK

It is highly desirable to extend the capability of our on-line computer technique beyond the kilohertz range. Extension to the mega- and gigahertz range has been recommended in Honeywell proposal 1D-E-3, "Effect of Frequency and Temperature on Rock Dielectric Parameters." The effect of temperature on rock impedance is illustrated by the results of the following preliminary tests.

Experiments were performed on basalt (IV) to determine the effect of temperature on rock impedance. The basaltic sample (IV) used in this experiment was a large circular disc 0.54 cm in thickness and 5.21 cm in diameter. It differed from the previous Dresser basalts (I), (II), and (III) used in previous experiment in both color and grain size. The new sample was darker in its greenish tint than the former samples. The change in texture may be attributed to a different phase of rock formation. Impedance was measured at both room temperature (22°C) and the melting point of ice (0°C). At the low frequency of 0.1 Hz, the impedance at the ice point is considerably higher than that at room temperature. As the frequency increases, the temperature effect becomes less pronounced. Table 8-1 gives the resistive and reactive impedance components at room temperature and at nominal frequencies ranging from 0.1 to 2000 Hz. The variation of the series reactance at room temperature, X_s , with log frequency is shown as curve A of Figure 8-1, while curve B shows the variation of the rock series resistance, R_s . Both curves indicate a turnover frequency, f_{\max} , of 9.96 Hz, which corresponds to a room temperature relaxation time, τ , of

$$\tau = \frac{1}{\omega_{\max}} = \frac{1}{2\pi f_{\max}} = 15.9 \text{ milliseconds} \quad (8-1)$$

When the previous experiment was repeated at the melting point of ice, the data in Table 8-2 were obtained. Variation of the impedance parameters, at room temperature with log frequency, is shown in Figure 8-2, where a turnover frequency, f'_{\max} , of 2.00 Hz is determined. At 0°C, the relaxation time is given by

$$\tau' = \frac{1}{2\pi f'_{\max}} = 79.5 \text{ milliseconds} \quad (8-2)$$

Figure 8-1. Variation of Impedance Parameters with Log Frequency for Dresser Basalt (IV) at Room Temperature, 22°C

Figure 8-2. Variation of Impedance Parameters with Log Frequency for Dresser Basalt (IV) at 0°C

The rock d-c resistance, R_0 , at 0°C is 191.8 megohms, which should be compared to the room temperature value of 37.3 megohm. Thus both rock d-c resistance and relaxation time decrease significantly with rise in temperature. At higher frequencies, the temperature effect becomes less pronounced.

According to Eyring's theory of absolute reaction rates (Ref. 26), the turnover or characteristic frequency is equal to the universal frequency (kT/h), modified by a free energy of activation term; thus

$$f_{\max} = \left(\frac{kT}{h}\right) e^{-\Delta F^\dagger/RT} \quad (8-3)$$

where k is Boltzmann's constant, T is the absolute temperature, ΔF^\dagger is the free energy of activation per mole of the relaxing unit within the rock matrix, and R is the molar gas constant.

The free energy of activation is related to the enthalpy of activation, ΔH , per mole of relaxing units by

$$\Delta F^\dagger = \Delta H^\dagger - T\Delta S^\dagger \quad (8-4)$$

where ΔS^\dagger is the entropy of activation. Applying Equation (8-4) into (8-3), one obtains

$$f_{\max} = \left(\frac{kT}{h}\right) e^{\Delta S^\dagger/R} e^{-\Delta H^\dagger/RT} \quad (8-5)$$

or

$$\ln (f_{\max}/T) = \ln \frac{k}{h} + \frac{\Delta S^\ddagger}{R} - \frac{\Delta H^\ddagger}{RT} \quad (8-6)$$

