14. ABSTRACT

The antifungal armamentarium for the treatment of systemic fungal infections has increased in recent years. Although very helpful to control/ eliminate fungal infections, the available antifungal drugs do have some limitations such as antifungal drug resistance. As an example, azole resistance is an issue in patients with chronic mucocutaneous candidiasis caused by C. albicans in the context of HIV-infected individuals with recurrent oropharyngeal and esophageal candidiasis. A similar trend in vaginal isolates of C. albicans has been seen in women prone to recurrent vaginal candidiasis exposed to long-term fluconazole (Bulik et al., 2009),(Shahid and Sobel, 2009). In the latter scenario – fortunately relatively rare to date – therapeutic options available for oral management of fluconazole-reduced susceptibility C. albicans are few, resulting in the inconvenient use of long-term topical imidazoles. These facts have generated greater interest in the development of new antifungal drugs using various synthetic and naturally occurring antimicrobial molecules. Natural antimicrobial peptides, such as defensins produced by epithelial cells, showed a broad range of antibacterial activity and could play a role in preventing microbial infections(Decanis et al., 2009), (Zaslof, 2002). These antimicrobial peptides generally exhibit selective toxicity for microorganisms and show fewer propensities to induce microbial resistance.

1-INTRODUCTION: The antifungal armamentarium for the treatment of systemic fungal infections has increased in recent years. Although very helpful to control/eliminate fungal infections, the available antifungal drugs do have some limitations such as antifungal drug resistance. As an example, azole resistance is an issue in patients with chronic mucocutaneous candidiasis caused by *C. albicans* in the context of HIV-infected individuals with recurrent oropharyngeal and esophageal candidiasis. A similar trend in vaginal isolates of *C. albicans* has been seen in women prone to recurrent vaginal candidiasis exposed to long-term fluconazole (Bulik *et al.*, 2009)·(Shahid and Sobel, 2009). In the latter scenario – fortunately relatively rare to date – therapeutic options available for oral management of fluconazole-reduced susceptibility *C. albicans* are few, resulting in the inconvenient use of long-term topical imidazoles. These facts have generated greater interest in the development of new antifungal drugs using various synthetic and naturally occurring antimicrobial molecules. Natural antimicrobial peptides, such as defensins produced by epithelial cells, showed a broad range of antibacterial activity and could play a role in preventing microbial infections(Decanis *et al.*, 2009)·(Zaslof, 2002). These antimicrobial peptides generally exhibit selective toxicity for microorganisms and show fewer propensities to induce microbial resistance.

***Scope of the research* :** For the development of alternative antifungal treatment, we have synthesized an α-helical antimicrobial decapeptide, KSL (KKVVFKVKFK), and its analog, KSL-W (KKVVFWVKFK)(Na *et al.*, 2007), which possess a broad range of antibacterial activity. It killed selected strains of non-oral and oral pathogens, including mutans streptococci. In combination with a surface-active agent, benzalkonium chloride, the peptide significantly reduces *in vitro* biofilm growth(Dixon *et al.*, 2008; Dixon *et al.*, 2009; Leung *et al.*, 2005; Leung *et al.*, 2009).

2-KEYWORDS: Fungal treatment, *C. albicans*, Antifungal molecules, fungi resistance, antimicrobial peptides, cationic peptides, chemical peptides, KSL-W.

3-**ACCOMPLISHMENTS:** There was no change as to the original proposal.

The primary goals of this study were:

1. To investigate the effect of antimicrobial peptide KSL-W on *C. albicans* growth and biofilm formation under the activation of virulence genes.
2. To investigate the effect of KSL-W on human gingival cell growth and migration/wound healing.

Accomplished work

Major activities: We conducted a complete study evaluation the effect of KSL-W on *C. albicans* growth and pathogenesis. **We also conducted a significant study investigating the effect of KSL-W on in vitro wound healing.**

Effect of KSL-W on *C. albicans*:

1) **We specifically** studied the *C. albicans growth, transition and virulence gene (*EFG1, NRG1, EAP1, HWP1, and SAP 2-4-5-6) expression following yeast contact with KSL-W.

