FOREWORD

This report discusses the in-house effort accomplished under Project 4519, Task 451902 (System 760C).

The authors are indebted to Mr. Alfred S. Kobos for his careful reading of and help in rewriting the manuscript and to Captain Robert G. McLaughlin for his generous aid on many knotty programming difficulties.

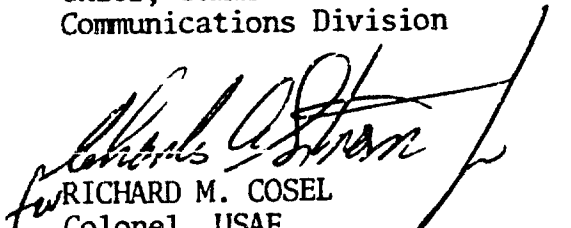

This technical report has been reviewed by the Foreign Disclosure Policy Office (EMLI). It is not releasable to the Clearinghouse for Federal Scientific and Technical Information because it contains information embargoed from release to Sino-Soviet Bloc countries by AFR 400-10, "Strategic Trade Control Program."

This report has been reviewed and is approved.

## ABSTRACT

A common type of digital communication system is binary frequency shift keying (FSK) whereby every  $T$  seconds the transmitter sends a pulse of one of two frequencies. The receiver makes a decision (every  $T$  seconds) as to which frequency was transmitted. A sub-optimum receiver for this case obtains estimates of the two noise waveforms by passing received signals through filters centered at the sending frequencies and then cross-correlates these estimates with the received waveform. Two slightly different versions of this cross-correlator were considered, and the probability of error for each case was calculated. The results seem to agree with previous experimental work by Cossette and Wolf.

## 1. INTRODUCTION

A common type of digital communication system is binary frequency shift-keying (FSK) whereby every  $T$  seconds the transmitter sends a pulse of one of two frequencies. The receiver then makes a decision (every  $T$  seconds) as to which frequency was transmitted. The method whereby the receiver makes this decision for various types of communications channels is the subject of this report.

The simplest model for a communications channel assumes that the input to the receiver is an attenuated version of the transmitted signal corrupted by additive Gaussian white noise (with zero mean and power spectral density  $S(\omega) = N_0/2$  for all  $\omega$ ). This model has been thoroughly analyzed in the literature<sup>(1)</sup> and the receiver structure which leads to the minimum probability of error is known. Specifically, let us assume that the received waveform,  $r(t)$ , is given as

$$r(t) = \left\{ \begin{array}{l} \sqrt{2E/T} \sin(\omega_0 t + \theta_0) \\ \text{or} \\ \sqrt{2E/T} \sin(\omega_1 t + \theta_1) \end{array} \right\} + n(t) \quad 0 \leq t \leq T \quad (1)$$

where

- (a)  $\omega_0 T = k2\pi$        $k$ , an integer
- (b)  $\omega_1 T = p2\pi$        $p$ , an integer not equal to  $k$
- (c)  $E\{n(t)\} = 0$ ,       $E\{n(t)n(t-\tau)\} = \frac{N_0}{2} \delta(\tau)$

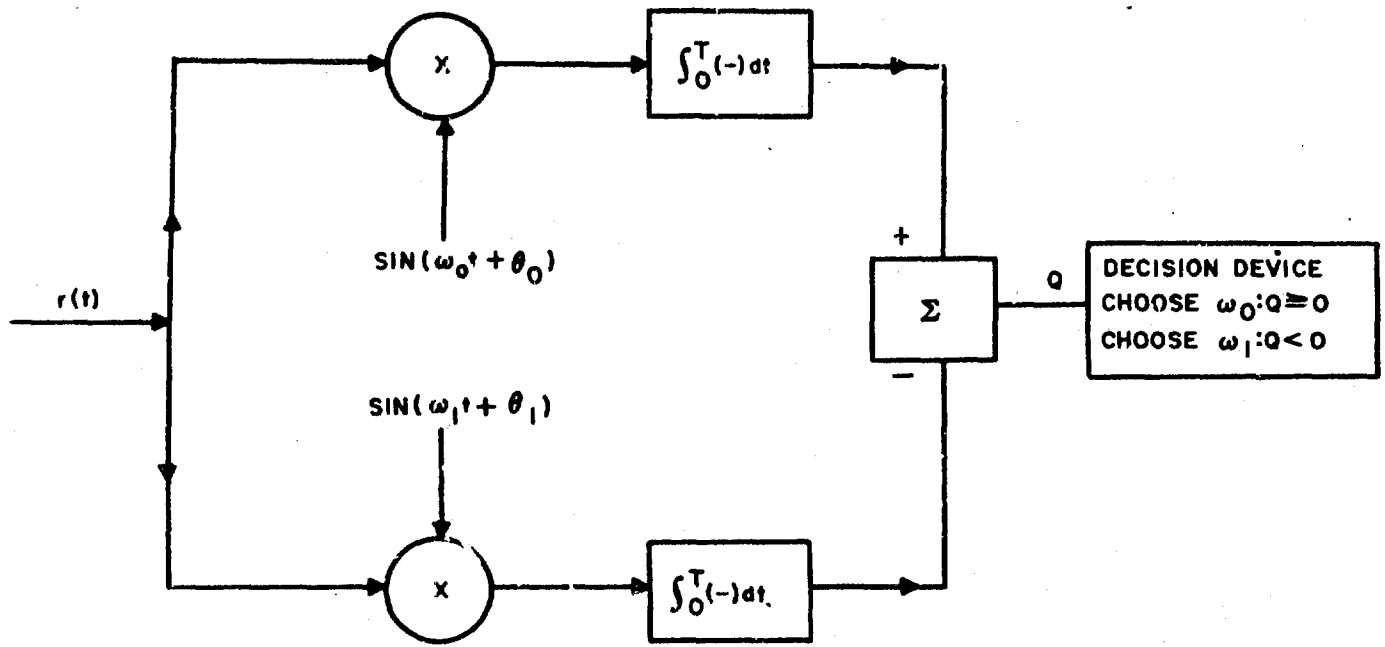

and

- (d) The a priori probabilities of each sinusoid are equal.