Normally one determines f_{\max} at a series of temperatures and establishes the validity of the foregoing equations by ascertaining that the plot of $\ln (f_{\max}/T)$ against $(1/T)$ is linear. From the slope of this linear plot one determines the enthalpy or heat of activation, ΔH^\ddagger ; thus,

$$\text{Slope} = - \frac{\Delta H^\ddagger}{R} \quad (8-7)$$

and from the intercept of the linear plot with the ordinate, one can determine the entropy of activation, ΔS^\ddagger ; thus,

$$\text{Intercept} = \ln \left(\frac{k}{h} \right) + \frac{\Delta S^\ddagger}{R} \quad (8-8)$$

Applying Equation (8-5) to the data obtained in this preliminary work, and remembering that $T = 295^\circ\text{K}$ for room temperature (22°C), and $T = 273^\circ\text{K}$ for the ice point, then

$$\frac{(f_{\max}/T)}{(f'_{\max}/T')} = e^{-\frac{\Delta H^\ddagger}{R} \left(\frac{1}{T} - \frac{1}{T'} \right)}$$

or

$$\ln \left[\frac{f_{\max} T'}{f'_{\max} T} \right] = \frac{\Delta H^\ddagger}{R} \left[\frac{1}{T'} - \frac{1}{T} \right] \quad (8-9)$$

The enthalpy of activation, ΔH^\ddagger , is calculated from Equation (8-9); thus

$$\Delta H^\ddagger = 2.303R \frac{TT'}{(T - T')} \log \left[\frac{f_{\max} T'}{f'_{\max} T} \right] = 10,700 \text{ calories}$$

For one mole of the relaxing unit within the rock (92 grams for the SiO_4 tetrahedron).

Hence, it is estimated that the activation energy for the relaxation process in basalt is about 11 Kcal per mole of relaxing units, or about 0.5 ev (1 ev = 23.05 Kcal/mole).

Future work in this area will further investigate the influence of temperature on the relaxation process and utilize it to compute both the enthalpy and entropy of activation. Further studies of the pressure effect should yield more information on the volume of activation and entropy of activation of aggregate interactions. This new set of data should yield deeper insights in rocks' ultimate structure and their petrogenesis.

The complex impedance of rock samples at a range of frequencies that brackets their turnover frequency would yield valuable information on the relaxation time(s) of the silica tetrahedra and other structural groups within the rock, and the presence or absence of conductive materials. In general, a Cole-Cole circular-arc plot would be obtained in the complex dielectric diagram. With complex structures, the resulting figure may be analyzed into a series of nearby semicircular arcs, each describing a given relaxation mechanism with some interaction coefficients among the various aggregates (Refs. 27 and 28). The same Cole-Cole plot can be obtained in a complex impedance diagram, sometimes called Argand diagram. Sinbel (Khalafalla) (Ref. 20) showed that the plot of the series reactance, X_g , against the series resistance, R_g (both determined at a given frequency), in a complex system should yield a semicircle arc. The intersection of this circular arc with the real (resistive)

axis will define the d-c resistance, R_0 (at the farthest right end). Any point on the arc will define the impedance radius vector with both its reactive and resistive components readily available.

Structural relaxation times in rocks can also provide valuable information in rock elastic moduli. Debye (Ref. 18) related relaxation times to viscosity in liquid systems. Elasticity corresponds to mechanically recoverable energy and viscous flow or friction to the conversion of mechanical energy into heat. Because of the similarity between viscous resistance to flow and friction between solid surfaces, the resistance to flow of a fluid is the analogue to internal friction or shear within a solid. These areas of endeavor in rock dielectric relaxation constitute our long range research goals.

In his opening remarks for "tables of dielectric materials" Professor Arthur R. Von Hippel (Ref. 9), a leading authority who heads this country's clearing house for information about dielectrics since World War II, states "We are fully aware that these data should be expanded, especially towards higher temperatures and frequencies; that a real dielectric analysis of the materials should be undertaken, linking the dielectric response to composition and structure..." We believe the rock data in this research are a step toward achieving these goals.