2) ***Results:*** We demonstrated that KSL-W markedly reduced *C. albicans* growth at both early and late incubation times. The significant effect of KSL-W on *C. albicans* growth was observed beginning at ten μg/ml after five h of contact by reducing *C. albicans* transition and at 25 μg/ml

by completely inhibiting *C. albicans* transition. Cultured *C. albicans*under biofilm-inducing conditions revealed that both KSL-W and amphotericin B significantly decreased biofilm formation at 2, 4, and six days of culture. KSL-W also disrupted mature *C. albicans* biofilms. The effect of KSL-W on *C. albicans* growth, transition, and biofilm formation/disruption may thus occur through gene modulation, as the expression of various genes involved in *C. albicans* growth, transition and biofilm formation were all down-regulated when *C. albicans* was treated with KSL-W. The effect was greater when *C. albicans* was cultured under hyphae-inducing conditions. These data provide new insight into the efficacy of KSL-W against *C. albicans* and its potential use as an antifungal therapy.

Effect KSL-W on *wound healing*:

1) **We** specifically investigated the effect of KSL-W on human gingival fibroblasts growth/proliferation, the secretion of metalloproteinas, and their inhibitors, fibroblast migration following wound/scratch, and the KSL-W interaction with fibroblasts to prevent infection by *S. mutans.*

2) **Results:** We were able to demonstrate that KSL-W increased the proliferation of gingival fibroblasts through the S and G2/M cell cycle phases. The peptide regulated the secretion of metalloproteinase (MMP)-1 and -2 and their inhibitors TIMP-1 and TIMP-2. Using an *in vitro* wound healing assay, we demonstrated that KSL-W increased the migration of fibroblasts following scratch. Interestingly, the addition of KSL-W peptide to *S. mutans* infected fibroblast culture prevents adverse effect of the bacteria through fibroblast growth and the secretion of IL-8.

All needed information's related to the different protocols we used, and the figures about to the results are included in the published or submitted manuscripts (see appendix 1). As a conclusion, we clearly demonstrated the efficacy of KSL-W on influencing *C. albicans* growth, phase transition and expression of virulence genes. This suggested the usefulness of KSL-W against *C. albicans* pathogenesis. We also demonstrated that KSL-W do not have an adverse effect on human gingival fibroblasts. Furthermore, KSL-W was contributing to increasing wound healing process in vitro. However, the use of KSL-W for clinical applications should first be supported by *in vitro* studies using human cells to confirm the non-toxicity of the peptide.

Training:

1. A student was involved in the project under his Master degree achievement. He was involved in the experimental protocols with *C. albicans*, data collections, and manuscript preparation.
2. The student contributed in presenting the work on antimicrobial peptide KSL-W on the research day of the Faculty of Dentistry, and at the Medical faculty of Laval University.
3. One Postdoc was involved in the objective 2 related to investigating the effect of KSL-W on wound healing. This Postdoc was also involved in writing and submitting the manuscript for publication in a pair review scientific journal.
4. The Postdoc contributed presenting the data related to the efficacy of KSL-W on wound healing at the 10th research day of the Faculty of Dentistry of Laval University.

Results dissemination:

The results were disseminated through publications and presentations.

4-IMPACT: The major accomplishment is the understanding the mechanism(s) by which antimicrobial peptide KSL-W in reducing *C. albicans* pathogenesis *in vitro*. The other important achievement is the demonstration for the first time that KSL-W can promote wound healing. This demonstrated by increasing primary human gingival fibroblast growth, migration and the secretion of IL-8 mediators. **It is important to conceive further studies to support such innovative results related to the implication of KSL-W in wound healing. This can include gingival human epithelial cells as monolayers, but also a three dimensional engineered human oral mucosa to mimic the real wound healing process in human.**

The impact on the development of the principal discipline(s) of the project
We clearly demonstrated that KSL-W was effective in reducing *C. albicans* growth, transition through the down-regulation of certain important genes involved in biofilm formation. This consolidates the previous studies on inhibition of bacterial growth and suggests the potential use of KSL-W against microbial infections in human. We also demonstrated for the first time the implication of KSL-W in promoting wound healing.

The impact on other disciplines
Nothing to Report.

The impact on technology transfer
Nothing to Report.