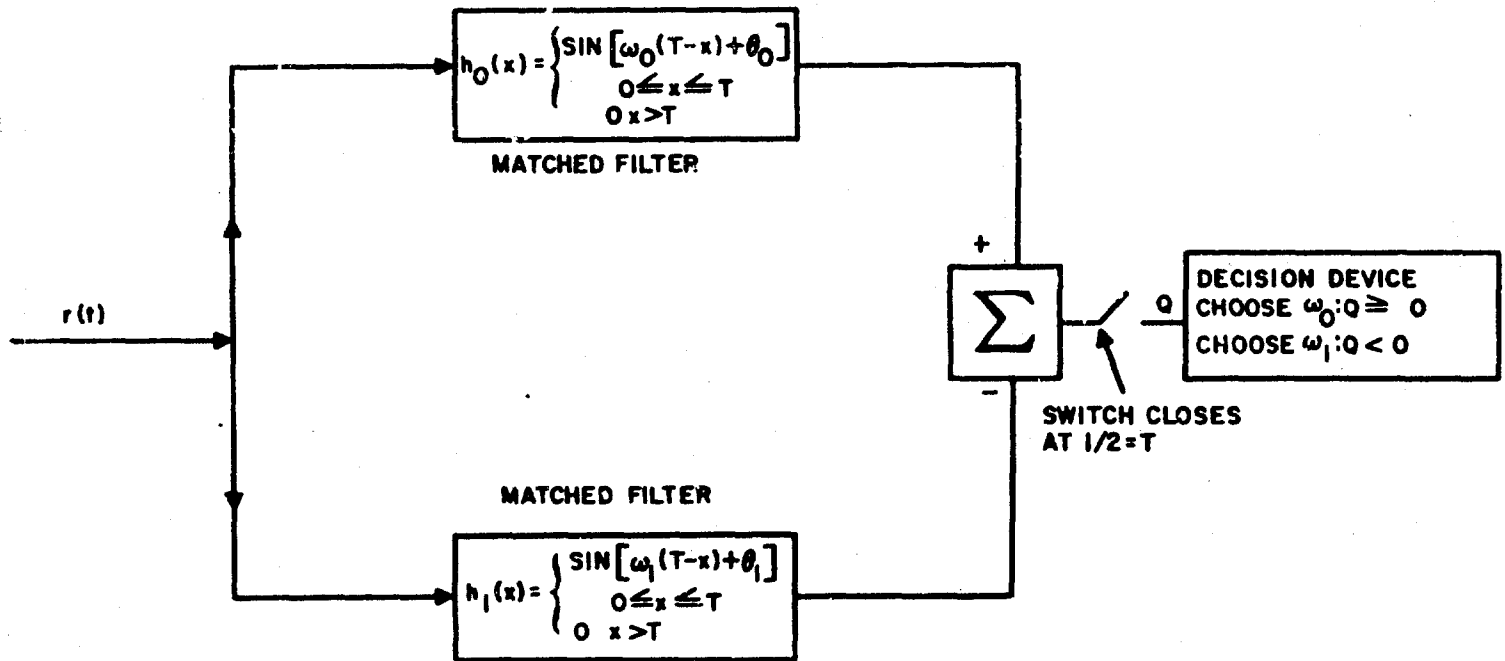

Many receiver structures can be given all of which have identical performance. Two receiver structures which lead to the minimum probability of error for this simple channel model are given in Figure 1. The probability of error for these receivers is:

$$P_e = \frac{1}{\sqrt{2\pi}} \int_0^{\infty} e^{-\frac{1}{2} z^2} dz \quad (2)$$

$$\sqrt{\frac{E}{N_0}}$$

(a) CORRELATION RECEIVER

(b) MATCHED FILTER RECEIVER

Figure 1. Two Realizations for Optimum Receiver for Additive Gaussian Noise Only

The above situation, termed coherent detection, may not be realistic for many reasons. One of these reasons is that it is assumed that the receiver has knowledge of the exact phase of both sinusoids. If the receiver knows nothing of the phase of the received sinusoids and it is either undesirable or impractical to assume that it has estimated this phase from previous pulses, then we can add the additional restriction that:

(e) The phases  $\theta_1$  and  $\theta_2$  are independent random variables, each having a probability density function which is uniform over the interval  $(0, 2\pi)$ .

Again the optimum receiver which leads to the minimum probability of error is known. Two such optimum receiver structures are given in Figure 2. The probability of error for these receivers is

$$P_e = \frac{1}{2} e^{-\frac{E}{2N_0}} \quad (3)$$

Continuing with the idea of making the mathematical model of the channel more general so that it applies to a wide class of channels, it is now assumed that there are statistical fluctuations in the amplitude of the FSK signals. The simplest situation to consider is the case where the amplitude  $\sqrt{2E/T}$  is constant over any one pulse period but varies in a statistical manner from pulse to pulse. In that case, the previous receiver structures are still optimum but the average probability of error is given as

$$\bar{P}_e = \int_0^{\infty} (\text{probability of error without fading}) p(E) dE \quad (4)$$

where  $p(E)$  is the probability density function of the signal energy  $E$ , which is a random variable. Amplitude fluctuations are usually accompanied by an unknown phase so (4) becomes:

$$\bar{P}_e = \int_0^{\infty} \frac{1}{2} e^{-\frac{E}{2N_0}} p(E) dE = M_E \left( -\frac{1}{2N_0} \right) \text{ (noncoherent case)} \quad (4a)$$

where  $M_E(jv)$  is the characteristic function of the signal energy "E".

If, however, the phase is known (or a very good estimate is made of the phase) then (4) becomes

$$\bar{P}_e = \int_0^{\infty} \left( \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} e^{-\frac{1}{2} z^2} dz \right) p(E) dE \text{ (coherent case)} \quad (4b)$$