SECTION IX COMPUTER ALGORITHMS

DATA PROCESSING AND COMPUTER PROGRAMS

The system is composed of three main programs:

These three programs are described in further detail on the following pages. Program listings are included for programs II and III. Program I contains much machine language code; therefore, its listing was not included.

SAMPLING AND A-D CONVERSION

Description

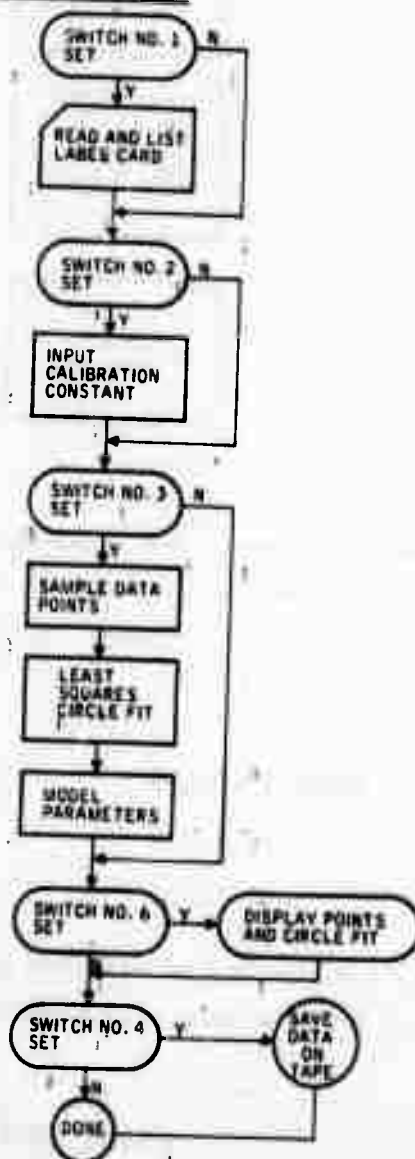

The output of the rock amplifier is sampled and converted to digital form. Provision is made to enter a calibration constant for the circuit. At each

frequency the series resistance R_s , series reactance X_s , series reactance X_s , and phase, angle are listed.

When all points have been sampled, a least-squares fit is made to the R_s , X_s data. This arc and the data points are optionally displayed on a CRT screen.

The data can also be stored on magnetic tape to be used by other programs in the system.

Flow Chart - Sampling and A-D Conversion

ELECTRODE CORRECTIONS

Description

This program calculates the electrode corrections based on the R_s , R_s data from two samples. As a further refinement in the correction technique, all pairs of three racks taken two at a time are averaged to yield a better correction for each rack.

For example,

- 1) Compute correction for K1 and K2
- 2) Compute correction for K2 and K4

Average results of (1) and (2) yield correction for K2.

The correction formula is derived as follows: consider two samples of the same rock,

For rock alone,

$$Z_R \propto \frac{d}{A}$$

$$\text{i. e., } R_R \propto \frac{d}{A}, X_R \propto \frac{d}{A}$$

Thus for two rocks,

$$\frac{R_{R_1}}{R_{R_2}} = \frac{X_{R_1}}{X_{R_2}} = \frac{d_1}{d_2} = \frac{1}{\beta} \quad (9-1)$$

We measure R_m , \bar{X}_m , which include electrode polarization effects.

Thus,

$$\left. \begin{aligned} R_{m_1} &= R_{R_1} + R_{e_1} \\ R_{m_2} &= R_{R_2} + R_{e_2} \end{aligned} \right\} \quad (9-2)$$

from (9-1) one gets

$$\frac{R_{m_1} - R_{e_1}}{R_{m_2} - R_{e_2}} = \frac{1}{\beta} \quad (9-3)$$

assuming

$$R_{e_1} = R_{e_2} = R_e$$

then R_e can be calculated as a correction to R_m ; thus,

$$\frac{R_{m_1} - R_e}{R_{m_2} - R_e} = \frac{1}{\beta} \quad (9-4)$$

yields

$$R_e = \frac{R_{m_2} - \beta R_{m_1}}{1 - \beta} \quad (9-5)$$

similarly

$$X_e = \frac{X_{m_2} - \beta X_{m_1}}{1 - \beta} \quad (9-6)$$

The electrode corrections R_e , X_e arrived at in this manner are listed on the console typewriter. Cards with these correction factors can then be punched to be used by the data analysis program.