The impact on society beyond science and technology
Our studies demonstrated the potential use of KSL-W to:

1. Control bacterial and fungal infections in human and probably in animals.
2. To promote wound healing in human, as the peptide increases in vitro wound healing parameters of human gingival fibroblasts.
3. Eventually the data generated through these studies may suggest the use of KSL-W to control infection and minimize the emergence of microbial resistance. Such improvement may be of great economic improvement in reducing infection and promoting person health. This will allow more active work, thus economic improvement. It may also be very important for the design of new antimicrobial molecules, thus giving good treatment alternative, and creating more jobs.

7-PARTICIPANTS & OTHER COLLABORATING ORGANIZATIONS

What individuals have worked on the project?

See below Tables.

Name:	Simon Theberge
Project Role:	Graduate Student
Researcher Identifier (e.g. ORCID ID):	University Laval Student
Nearest person month worked:	20 h a week
Contribution to Project:	M. Theberge has performed a large part of the experimental protocol related to the evaluation of the effect of KSL-W on C. albicans.
Funding Support:	

Name:	M. Abdelhabib Semlali
Project Role:	Post-Doc, then collaborator, visiting professor
Researcher Identifier (e.g. ORCID ID):	
Nearest person month worked:	Five h a week
Contribution to Project:	M. Semlali has supervised the grad student.
Funding Support:	Laval University Foundation

Name:	Abdullah Alamri
Project Role:	Graduate Student
Researcher Identifier (e.g. ORCID ID):	University Laval student
Nearest person month worked:	5
Contribution to Project:	M. Alamri contributed, with the grad student M. Teberge to perform the genes expression protocols and data collection and analyses.
Funding Support:	

Name:	Mabrouka Salem

Project Role:	Technical support
Researcher Identifier (e.g. ORCID ID):	University Laval student
Nearest person month worked:	5
Contribution to Project:	She was involved in the cell preparation to perform the wound healing experiments.
Funding Support:	

Name:	Hyun Jin Park
Project Role:	Postdoc student
Researcher Identifier (e.g. ORCID ID):	University Laval student
Nearest person month worked:	15
Contribution to Project:	She was involved in performing most of the study related to the wound healing with KSL-W
Funding Support:	

Name:	Leung KP
Project Role:	Collaborator
Researcher Identifier (e.g. ORCID ID):	
Nearest person month worked:	5
Contribution to Project:	K. Leung has contributed the study design and manuscript revision.
Funding Support:	

Has there been a change in the active other support of the PD/PI(s) or senior/key personnel since the last reporting period?
Nothing to Report.

The Organizations involved as partners

The University Laval as an involved organization.

At the dental Faculty of Laval University, I was able to use different equipment to perform the study and get publishable results. Without such in-kind supports, the study would be very

difficult/impossible to realize. The equipment's at the research center of the Dental Faculty at Laval University were obtained thanks to the financial supports of University Laval and different funds that Dr Rouabhia obtained previously from different funding agencies. These include the CIHR, NSERC, FRSQ, the Fonds Émile-Beaulieu at the dental Faculty of Laval University, and so.

RESEARCH ARTICLE Open Access

C. albicans growth, transition, biofilm formation, and gene expression modulation by antimicrobial decapeptide KSL-W

Simon Theberge[1], Abdelhabib Semlali[1,2], Abdullah Alamri[1], Kai P Leung[3] and Mahmoud Rouabhia[1*]

Abstract

Background: Antimicrobial peptides have been the focus of much research over the last decade because of their effectiveness and broad-spectrum activity against microbial pathogens. These peptides also participate in inflammation and the innate host defense system by modulating the immune function that promotes immune cell adhesion and migration as well as the respiratory burst, which makes them even more attractive as therapeutic agents. This has led to the synthesis of various antimicrobial peptides, including KSL-W (KKVVFWVKFK-NH_2), for potential clinical use. Because this peptide displays antimicrobial activity against bacteria, we sought to determine its antifungal effect on *C. albicans*. Growth, hyphal form, biofilm formation, and degradation were thus examined along with EFG1, NRG1, EAP1, HWP1, and SAP 2-4-5-6 gene expression by quantitative RT-PCR.