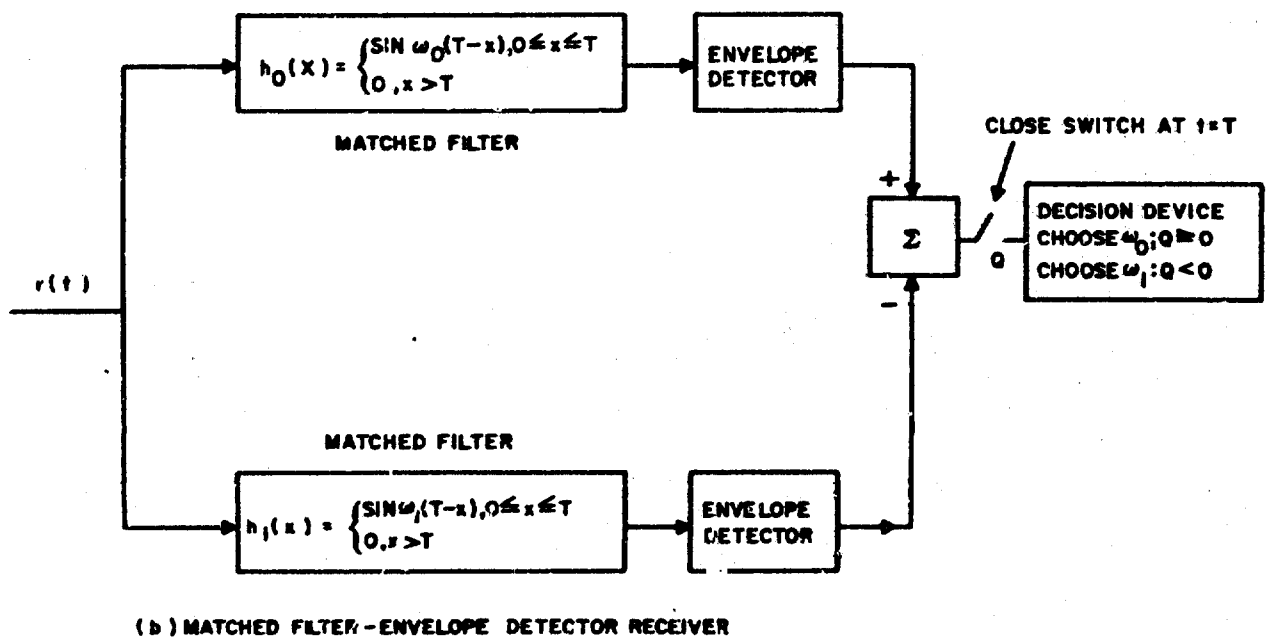

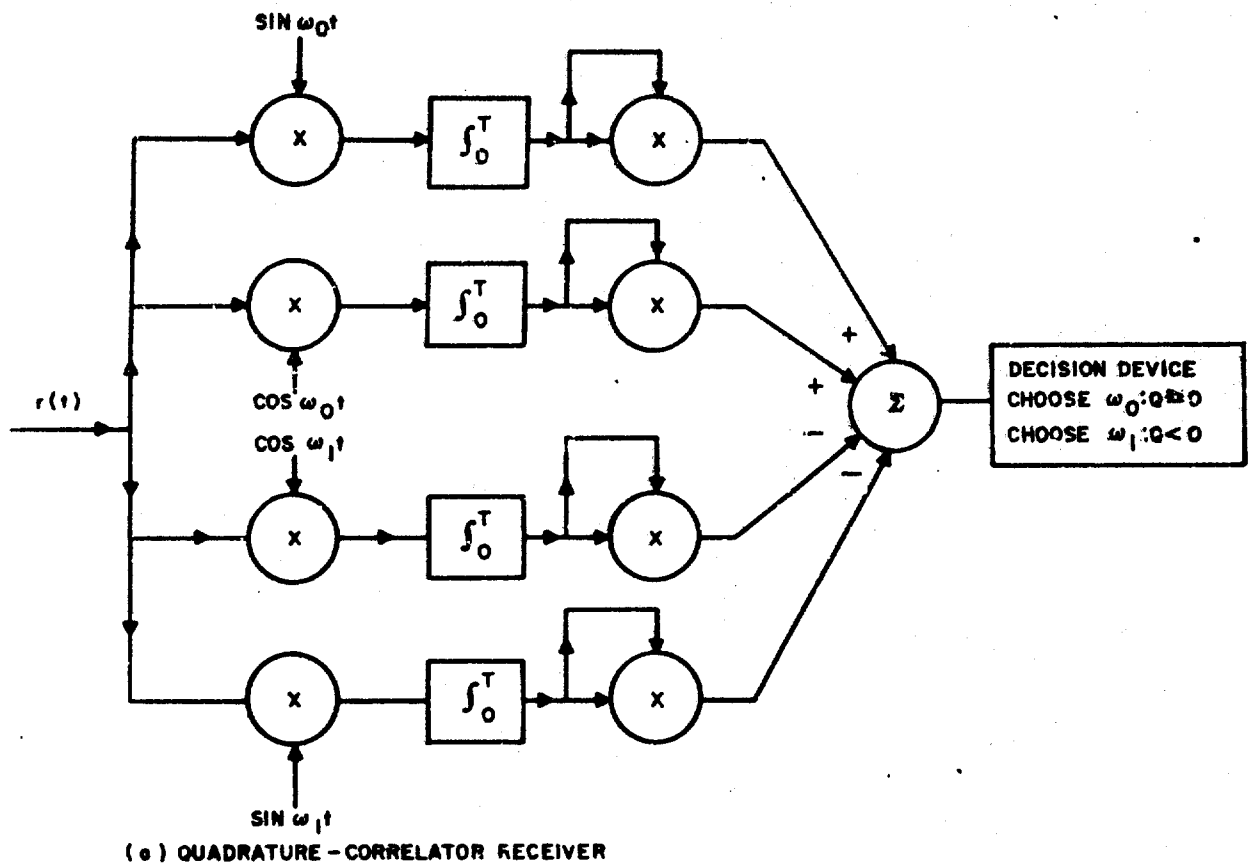

Figure 2. Two Realizations for Optimum Receiver for Additive Gaussian Noise and No Phase Information

A common type of fading experiment in practice is so-called Rayleigh fading where the envelope  $\sqrt{2E/T}$  is distributed in accordance with the Rayleigh distribution. For that case, equations (4a) and (4b) become:

$$\bar{P}_e = \frac{1}{2 + \frac{\bar{E}}{N_0}} \quad (\text{noncoherent case}) \quad (5a)$$

and

$$\bar{P}_e = \frac{1}{2} \left[ 1 - \frac{\sqrt{\bar{E}/N_0}}{2 + \bar{E}/N_0} \right] \quad (\text{coherent case}) \quad (5b)$$

respectively, where  $\bar{E}$  is the average value of the random variable  $E$ .

It is important to realize that equations (4) and (5) above do not apply to situations where the envelope fluctuates during one pulse period. Specifically, the above results do not apply to communications channels where the fading rate is of the same order or faster than the keying rate.

Mathematical expressions have been derived<sup>(3)</sup>, the solutions of which give the optimum receiver for a fast fading case. Unfortunately, these equations have not been solved in general nor has the minimum probability of error been estimated. (Price<sup>(4)</sup> has derived the minimum probability of error for on-off keying with fast fading but not for FSK.) The aim of this report is to evaluate the performance of a particular (sub-optimum) receiver for this situation. The reason for the choice of the receiver chosen will be presented later.

## 2. MATHEMATICAL MODEL

In the model to be considered it is assumed that the receiver has as its input waveform a narrow band Gaussian signal centered either at frequency  $\omega_0$  or  $\omega_1$  which is also corrupted by additive Gaussian white noise (again with zero mean and power spectral density  $S_n(\omega) = N_0/2$  for all  $\omega$ ). In particular, the received waveform  $r(t)$  is given as

$$r(t) = \left\{ \begin{array}{l} n_0(t) \\ \text{or} \\ n_1(t) \end{array} \right\} + n(t) \quad 0 \leq t \leq T \quad (6)$$

where

- (a)  $n_0(t)$ ,  $n_1(t)$  and  $n(t)$  are independent Gaussian processes all with zero mean
- (b)  $E \{n(t)n(t - \tau)\} = \frac{N_0}{2} \delta(\tau)$
- (c)  $E \{n_0(t)n_0(t - \tau)\} = R_0(\tau)$   
 $E \{n_1(t)n_1(t - \tau)\} = R_1(\tau)$
- (d) The a priori probabilities of  $n_1(t)$  and  $n_0(t)$  are equal.

The receiver must operate on the received waveform  $r(t)$  during the interval  $(0, T)$  and make a decision whether  $n_0(t)$  or  $n_1(t)$  was present during that interval.

The physical reasoning for such a mathematical model is that when a sinusoid is transmitted over a scatter communications channel, it travels over many different paths, each path introducing amplitude, phase and perhaps frequency changes. The sum of the signals from all these paths then (from Central Limit Theorem arguments) can be considered as a narrow band Gaussian process with center frequency given by the frequency of the transmitted carrier. An artificial channel which was constructed and exhibits this type of perturbation was the Needles belt<sup>(6)</sup>.

An intuitive argument might suggest that a natural method for deciding between the two noise sources is to estimate the energy in the received waveform in the two narrow frequency bands centered at  $\omega_0$  and  $\omega_1$  and then choose that frequency having the largest energy. A breadboard simulation of such a system was reported by Cossette and Wolf<sup>(7)</sup>. Theoretical analyses of such a system have been made by Jacobs<sup>(8)</sup> (for one type of spectrum) and by Kobos and Meyer<sup>(9)</sup>.

Another sub-optimum receiver is suggested by the following ideas. Note that the correlator receiver given in Figure 1 cross-correlated the received waveform with stored replicas of the transmitted signals. Thus it would seem that a logical design for a receiver would be to obtain estimates of the two noise waveforms  $n_0(t)$  and  $n_1(t)$  by passing the received signal through filters centered at  $\omega_0$  and  $\omega_1$  and then cross-correlating these estimates with the received waveform  $r(t)$ . Such a receiver, called a cross-correlator receiver, is shown in Figure 3. This receiver is analyzed in the remaining sections of this report.

It should be clearly understood that no claim for optimality is made for this receiver. However, it is interesting to note that one form for the block diagram of the optimum receiver (which leads to minimum probability of error) is similar to this receiver<sup>(10)</sup>. The optimum receiver, however, utilizes time varying filters in place of narrow band filters. The time-varying impulse responses for these filters are not known, but are only known to be the solutions to certain integral equations. Furthermore, since time varying filters may be difficult to build, there appears to be adequate justification for considering this simpler, but sub-optimum, receiver.