Flow Chart -- Electrode Correction

The Data Analysis Program consists of the main program and 5 subroutines. In brief the program does the following:

- Recalls, from magnetic tape, data points resulting from a specified experimental run.
- Selects some or all of the data points for further analysis.
- Makes phase, amplitude, and, optionally, electrode corrections to the data points before further analysis.
- Fits a "best" circle to the data points
- Determines parameters of our model from this circle.
- Determines miscellaneous parameter from the data points.

Each of these is described in more detail in the following pages, with a general flow chart of the program and a program listing.

LOADING EXPERIMENTAL DATA

The data from each experiment consists of 5 physical records on magnetic tape. To locate required data, the appropriate number of records is skipped and the desired 5 data records are read. The following is a brief description of these records.

- Record 1, 8 words
- Words 1-4 - label describing experiment (e. g., K4 9/17/71 77 Hr)
- Words 5, 6 - unused

- - Word 7 - N = number of data points
- Word 8 - unused.
- Record 2, 50 words (2 words/data point)

Frequency:

$$F(I) = I = 1, \dots, N \quad N \leq 25$$

- Record 3, 50 words (2 words/data point)

R_s :

$$R_s(I) \quad I = 1, \dots, N \quad N \leq 25$$

- Record 4, 50 words, (2 words/data point)

X_s :

$$X_s(I) \quad I = 1, \dots, N \quad N \leq 25$$

- Record 5, 80 words (2 words/data point)

Working array Q:

$$Q(I) \quad I = 1, \dots, 40$$

This is an array where intermediate information is stored for communication between the main program and its subroutines. For example, $Q(40)$ is the calibration constant used in the experiment.

DATA SELECTION

Selection of the data points is done by the following technique.

A card is read containing the number of points to delete from further analysis $NDEL \ 0 \leq NDEL \leq N$. N is then decreased by this amount; $N = N - NDEL$.

Another card is then read specifying which points to select for this run. The points must be in ascending order and the total number of points must equal this revised N. The F, X, and Y arrays are then "compressed" (i. e., any points not selected are deleted) for ease of processing by the rest of program.

For example, assume original N = 7 and we wish to delete 2 points (2, 5):

- Card 1 contains ϕ_2
- Card 2 contains $\phi_1 \phi_3 \phi_4 \phi_6 \phi_7$

CORRECTIONS TO DATA

Uncorrected phase angle PHIM is corrected to PHI. The following equation is used.

To correct for phase X frequency errors from the frequency generator used in the experiment.

$$R_s = \frac{X(I) \cos (PHI)}{\cos (PHIM)}$$

$$X_s = \frac{Y(I) \sin (PHI)}{\sin (PHIM)}$$

In addition, X_s , R_s are further corrected if the frequency F(I) is >1000 Hz.

Optional electrode corrections R_e , X_e are read in on cards.

$$R_s = R'_s - R_e$$

$$X_s = X'_s - X_e$$

$$Z = \sqrt{X_s^2 + R_s^2}$$

The corrected X_s , R_s are then stored back into $X(I)$, $Y(I)$; X_s , R_s , Z are all multiplied by A/d (AOD) for the given sample

The following are listed if desired on the console typewriter.

$$F(I), R_s, X_s R * \frac{A}{d}, X * \frac{A}{d}, PHI, Z, Z * \frac{A}{d}$$

FITTING CIRCLE TO DATA POINTS

Subroutine CENTER and EVAL are used together to fit a circle to $X(I)$, $Y(I)$
 $I = 1, \dots, N$.