Results: This study demonstrates that KSL-W markedly reduced *C. albicans* growth at both early and late incubation times. The significant effect of KSL-W on *C. albicans* growth was observed beginning at 10 μg/ml after 5 h of contact by reducing *C. albicans* transition and at 25 μg/ml by completely inhibiting *C. albicans* transition. Cultured *C. albicans* under biofilm-inducing conditions revealed that both KSL-W and amphotericin B significantly decreased biofilm formation at 2, 4, and 6 days of culture. KSL-W also disrupted mature *C. albicans* biofilms. The effect of KSL-W on *C. albicans* growth, transition, and biofilm formation/disruption may thus occur through gene modulation, as the expression of various genes involved in *C. albicans* growth, transition and biofilm formation were all downregulated when *C. albicans* was treated with KSL-W. The effect was greater when *C. albicans* was cultured under hyphae-inducing conditions.

Conclusions: These data provide new insight into the efficacy of KSL-W against *C. albicans* and its potential use as an antifungal therapy.

Keywords: Antimicrobial peptide, KSL-W, *C. albicans*, Growth, Hyphae, Gene, EFG1, NRG1, HWP1, SAPs

Background

The innate defense system plays a key role in protecting the host against microorganism-fueled infections such as candidiasis caused by *Candida albicans*. *C. albicans* colonizes several body sites, including the oral cavity; however, as a commensal organism, it causes no apparent damage or inflammation in the surrounding tissue [1,2]. *C. albicans* is a polymorphic organism that adheres to different surfaces in the body and can grow as yeast, pseudohyphae, and hyphae [3], usually in the form of biofilm. *C. albicans* transition, biofilm formation, and pathogenesis are under the control of various genes. The *HWP1* gene encodes the hyphal cell wall protein, which is a hyphal-specific adhesin that is essential to biofilm formation [4]. The involvement of *HWP1* in *C. albicans* adhesion is supported by the *EAP1* gene which encodes a glucan-crosslinked cell wall protein (adhesin Eap1p). Together, these components mediate *C. albicans* adhesion to various surfaces, such as epithelial cells and polystyrene [5]. Like many other genes, *HWP1* and *EAP1* are downstream effectors of EFG1 and NRG1 as transcription factors [6,7]. *EFG1* mutant strain has been shown to exhibit defects in growth, biofilm formation, and virulence [8], while NRG1 represses filamentous growth [3]. This occurs through the DNA binding protein Nrg1p in conjunction with the global transcriptional repressor

Full list of author information is available at the end of the article

Tup1p to suppress hyphal formation. Elevated NRG1 expression represses the expression of a number of hypha-specific genes, although NRG1 downregulation is associated with *C. albicans* filaments [3].

C. albicans virulence is also mediated by proteolytic enzymes, including secreted aspartyl proteinases (SAPs) [9,10]. The contribution of SAPs in *C. albicans* adherence, tissue damage, and evasion of host immune responses has been reported [9]. SAP2 is crucial to *C. albicans* growth in protein-containing media [11]. SAP1 and SAP3 are expressed during phenotypic switching [12,13], while SAP4, SAP5, and SAP6 are expressed upon hyphal formation [14], and SAPs 1-6 and 9-10 are involved in the adhesion mechanism to host cells [15].

To control *C. albicans* pathogenesis, the host innate immunity uses small molecules such as proteins and peptides that display a broad antimicrobial spectrum. The number of identified potentially antimicrobial peptides is significant and continues to increase [16]. Antimicrobial peptides often possess common attributes, such as small size, an overall positive charge, and amphipathicity [17,18]; however, they also fall into a number of distinctively diverse groups, including α-helical peptides, β-sheet peptides, peptides with mixed α-helical and β-sheet structures, extended peptides, and peptides enriched in specific amino acids [16].

In humans, epithelial cells and neutrophils are the most important cells producing antimicrobial peptides [19,20]. These peptides are most often antibacterial, although antifungal activity has also been reported [16,21]. The major peptide groups known to date are the histatins, cathelicidins, defensins, and lactoferricins [22]. The antimicrobial activity of these peptides has been reported by different *in vitro* and *in vivo* studies [19,20,22]. Their complex role as well as their contribution to host defenses may be related to the functional interrelationship between innate and adaptive immunity [23,24].

The interest in antimicrobial peptides lies in the possible resistance of microorganisms to conventional antimicrobial strategies used against microbial pathogens in both agriculture and medicine [25,26]. Natural antimicrobial peptides are necessary in the control of microbial infections. For example, the use of AMPs provided protection against such microbial pathogens as fungal pathogens, with no reported effect on the host [27,28]. Based on these promising data, a number of synthetic AMPs have been designed to overcome microbial infections [29]. In the pursuit of a novel alternative antifungal treatment, we developed a synthetic α-helical antimicrobial decapeptide, KSL (KKVVFKVKFK), and its analogue KSL-W (KKVVFWVKFK) [30].