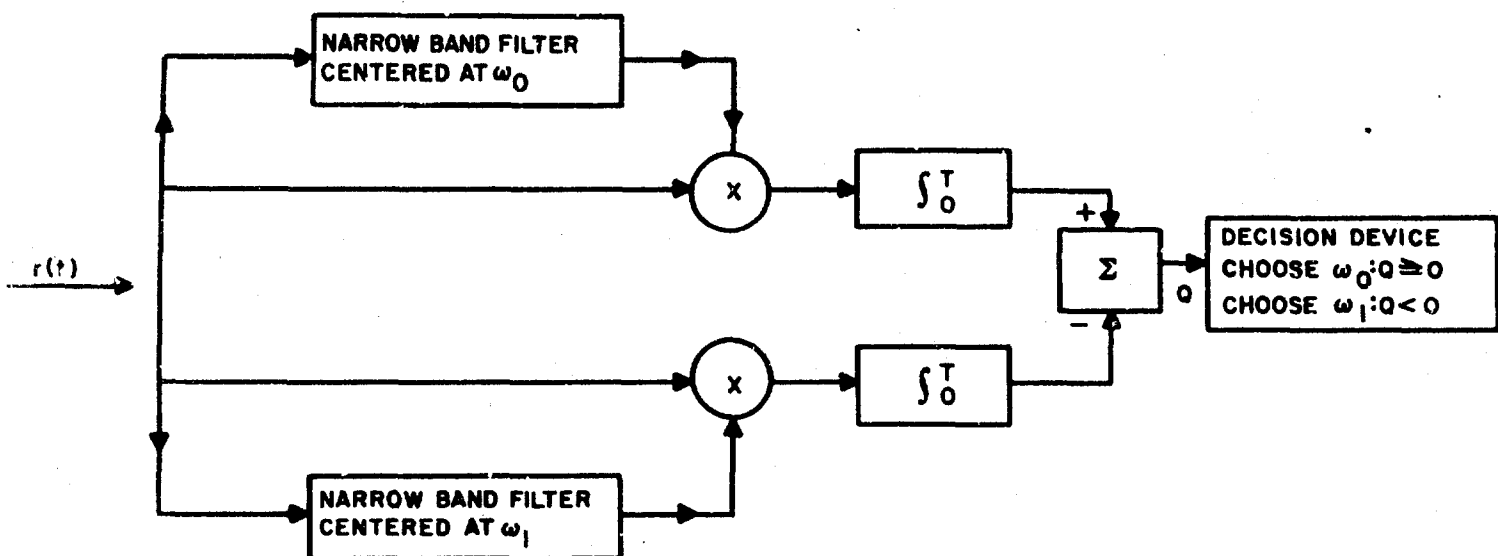

Figure 3. Cross-Correlator Sub-Optimum Receiver for Noise-Like FSK Reception

### 3. MATHEMATICAL ANALYSIS

In the following analysis specific forms are assumed for the transfer functions of the filters in Figure 3, as well as for the autocorrelation functions of the noise processes. Although the problem could be analyzed in greater generality, this approach was taken since a more general analysis would be more complicated and the salient points are illustrated in the analysis which follows.

Specifically, we assume that the noise processes  $n_0(t)$  and  $n_1(t)$  have autocorrelation functions identical to those which would result by passing white noise through single-tuned, high  $Q$ , RLC filters centered at  $\omega_0$  and  $\omega_1$  respectively. Thus, if we write  $n_0(t)$  and  $n_1(t)$  as

$$n_i(t) = x_i(t) \cos \omega_i t + y_i(t) \sin \omega_i(t) \quad i = 0, 1 \quad (7)$$

Then  $R_{x_i x_i} = R_{y_i y_i}(\tau) = e^{-\alpha |\tau|} \quad i = 0, 1 \quad (8)$

$$R_{x_i y_i}(\tau) = 0 \quad i = 0, 1 \quad (9)$$

Note that "S" is the power in  $x_1(t)$  and  $y_1(t)$ . As a consequence of equation (9), however, it is also the power in  $n_1(t)$ . Furthermore, the impulse response of the receiver filters are:

Narrow band filter centered at  $\omega_0$

$$h_0(x) = \begin{cases} e^{-\alpha x} \cos \omega_0 x & x \geq 0 \\ 0 & x < 0 \end{cases} \quad (10)$$

Narrow band filter centered at  $\omega_1$

$$h_1(x) = \begin{cases} e^{-\alpha x} \cos \omega_1 x & x \geq 0 \\ 0 & x < 0 \end{cases} \quad (11)$$

That is, these receiver filters are just RLC, high Q filters centered at  $\omega_0$  and  $\omega_1$ , respectively. Furthermore, we assume that the center frequencies  $\omega_0$  and  $\omega_1$  are separated far enough, so that there is no output of filter centered at  $\omega_1$  due to the narrow band noise  $n_0(t)$  (centered at  $\omega_0$ ) and there is no output of filter centered at  $\omega_0$  due to the narrow band noise  $n_1(t)$  (centered at  $\omega_1$ ). Of course, both filters have outputs due to the additive white noise  $n(t)$ .

Two slightly different versions of the problem will be considered. They are described below and referred to as case 1 and case 2. In both situations we will assume that the received waveform actually contained the narrow band noise  $n_0(t)$  plus the additive Gaussian white noise  $n(t)$ . We then calculate the probability of error as the probability that the receiver decides that  $n_1(t)$  was present. This, of course, is just one type of error that the receiver could make but due to the symmetry of the problem, this error probability is equal to the overall error probability.

#### 4. CASE 1

Consider the receiver shown in Figure 4, where the received waveform is given as

$$r(t) = n_0(t) + n(t), \quad 0 \leq t \leq T \quad (12)$$

The probability of error for this receiver is then

$$P_e = P_r [Q < 0] = P_r [Q_1 > Q_0]. \quad (13)$$

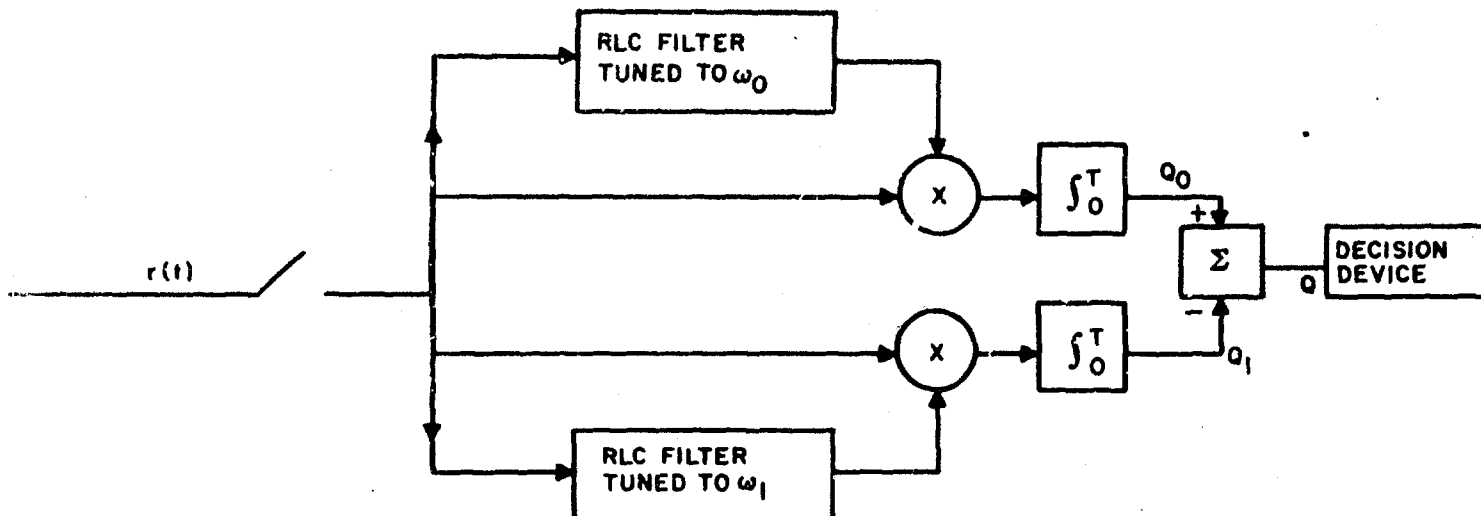

Figure 4. Correlator Receiver for Case 1.