Subroutine EVAL(CX, CY, R, RV, NSTEPS) does the following:

find

$$T_i = [CX - X(I)]^2 + [CY - Y(I)]^2$$

and

$$R = \sum_{i=1}^N T_i / N$$

$$RV = \left[\sum_{i=1}^N T_i^2 / N - R^2 \right]^{1/2} \quad RV \geq 0$$

That is, it calculates the mean and standard deviation of the data points about a given center (CX, CY).

If the standard deviation is less than the previous standard deviation, the new center coordinates are stored along with the new mean and standard deviation. NSTEPS is increased by 1 and the subroutine is exited.

Subroutine CENTER utilizes subroutine EVAL as follows. A guess is made for the initial CX, CY and a counter Ns is set to zero. Call EVAL and store CX, CY, and standard deviation.

By successively modifying CX, CY and calling EVAL, a search is made for the CX, CY yielding the lowest standard deviation. These coordinate CX, CY, the radius, and

$$\text{FIT} = \frac{100 * \text{standard deviation}}{R}$$

is printed and control returns to the main program

MODEL PARAMETERS

Having found the "best" circle fit to the data points, the following parameters are calculated and printed.

R_p , r_2 , r_1 are determined from the circular arc.

In addition

$$C_p = \frac{\sum_{i=2}^N \frac{1}{2} (f_i - f_{i-1}) \times (C_i - C_{i-1})}{f_n - f_1}$$

where f_i is frequency at point i ,

and

$$C_i = - \frac{X_{s_i}}{2\pi f_i \left[(R_{s_i} - R_2)^2 + X_s^2 \right]}$$

$RHO = R_0 \left(\frac{A}{d} \right)$ ohm-cm is also printed.

Also calculated and printed in subroutine EPSILN are the following:

$$\tau = (R_0 - R_\infty) C_p \sqrt{1 + \cotan^2 \varphi}$$

where

$$\varphi = \sin^{-1} \left[\frac{R_0 - R_\infty}{2r} \right], \quad r = \text{radius of circle}$$

$$\epsilon_0 = \frac{\tau}{\frac{A}{d} R_\infty}, \quad \epsilon_\infty = \frac{\tau}{\frac{A}{d} R_0}$$

also printed for each frequency f_i

$$\epsilon' = \epsilon_\infty + \frac{\epsilon_0 - \epsilon_\infty}{2} \left[1 - \frac{\sin h(1-\alpha) s}{\cos h(1-\alpha) s + \cos \frac{\alpha \pi}{2}} \right]$$

and

$$\epsilon'' = \frac{\frac{1}{2} (\epsilon_0 - \epsilon_\infty) \cos \left(\frac{\alpha\pi}{2} \right)}{\cosh(1-\alpha)s + \sin \frac{\alpha\pi}{2}}$$

where $s = \log_e (\omega\tau)$ and Cole-Cole parameter α is related to the rock phase angle φ ; thus

$$\varphi = \frac{\pi}{2} (1-\alpha)$$

MISCELLANEOUS PARAMETERS

For each of the samples K1, K2, K4 under various conditions, the following calculations were made on the uncorrected data for each frequency

$$r_1 = \frac{R_0 [X_s^2 + (R_s^2 - R_\omega)^2]}{R_0 [R_s - R_\omega] - [X_s^2 + (R_s - R_\omega)^2]} \quad (9-7)$$