The efficacy of KSL on a wide range of microorganisms has been established [31-33], as well as its ability to disrupt oral biofilm growth [34]. KSL-W, a recently synthesized KSL analogue, was shown to display improved stability in simulated oral and gastric conditions with *in vitro* preserved antimicrobial activity [30]. Furthermore, combined with sub-inhibitory concentrations of benzalkonium chloride, a known cationic surface-active agent [35], KSL was shown to significantly promote bacterial biofilm susceptibility. We also recently demonstrated that KSL-W had a selective effect on *C. albicans* growth, while exhibiting no toxic effect on epithelial cells [36].

As this KSL-W analogue displays a wide range of microbicidal activities, effectively kills bacteria, controls biofilm formation, and destroys intact biofilms, we hypothesized that KSL-W may also possess antifungal potential. Our goal was thus to investigate the ability of KSL-W to inhibit *C. albicans* growth and transition from blastospore to hyphal form. The action of KSL-W on biofilm formation/disruption was also assessed. Finally, we examined the effect of KSL-W on various *C. albicans* genes involved in its growth, transition, and virulence.

Results

Antimicrobial peptide KSL-W reduced *C. albicans* growth and transition from blastospore to hyphal form

C. albicans cultures were incubated with KSL-W for 5, 10, and 15 h to determine whether this antimicrobial peptide had any adverse effect on *C. albicans* growth. As shown in Figure 1, KSL-W significantly reduced *C. albicans* proliferation. After 5 h of contact with KSL-W, the growth inhibition of *C. albicans* was between 30 and 80%, depending on the concentration of KSL-W used (Figure 1A). After 10 h of contact with KSL-W, growth inhibition was significant, beginning at 25 μg/ml (Figure 1B). At later culture periods, *C. albicans* growth continued to be significantly affected by the presence of KSL-W (Figure 1C). Indeed, with 25 μg/ml of KSL-W, *C. albicans* growth was almost half that in the controls (non-treated *C. albicans* cultures), and with 100 μg/ml of KSL-W, *C. albicans* growth was reduced by almost 60%. It is interesting to note that KSL-W in as low as 25 μg/ml was effective at both the early and late culture periods.

As KSL-W contributed to *C. albicans* growth inhibition, we hypothesized that it would also downregulate *C. albicans* transition from yeast form to hyphal phenotype. Yeast cultures supplemented with 10% FBS and the KSL-W peptide were maintained for various incubation periods. As shown in Figure 2, germ tube formation was inhibited as early as 4 h following exposure to the peptide, compared to that in the cultures incubated in the absence of KSL-W. Of interest is the elevated number of *C. albicans* hyphal forms in the negative control culture (no KSL-W or amphotericin B) compared to the low number in the presence of KSL-W. The effect of this