As in equation (7), we write

$$n_o(t) = x_o(t) \cos \omega_o t + y_o(t) \sin \omega_o t \quad (14)$$

The switch in the front end of the receiver, which closes at  $t = 0$ , is included to specifically indicate that the receiver filters are inert (have no initial conditions) at the start of the keying interval. (In practice the energy in these filters would have to be dumped at the end of every pulse period.)

To calculate the output voltage  $Q_o$ , we write the white noise  $n(t)$  as\*

$$n(t) = x_n(t) \cos \omega_o t + y_n(t) \sin \omega_o t \quad (15)$$

where  $E[x_n(t)x_n(t - \tau)] = E[y_n(t)y_n(t - \tau)] = \frac{N_o}{2} \delta(\tau)$  (16)

and  $E[x_n(t)y_n(t - \tau)] = 0$  (17)

\*The complications of writing white noise in the form given in equation (15) are discussed by Helstrom<sup>(11)</sup>.

Since  $n_0(t)$  and  $n(t)$  are statistically independent processes, we then have

$$r(t) = x_R(t) \cos \omega_0 t + y_R(t) \sin \omega_0 t \quad (18)$$

where

$$E[x_R(t) x_R(t - \tau)] = S e^{-\alpha|\tau|} + \frac{N_0}{2} \delta(\tau) = E[y_R(t) y_R(t - \tau)], \quad (19)$$

and

$$E[x_R(t) y_R(t - \tau)] = 0 \quad (20)$$

Now

$$Q_0 = \int_0^T \left\{ \int_0^{t-\eta} e^{-\alpha(t-\eta)} \cos \omega_0(t-\eta) [x_R(\eta) \cos \omega_0 \eta + y_R(\eta) \sin \omega_0 \eta] d\eta \right\} [x_R(t) \cos \omega_0 t + y_R(t) \sin \omega_0 t] dt \quad (21)$$

But if  $f(x, y) = f(y, x)$ , then

$$\int_0^T \left[ \int_0^y f(x, y) dx \right] dy = \frac{1}{2} \int_0^T \int_0^T f(x, y) dx dy \quad (22)$$

so that  $Q_0$  can be written as

$$Q_0 = \frac{1}{2} \int_0^T \int_0^{T-\alpha(t-\eta)} e^{-\alpha(t-\eta)} \cos \omega_0(t-\eta) [x_R(\eta) \cos \omega_0 \eta + y_R(\eta) \sin \omega_0 \eta] [x_R(t) \cos \omega_0 t + y_R(t) \sin \omega_0 t] dt d\eta \quad (23)$$

After expanding all trigonometric products in sums of trigonometric functions, we can ignore all terms which involve  $\cos \omega_0 t$ ,  $\sin \omega_0 t$ ,  $\cos \omega_0 \eta$ , or  $\sin \omega_0 \eta$ , since their contributions to  $Q_0$  will be negligible after performing the integration. We are then left with the expression

$$Q_0 = \frac{1}{8} \int_0^T \int_0^{T-\alpha|t-\eta|} e^{-\alpha|t-\eta|} [x_R(t) x_R(\eta) + y_R(t) y_R(\eta)] dt d\eta \quad (24)$$

Let us now consider the orthonormal set of functions  $\phi_i(t), i = 1, 2, \dots$  which are solutions to the integral equation

$$\int_0^T e^{-\alpha|t-\tau|} \phi_1(\tau) d\tau = \lambda_1 \phi_1(t) \quad 0 \leq t \leq T \quad (25)$$

where

$$\int_0^T \phi_i(t) \phi_j(t) dt = \delta_{ij} \quad (26)$$

If we expand  $x_r(t)$  and  $y_r(t)$  in terms of these functions  $\phi_i(t)$  to obtain

$$x_r(t) = \sum_{j=1}^{\infty} x_j \phi_j(t) \quad (27)$$

$$y_r(t) = \sum_{j=1}^{\infty} y_j \phi_j(t) \quad (28)$$

then it is easy to show that

$$E[x_i x_j] = (S\lambda_j + \frac{N_0}{2}) \delta_{ij} = E[y_i y_j] \quad (29)$$

We can thus rewrite  $Q_0$  in terms of the coefficients  $x_j, y_j$  and the functions  $\phi_j(t)$  as

$$Q_0 = \frac{1}{8} \int_0^T \int_0^T e^{-\alpha|t-\eta|} \left[ \sum_{j=1}^{\infty} (x_j + y_j) \phi_j(\eta) \right] \left[ \sum_{k=1}^{\infty} (x_k + y_k) \phi_k(t) \right] dt d\eta \quad (30)$$

But making use of Equations (25) and (26), this becomes

$$Q_0 = \frac{1}{8} \sum_{j=1}^{\infty} \lambda_j (x_j^2 + y_j^2) \equiv \sum_{j=1}^{\infty} \epsilon_j \quad (31)$$

where

$$\epsilon_j = \frac{1}{8} (x_j^2 + y_j^2) \lambda_j \quad (32)$$

Since all processes under consideration are Gaussian,  $x_j$  and  $y_j$  are Gaussian random variables so that  $\epsilon_j$  is chi-square distributed with mean value

$$E[\epsilon_j] = \frac{1}{4} \lambda_j (S\lambda_j + \frac{N_0}{2}) \equiv \bar{\epsilon}_j \quad (33)$$

Thus the probability density function of  $\epsilon_j$  is given as

$$p(\epsilon_j) = \frac{1}{\bar{\epsilon}_j} e^{-\epsilon_j/\bar{\epsilon}_j}, \quad \epsilon_j \geq 0, \quad (34)$$

and its characteristic function  $M_{\epsilon_j}(jv)$  is

$$M_{\epsilon_j}(jv) = \int_0^{\infty} p(\epsilon_j) e^{+jv\epsilon_j} d\epsilon_j = \left( \frac{1}{1 - jv\bar{\epsilon}_j} \right) \quad (35)$$

Since the  $\epsilon_j$  are all statistically independent, the characteristic function of  $Q_0$  is then

$$M_{Q_0}(jv) = \prod_j \frac{1}{1 - jr\bar{\epsilon}_j} \quad (36)$$

where  $\bar{\epsilon}_j$  is given in Equation (33).