An equation of the form

$$r_1 = \frac{g}{f^n}$$

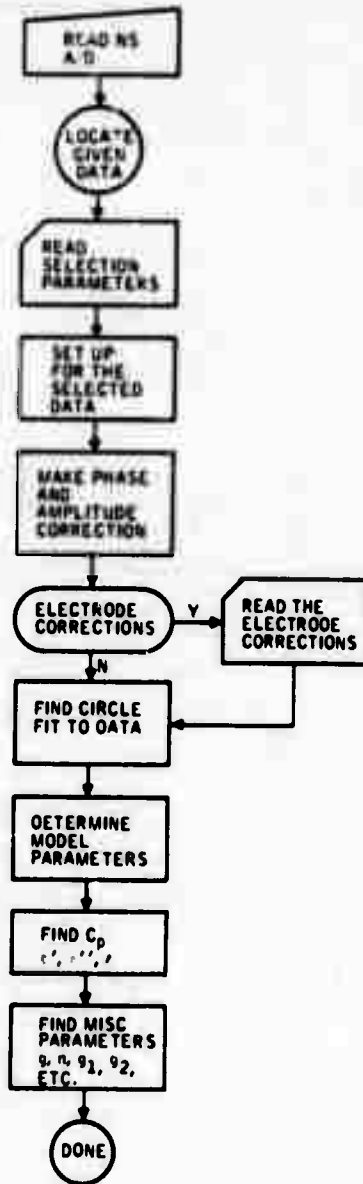

was assumed and a least-squares fit was done on the points calculated from (9-7).

An equation of form

$$r_1 = \frac{g_1}{\sqrt{f}} + \frac{g_2}{f} \quad (9-9)$$

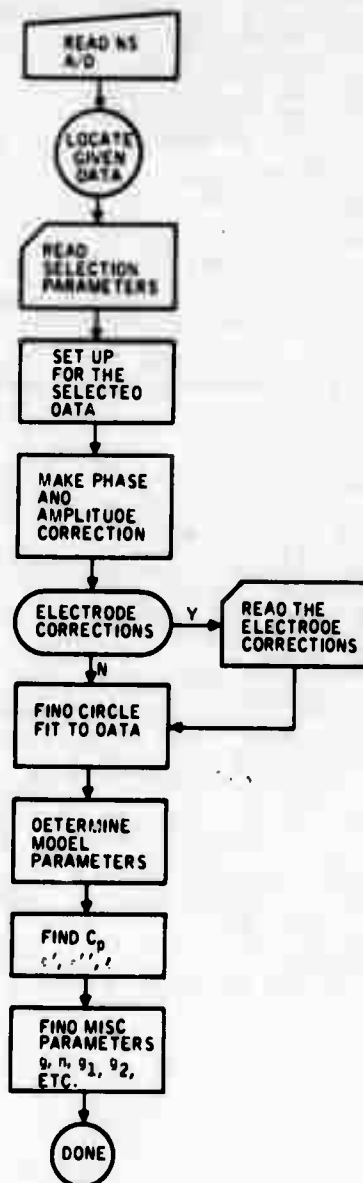

was also assumed and another least-squares fit was done on points from (9-7).

DATA PROCESSING FLOW DIAGRAM PROGRAM LOGIC

was also assumed and another least-squares fit was done on points from (9-7).

APPENDIX A

PARALLEL TO SERIES TRANSFORMATION OF ELECTRICAL MODELS WITH A SINGLE TIME CONSTANT AND FREQUENCY-INDEPENDENT COMPONENTS

This appendix presents an analytical proof of the semicircle equation relating X_s to R_s . It is easy to show that a transformation of a parallel $R_p C_p$ unit with frequency-independent components to an isoimpedic $R_s C_s$ unit with adjustable components will result in a circular plot between X_s and R_s .