Let us now concentrate on calculating the statistics of  $Q_1$ . Since the center frequency of this filter is  $\omega_1$ , it is convenient to write the noise as

$$n(t) = x'_n(t) \cos \omega_1 t + y'_n(t) \sin \omega_1 t \quad (37)$$

so that the input to the filter becomes

$$r(t) = x_0(t) \cos \omega_0 t + y_0(t) \sin \omega_0 t + x'_n(t) \cos \omega_1 t + y'_n(t) \sin \omega_1 t \quad (38)$$

The output  $Q_1$  is then

$$Q_1 = \int_0^T \left\{ \int_0^t e^{-\alpha(t-\eta)} \cos \omega_1(t-\eta) [r(\eta)] d\eta \right\} r(t) dt \quad (39)$$

where  $r(t)$  is as given in Equation 38. Substituting Equation (38) into (39) (twice) and ignoring all terms which have sinusoidal variations, results in

$$Q_1 = \frac{1}{4} \int_0^T \int_0^t e^{-\alpha(t-\eta)} [x'_n(\eta) x'_n(t) + y'_n(\eta) y'_n(t)] d\eta dt \quad (40)$$

or

$$Q_1 = \frac{1}{8} \int_0^T \int_0^T e^{-\alpha|t-\eta|} [x'_n(\eta) x'_n(t) + y'_n(\eta) y'_n(t)] d\eta dt \quad (41)$$

Expanding  $x'_n(t)$  and  $y'_n(t)$  in terms of the functions  $\phi_j(t)$  previously defined, as

$$x'_n(t) = \sum_{j=1}^{\infty} x'_j \phi_j(t) \quad (42)$$

$$y'_n(t) = \sum_{j=1}^{\infty} y'_j \phi_j(t) \quad (43)$$

and substituting into Equation (41) yields

$$Q_1 = \frac{1}{8} \sum_{j=1}^{\infty} \lambda_j [(x'_j)^2 + (y'_j)^2] \equiv \sum_{j=1}^{\infty} \epsilon'_j \quad (44)$$

By a similar set of steps to that which led to Equation (36) we obtain

$$M_{Q_1}(j\omega) = \frac{\pi}{j} \frac{1}{(1 - j\omega\bar{\epsilon}'_j)} \quad (45)$$

where

$$\bar{\epsilon}'_j = \frac{1}{8} N_o \lambda_j \quad (46)$$

We are now in a position to calculate the probability of error. Returning to Equation (13) we see that the probability of error is given as

$$P_e = P_r [Q_1 > Q_0] = \int_0^{\infty} p(Q_0) \left[ \int_{Q_0}^{\infty} p(Q_1) dQ_1 \right] dQ_0 \quad (47)$$

But the probability density functions  $p(Q_1)$  and the characteristic functions  $M_{Q_1}(jv)$  are related by the equation

$$P(Q_1) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} M_{Q_1}(jv) e^{-jvQ_1} dv = \frac{1}{2\pi} \int_{-\infty}^{+\infty} M_{Q_1}^*(jv) e^{+jvQ_1} dv \quad (48)$$

Substituting one form of Equation (48) into Equation (47) we obtain

$$P_e = \int_0^{\infty} p(Q_0) \left[ \int_{Q_0}^{\infty} \left[ \frac{1}{2\pi} \int_{-\infty}^{+\infty} M_{Q_1}^*(jv) e^{+jvQ_1} dv \right] dQ_1 \right] dQ_0 \quad (49)$$

or

$$P_e = \int_0^{\infty} p(Q_0) \left[ \frac{1}{2\pi} \int_{-\infty}^{+\infty} M_{Q_1}^*(jv) \frac{e^{+jvQ_0}}{-jv} dv \right] dQ_0, \text{ if } \text{Re}(jv) < 0. \quad (50)$$

Performing the integration with respect to  $Q_0$  yields

$$P_e = -\frac{1}{2\pi j} \int_{-\infty}^{+\infty} \frac{M_{Q_0}(jv) M_{Q_1}^*(jv) dv}{v} \text{ if } \text{Re}(jv) < 0 \quad (51)$$

Finally, we can rewrite Equation (51) in terms of a complex variable  $s$ , as

$$P_e = -\frac{1}{2\pi j} \int_C \frac{M_{Q_0}(s) M_{Q_1}^*(s)}{s} ds \quad (52)$$

where  $C$  is a contour along the imaginary axis but to the left of all the poles on this axis.

From Equations (36) and (45) we have that

$$M_{Q_0}(s) = \lim_{N \rightarrow \infty} \frac{N}{\prod_{j=1}^N} \frac{1}{(1 - S \bar{\epsilon}_j)} \quad (53)$$

and

$$M_{Q_1}^*(s) = \lim_{N \rightarrow \infty} \frac{N}{\prod_{j=1}^N} \frac{1}{(1 - S \epsilon'_j)} \quad (54)$$

where

$$\bar{\epsilon}_j = \frac{1}{4} \lambda_j (S \lambda_j + \frac{N_0}{2}) \quad (55)$$

and

$$\epsilon'_j = \frac{1}{8} \lambda_j N_0 \quad (56)$$

Thus we can write (assuming that we can take the limit after integrating)

$$Pe = \lim_{N \rightarrow \infty} -\frac{1}{2\pi j} \int_C \frac{ds}{S \prod_{i=1}^N (1 - S \bar{\epsilon}_i) (1 + S \bar{\epsilon}_i)} \quad (57)$$

Defining the pole locations  $S_j$  and  $S'_j$  as

$$S_j = -\frac{1}{\bar{\epsilon}_j} = \frac{4}{\lambda_j (S \lambda_j + \frac{N_0}{2})} \quad (58)$$

$$S'_j = \frac{1}{\epsilon'_j} = \frac{8}{\lambda_j N_0} \quad (59)$$

we then have

$$Pe = \lim_{N \rightarrow \infty} \frac{(-1)^{N+1}}{2\pi j} \int_C \frac{\prod_{i=1}^N S_i S'_i ds}{S \prod_{i=1}^N (S - S_i) (S + S'_i)} \quad (60)$$

In order to perform the integration indicated in Equation (60) we note the pole plot shown in Figure 5. (The eigenvalues,  $\lambda_i$ , have been ordered such that  $\lambda_1 > \lambda_2 > \lambda_3 \dots$ ). Let us write Equation (60) as

$$P_e = \lim_{N \rightarrow \infty} \frac{1}{2\pi j} \int_C f_N(s) ds \quad (61)$$

Then from the residue theorem, the probability of error is the sum of the residues of  $f_N(s)$  for the left half plane poles. The residue of  $f_N(s)$  at  $S = -S'_j$  is given as:

$$S = -S'_j = (-1)^{N+1} \frac{\prod_{i=1}^N S_i S'_i}{(-S_j) \prod_{i=1}^N (-1)^N (S_j + S_i) \prod_{i=1, i \neq j}^N (S'_i - S'_j)} \quad (62)$$

or

$$\text{residue of } f_N(s) \text{ at } S = -S'_j = \frac{1}{\left(1 + \frac{S'_j}{S_j}\right) \prod_{i=1, i \neq j}^N \left(1 + \frac{S'_j}{S_i}\right) \left(1 - \frac{S'_j}{S'_i}\right)} \quad (63)$$

the probability of error is then

$$P_e = \lim_{N \rightarrow \infty} \sum_{j=1}^N \frac{1}{\left(1 + \frac{S'_j}{S_j}\right) \prod_{i=1, i \neq j}^N \left(1 + \frac{S'_j}{S_i}\right) \left(1 - \frac{S'_j}{S'_i}\right)} \quad (64)$$

Finally, substituting the values for  $S_j$  and  $S'_j$  given in Equations (58) and (59) yields

$$P_e = \lim_{N \rightarrow \infty} \sum_{j=1}^N \frac{1}{2 \left(1 + \frac{S\lambda_j}{N_0}\right) \prod_{i=1, i \neq j}^N \left[1 + \left(1 + \frac{2S\lambda_i}{N_0}\right) \frac{\lambda_i}{\lambda_j}\right] \left[1 - \frac{\lambda_i}{\lambda_j}\right]} \quad (65)$$

Figure 5. Pole Plot and Path of Contour Integration for Equation (60)

Equation (65) is the desired result. Note that this equation gives the probability of error in terms of eigenvalues  $\lambda_j$  of the integral equations given by Equation (25) and also the ratio  $S/N_0$  where  $S$  is the power in the "signal",  $n_0(t)$  and  $N_0$  is the noise per cycles/second of bandwidth for the additive white noise. A computer was used to calculate  $P_e$  for various values of  $(\alpha T)$  as  $ST/N_0$  varied over a range of values. These results are discussed in a later section.

## 5. CASE 2

The second case differs from the first in the way in which the additive white noise is treated. Now it is assumed that the cross-correlations are each preceded by additional RLC filters which are not dumped at the end of each pulse period. Furthermore,

the spectrum of the noise  $n_0(t)$  is assumed to be wide compared to the bandwidth of the RLC filter centered at  $\omega_0$  so that it can be considered as a white noise input. However, the separation between  $\omega_0$  and  $\omega_1$  is assumed wide enough so that  $n_0(t)$  can be ignored as an input to the filters centered at  $\omega_1$ . The actual receiver structure and the circuit which is claimed as equivalent for calculation purposes are shown in Figure (6a) and (6b) respectively.

The analysis for Case 2 is performed in a similar fashion to that of Case 1. The resultant expression for probability of error is

$$P_e = \lim_{N \rightarrow \infty} \sum_{j=1}^N \frac{1}{(1 + \mu) \prod_{\substack{i=1 \\ i \neq j}}^N \left(1 + \mu \frac{\lambda_i^2}{\lambda_j^2}\right) \left(1 - \frac{\lambda_i^2}{\lambda_j^2}\right)} \quad (66)$$

where 
$$\mu = \frac{\text{signal power} + \text{noise power}}{\text{noise power}} \quad (67)$$

and again  $\lambda_j$  are the eigenvalues of the integral equation given in Equation (25). Computer results are also given for Case 2 in the next section.

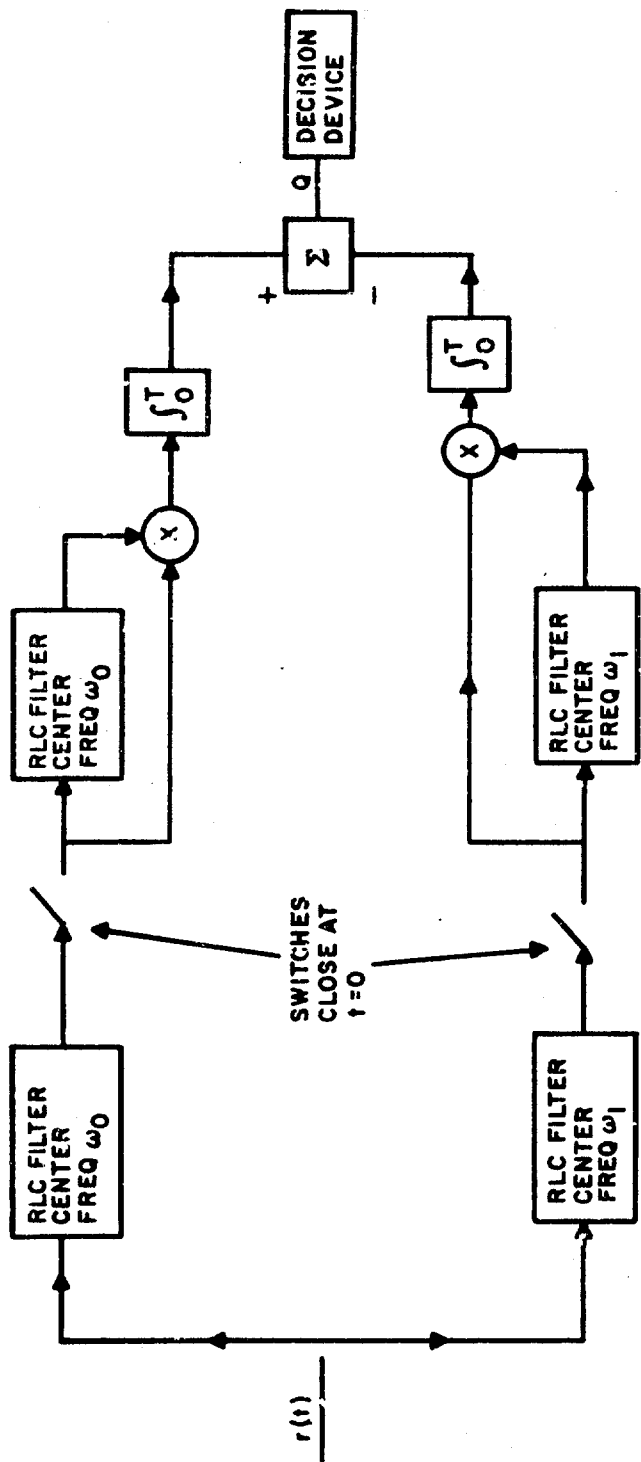

## 6. COMPUTER EVALUATION OF ERROR PROBABILITIES

In order to compare Cases 1 and 2, a common set of parameters must be defined. In the introduction, it was seen that error probability expressions were always expressed in terms of the ratio  $E/N_0$  where

$$\frac{E}{N_0} = \frac{\text{energy in the signal for one pulse period}}{\text{noise power density}} \quad (68)$$

This ratio will also be used for the two cases considered here. The second parameter was chosen as the dimensionless "time-bandwidth" product,  $\beta$ , defined as

$$\beta = \frac{\alpha T}{2} \quad (69)$$

(a) ACTUAL CIRCUIT FOR CASE 2.

(b) EQUIVALENT CIRCUIT FOR CASE 2.

Figure 6. Receiver for Case 2

Furthermore, it is easily shown that the expressions for error probability depend only on the parameter  $\beta$  and not on the individual values of  $\alpha$  and  $T$ . Thus we can arbitrarily set  $\alpha$  equal to 10 so that

$$\beta = 5T$$

In terms of these two parameters ( $\beta$  and  $E/N_0$ ) the two expressions for probability of error become

Case 1

$$P_e = \lim_{N \rightarrow \infty} \sum_{j=1}^N \frac{1}{2 \left(1 + \frac{5E}{N_0} \frac{\lambda_j}{\beta}\right) \prod_{\substack{i=1 \\ i \neq j}}^N \left[1 + \left(1 + \frac{10E}{N_0} \frac{\lambda_i}{\beta}\right) \frac{\lambda_i}{\lambda_j}\right] \left[1 - \frac{\lambda_i}{\lambda_j}\right]} \quad (70)$$

Case 2

$$P_e = \lim_{N \rightarrow \infty} \sum_{j=1}^N \frac{1}{(1 + \mu) \prod_{\substack{i=1 \\ i \neq j}}^N \left(1 + \mu \frac{\lambda_i^2}{\lambda_j^2}\right) \left(1 - \frac{\lambda_i^2}{\lambda_j^2}\right)} \quad (71)$$

where

$$\mu = 1 + \frac{E}{N_0} \frac{\pi}{2\beta}$$

A slightly different parameter that could be used in describing the performance of the system is the one-sided three db bandwidth "B" given as:

$$B = \frac{\alpha}{2\pi} = \frac{\beta}{\pi T} \text{ (cycles/second)} \quad (72)$$

In terms of this parameter, the two probabilities of error become:

Case 1:

$$P_e = \lim_{N \rightarrow \infty} \sum_{j=1}^N \frac{1}{2 \left(1 + \frac{5}{\pi} \frac{E}{N_0} \frac{\lambda_j}{BT}\right) \prod_{\substack{i=1 \\ i \neq j}}^N \left[1 + \left(1 + \frac{10}{\pi} \frac{E}{N_0} \frac{\lambda_i}{BT}\right) \frac{\lambda_i}{\lambda_j}\right] \left[1 - \frac{\lambda_i}{\lambda_j}\right]} \quad (73)$$

Case 2:

$$P_e = \lim_{N \rightarrow \infty} \prod_{j=1}^N \frac{1}{(1 + \mu) \prod_{\substack{i=1 \\ i \neq j}}^N \left(1 - \mu \frac{\lambda_i^2}{\lambda_j^2}\right) \left(1 - \frac{\lambda_i^2}{\lambda_j^2}\right)} \quad (74)$$

where

$$\mu = 1 + \frac{E}{N_0 (2BT)}$$

The performance curves to be presented give the probability of error versus  $E/N_0$  (measured in db.) for various values of  $BT$ .