The impedance of the parallel $R_p C_p$ unit is given by

$$\begin{aligned} Z_p &= \frac{jR_p X_p}{R_p + jX_p} = \frac{R_p X_p^2 + jR_p^2 X_p}{R_p^2 + X_p^2} \\ &= \frac{R_p X_p^2}{R_p^2 + X_p^2} + j \frac{R_p^2 X_p}{R_p^2 + X_p^2} \end{aligned} \tag{A1}$$

Comparing this equation with the series parameters $Z_s = R_s + jX_s$, one obtains

$$R_s = R_p \left/ \left[1 + \frac{R_p^2}{X_p^2} \right] \right. \tag{A2}$$

and

$$X_s = \left(\frac{R_p^2}{X_p} \right) \left/ \left[1 + \frac{R_p^2}{X_p^2} \right] \right. \tag{A3}$$

From Equations (A2) and (A3), the following identity can be deduced

$$X_s X_p = R_s R_p = R_s^2 + X_s^2 \tag{A4}$$

Let R_p represent a constant quantity characteristic of the rock system, call it $2a$, then according to Equations (A2) and (A4) one has

$$R_p = 2a = R_s \left[1 + \frac{R_p^2}{X_p^2} \right] = R_s \left[1 + \frac{X_s^2}{R_s^2} \right] \quad (A5)$$

Rearranging Equation (A5), one obtains

$$X_s^2 + R_s^2 = 2a R_s$$

or

$$X_s^2 + R_s^2 - 2a R_s + a^2 - a^2 = 0$$

hence,

$$(R_s - a)^2 + X_s^2 = a^2 \quad (A6)$$

Equation (A6) is the analytical equation of a circle of radius $a = \frac{1}{2} R_p$, and whose center has the coordinates $(0, a)$ in the X_s, R_s diagram, or the Argand diagram.

The transformation from the parallel to series combination describes a semicircle in the series domain for constant parallel circuit parameters. This condition represents an ideal situation in which the system has no polarization and in which the capacitance C_p is regarded as a perfect condenser, and hence the semicircle has its center on the real axis and will pass through the origin. In all rock systems studied thus far, one always obtained a circular arc; i. e., the semicircle was translated vertically downwards, so that its center has the coordinates $(m$ and $-n)$. This situation can be described as follows

$$(R_s - m)^2 + (X_s + n)^2 = a^2 \quad (A7)$$

The phase angle, φ , of the rock system is defined such that

$$\cos \varphi = \frac{n}{a} \quad (\text{A8})$$

Note that φ is not the same as the impedance phase angle, ϕ , defined by

$$\tan \phi = \frac{X_s}{R_s} = \frac{R_p}{X_p} \quad (\text{A9})$$

The attachment of a "leak" resistance, r_2 , in series with the parallel $R_p C_p$ unit, as shown in Figure 4-1a of Section IV will also result in a semicircle with radius $\frac{1}{2} R_p$, and whose center has the coordinates $(\frac{1}{2} R_p + r_2)$ and 0. This is because the impedance of this system is given by

$$\begin{aligned} Z_p &= r_2 + \frac{jX_p R_p}{R_p + jX_p} \\ &= r_2 + \frac{R_p}{\left[1 + \frac{X_p^2}{R_p^2}\right]} + j \frac{R_p^2/X_p}{\left[1 + \frac{X_p^2}{R_p^2}\right]} \end{aligned} \quad (\text{A10})$$

Comparing Equation (A10) with the isoimpedic series parameters $Z_s = R_s + jX_s$, one obtains

$$R_s - r_2 = R_p / \left[1 + \frac{R_p^2}{X_p^2}\right] \quad (\text{A11})$$

and

$$X_s = \frac{R_p^2}{X_p} / \left[1 + \frac{R_p^2}{X_p^2}\right] \quad (\text{A12})$$

These relationships lead to

$$\frac{X_s X_p}{R_p} = R_s - r_2$$

or

$$\frac{R_p}{X_p} = \frac{X_s}{R_s - r_2} \quad (A13)$$

Combining Equations (A11), (A12) and (A13) and letting $R_p = 2a$, one obtains

$$(R_s - r_2) \left[1 + \frac{X_s^2}{(R_s - r_2)^2} \right] = 2a$$

or

$$(R_s - r_2)^2 + X_s^2 = 2a (R_s - r_2)$$

hence

$$(R_s - r_2)^2 + X_s^2 - 2a (R_s - r_2) + a^2 = a^2$$

and

$$\left[R_s - (r_2 + a) \right]^2 + X_s^2 = a^2 \quad (A14)$$

This equation represents a circle with radius $a = \frac{1}{2} R_p$, and center at $(a + r_2) = \left(\frac{R_p}{2} + r_2 \right)$, located on the real axis.