## 7. COMPUTATION OF EIGENVALUES

The next step is the computation of the eigenvalues ( $\lambda_i$ 's) to be substituted into Equations (70) and (71). These eigenvalues which satisfy the integral equation given by Equation (25) have been shown<sup>(12)</sup> to be related to the non-negative roots of the transcendental equations

$$\tan z = \beta/z \quad (75a)$$

$$\cot z = -\beta/z \quad (75b)$$

As can be seen from Figure 7, the smallest root,  $z_1$ , is a solution of (75a), the next smallest root,  $z_2$ , is a solution of (75b), etc., with the roots alternating between the two equations. The derived eigenvalues are related to the roots by the equation:

$$\lambda_i = \frac{\beta T}{\beta^2 + z_i^2} \quad (76)$$

Two checks that were used in the computation of these eigenvalues were:

- (a) The sum of the eigenvalues should equal  $T$
- (b) The  $n^{\text{th}}$  root of Equation (75a) should fall in the interval  $(n-1)\pi < z < (n-1/2)\pi$  while the  $n^{\text{th}}$  root of Equation (75b) should fall in the interval  $(n-1/2)\pi < z < n\pi$ . Furthermore, as  $n$  increases, the root occurs very close to the lower limit of allowed values.

Figure 7

## 8. COMPUTATION OF ERROR PROBABILITIES

The mathematical forms of the computation [Equations (70), (71), (75), (76)] were programmed in FORTRAN IV. The programs for cases 1 and 2 are given in the Appendix. BT products of 0.5, 1.0, 2.0, 3.0, 4.0, and 5.0 were evaluated for  $E/N_0$  ratios of 6 db through 24 db in increments of two db. Tabulations of these outcomes follow with their corresponding graphs. (Figures 9 through 11.)

## 9. CALCULATIONS FOR OTHER FILTERS

The techniques outlined in this paper can be used for filter forms other than the RLC. In particular, if the noise processes  $n_0(t)$  and  $n_1(t)$ , as given in equation (7), are such that

$$S_{x_i x_i}(\omega) = \mathcal{F}[R_{x_i x_i}(\tau)] = \begin{cases} \frac{S}{2B}, & |\omega| \leq 2\pi B \\ 0, & |\omega| > 2\pi B \end{cases} \quad (77)$$

$$s_{y_i y_i}(\omega) = \mathcal{F}[R_{y_i y_i}(\tau)] = \begin{cases} \frac{S}{2B}, & |\omega| \leq 2\pi B \\ 0, & |\omega| > 2\pi B \end{cases} \quad (78)$$

and if the receiver filters given in Figures 4 and 6 have transfer functions which have unity gain over a pass-band of bandwidth  $2B$  (cycles/second) centered at  $\omega_0$  and  $\omega_1$ , and zero gain elsewhere, then the error probabilities given in Equations (73) and (74) still apply if the  $\lambda_i$  are the solutions to the integral equation

$$\int_0^T \frac{\sin 2\pi B \tau}{2\pi B \tau} \phi_i(\tau) d\tau = \lambda_i \phi_i(t) \quad 0 \leq t \leq T \quad (79)$$

Eigenvalues for this integral equation with a different normalization are given by Jacobs<sup>(8)</sup>.

To arrive at an appropriate normalization consider the following. In the cases first examined a one-sided filter bandwidth was used exclusively, that is,

$$B = \frac{\alpha}{2\pi}$$

For the case of the flat spectrum, the double-sided bandwidth is used

$$B' = \frac{\alpha}{\pi} \quad (80)$$

CASE 1: FLAT SPECTRUM

Figure 14

Thus, to get correct results, we must divide the flat spectrum eigenvalues by  $B'$ , or

$$\lambda_i = (\lambda'_i) \frac{B'}{10} \quad (83)$$

Note that when the flat spectrum eigenvalues are used, the normalization in Equation (83) will not make any difference since the eigenvalues always occur as  $\lambda_i^2/\lambda_j^2$ , thereby canceling the normalization. It will, however, make a difference in case one.

These eigenvalues normalized such that  $\sum_1 \lambda_i = T$  are listed in Table 7 (Appendix).

The results obtained using these eigenvalues for the two cases are given in Figures 13 and 15.

## 10. CONCLUSIONS

This report considers a sub-optimum receiver for binary frequency shift keyed (FSK) transmission which experiences fast fading and additive Gaussian white noise. The received signal is modeled as one of two narrow band Gaussian processes (whose center frequencies correspond to the frequencies used in the binary FSK transmission) corrupted by additive Gaussian white noise. The half-bandwidth of each narrow band process is  $B$  (cps) and the pulse duration is  $T$  (seconds).

A receiver is considered which passes the received waveforms through one of two narrow band filters (with center frequencies as above) and cross-correlates the outputs of these filters with the received waveform. The receiver makes a decision every  $T$  seconds as to which frequency was transmitted by choosing that frequency corresponding to the larger value of the cross-correlation. Two slightly different forms of this receiver are analyzed and curves for the probability of error versus the ratio of energy per bit to noise power density ( $E/N_0$ ) for each receiver are presented with the product  $BT$  as a parameter. Two different spectra for the narrow band processes are studied.

The following conclusions were derived from the results. First, increasing  $BT$  does not give a constant improvement in probability of error for a fixed value of  $E/N_0$ . In fact, the rate of improvement diminishes as  $BT$  increases. It can further be noted that for  $E/N_0$  greater than about 13 db a higher  $BT$  corresponds to a better system with the opposite effect for lower  $E/N_0$ . The results for  $BT = 0.5, 1.,$  and  $2.$  (for a particular spectrum) appear to be in essential agreement with those obtained experimentally by Cossette and Wolf<sup>(7)</sup> who used a slightly different receiver.

The results of this report would have practical importance if it were found that the receivers analyzed were easier to construct than the conventional receiver for this type of modulator and channel behavior. However, the practical aspects of the receiver design lay outside the realm of this study.

13. ABSTRACT		
<p>A common type of digital communication system is binary frequency shift keying (FSK) whereby every T seconds the transmitter sends a pulse of one of two frequencies. The receiver makes a decision (every T seconds) as to which frequency was transmitted. A sub-optimum receiver for this case obtains estimates of the two noise waveforms by passing received signals through filters centered at the sending frequencies and then crosscorrelates these estimates with the received waveform. Two slightly different versions of this cross-correlator were considered, and the probability of error for each case was calculated. The results seem to agree with previous experimental work by Cossette and Wolf.</p>