APPENDIX B

RELAXATION TIME AND TURNOVER FREQUENCY OF A MODEL
WITH A SINGLE TIME CONSTANT AND ONE FREQUENCY-
DEPENDENT POLARIZATION RESISTANCE

Using the model in Figure 7-1, and starting with Equation (7-8) one has

$$X_s = \frac{r_1^2 R_p^2 X_p}{r_1^2 R_p^2 + X_p^2 (r_1 + R_p)^2}$$

The objective is to maximize X_s with respect to ω (or f). The various components are given by:

$$\begin{aligned} r_1 &= \frac{g}{f}; \quad X_p = \frac{-1}{\omega C_p} = \frac{-1}{2\pi f C_p}; \quad \text{and } R_p \text{ is independent of } f. \\ \frac{1}{X_s} &= \frac{1}{X_p} + X_p \frac{(r_1 + R_p)^2}{r_1^2 R_p^2} \\ &= \frac{1}{X_p} + X_p \left[\frac{1}{R_p} + \frac{1}{R_1} \right]^2 \\ &= \frac{1}{X_p} + \frac{X_p}{R_p^2} + \frac{X_p}{r_1^2} + \frac{2X_p}{r_1 R_p} \end{aligned} \tag{B1}$$

Substituting the values of r , and X_p in Equation (B1), one obtains

$$-\frac{1}{X_s} = 2\pi f C_p + \frac{1}{2\pi f C_p R_p^2} + \frac{f}{2\pi g^2 C_p} + \frac{2}{2\pi g R_p C_p} \tag{B2}$$

$$-\frac{d \left[\frac{1}{X_s} \right]}{df} = 2\pi C_p + \frac{1}{2\pi g^2 C_p} + \frac{1}{2\pi C_p R_p^2 f^2} \tag{B3}$$

X_s will be a maximum when $\frac{1}{X_s}$ is a minimum. This happens at the turn-over frequency, f_{\max} , which is given by

$$\frac{1}{2\pi C_p R_p^2 f_{\max}^2} = \frac{4\pi^2 g^2 C_p^2 + 1}{2\pi g^2 C_p}$$

or

$$\frac{g^2}{R_p^2 f_{\max}^2} = 1 + 4\pi^2 g^2 C_p^2 \quad (B4)$$

Equation (7-9) defines g as $\frac{1}{2\pi K C_p}$ and Equation (7-11) equates K to $\cotan \varphi$. Using these relations in Equation (B4), one obtains

$$\frac{1}{4\pi^2 R_p^2 C_p^2 f_{\max}^2} = 1 + K^2$$

or

$$\begin{aligned} \frac{1}{4\pi^2 f_{\max}^2} &= R_p^2 C_p^2 (1 + K^2) \\ &= R_p^2 C_p^2 (1 + \cotan^2 \varphi) \end{aligned} \quad (B5)$$

The relaxation time $\tau = \frac{1}{\omega_{\max}} = \frac{1}{2\pi f_{\max}}$

hence; $\tau^2 = R_p^2 C_p^2 (1 + \cotan^2 \varphi)$

and $\tau = R_p C_p \sqrt{1 + \cotan^2 \varphi} \quad (B6)$

One chooses the positive root because τ is always greater than zero.

From the experimental data,
one measures R_0 , R_∞ and φ .

$$R_p = (R_0 - R_\infty)$$

Hence τ can be calculated as

$$\tau = (R_0 - R_\infty) C_p \sqrt{1 + \cot^2 \varphi}$$