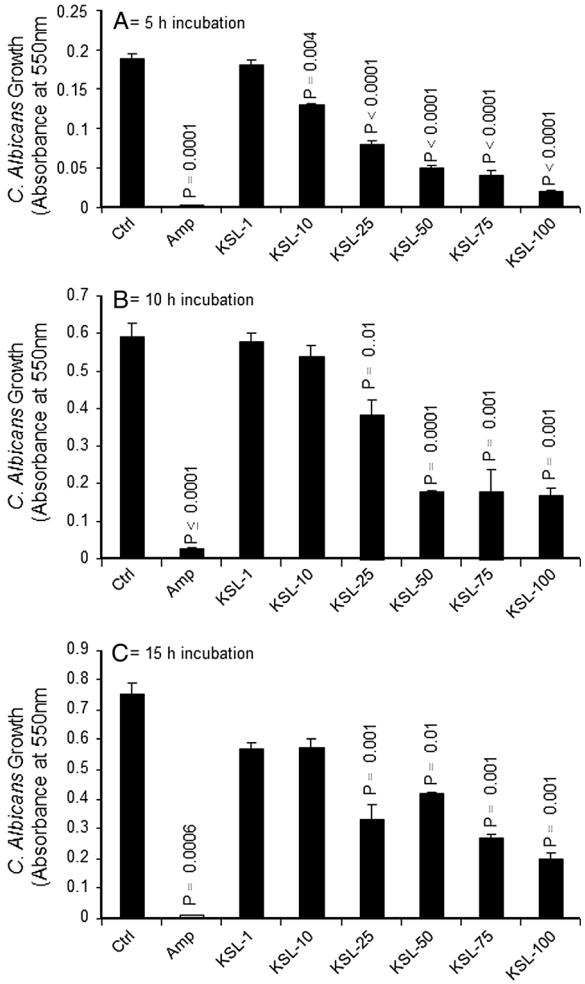

Figure 1 KSL-W inhibited *C. albicans* growth. The yeast was cultured in Sabouraud supplemented medium with or without KSL-W at various concentrations. The cultures were maintained for 5, 10, and 15 h at 37°C, after which time an MTT assay was performed for each culture condition. The growth was plotted as means ± SD of the absorbance at 550 nm. **(A)** *C. albicans* growth with KSL-W for 5 h; **(B)** *C. albicans* growth with KSL-W for 10 h; and **(C)** *C. albicans* growth with KSL-W for 15 h. The levels of significance for *C. albicans* growth in the presence or not of KSL-W or amphotericin B (10 μg/ml) were considered significant at $P < 0 \cdot 05$.

antimicrobial peptide on *C. albicans* transition was also dose-dependent: at 1 μg/ml, a significant number of hyphal forms remained, and at only 5 μg/ml of KSL-W, *C. albicans* transition was completely inhibited (Figure 2). Semi-quantitative analyses using inverted microscope observations to estimate the hyphal forms confirmed the inhibited *C. albicans* transition when treated with KSL-W (Table 1). The density of the hyphae was reduced as early as 4 h of contact with 5 μg/ml of KSL-W. This effect was further supported when *C. albicans* was placed in contact with KSL-W for 8 h (Table 1), thus confirming that KSL-W downregulated *C. albicans* growth and transition.

KSL-W reduced *C. albicans* biofilm formation

As KSL-W contributed to reducing *C. albicans* growth and transition, we sought to determine whether it also displayed inhibitory activity against *C. albicans* biofilm formation. Using a biofilm-promoting scaffold, SEM analyses, and an XTT assay, we were able to demonstrate the inhibitory effect of KSL-W on biofilm formation (Figure 3). SEM analyses revealed a significant density of *C. albicans* in the untreated culture, compared to a lower density in the scaffold in the presence of KSL-W (1 and 25 μg/ml) after 4 days of culture. The decreases obtained with the KSL-W, particularly at 25 μg/ml (Figure 3), were comparable to that obtained with amphotericin B at 10 μg/ml. To confirm these observations, we performed quantitative analyses using the XTT assay. Figure 4A shows that after 2 days of culture, KSL-W was able to inhibit biofilm formation. This inhibitory effect was observed beginning at 25 μg/ml of KSL-W. At concentrations of 50, 75, and 100 μg/ml of KSL-W, the inhibition of *C. albicans* biofilm formation was comparable to that caused by amphotericin B at 10 μg/ml. Similar results were obtained after 4 days (Figure 4B) and 6 days (Figure 4C) of culture for biofilm formation with a persistent inhibitory effect of KSL-W on *C. albicans* biofilm formation.

KSL-W disrupted mature *C. albicans* biofilms

After 6 days of incubation in glucose-rich Sabouraud medium, scaffolds seeded with *C. albicans* strain SC5314 produced mature biofilms displaying highly dense populations of *Candida* cells (Figure 5). Significant reductions and disruptions of the pre-formed *Candida* biofilms were observed when the reference antifungal agent (amphotericin B, 10 μg/ml) was added to the mature biofilms upon further incubation up to 6 days. Similarly, antimicrobial peptide KSL-W at 75 and 100 μg/ml also reduced *C. albicans* density in the biofilms. The observed reduction was noticed with KSL-W concentrations ranging from 25 to 100 μg/ml. Indeed, when quantitatively investigated by XTT reduction assay, the KSL-W-treated biofilms rendered a significantly lower number of cells, as reflected by the lower absorbance readings, than did the untreated control. This effect was observed after 2, 4, and 6 days of treatment with amphotericin B. Furthermore, the effect of KSL-W on the mature *C. albicans* biofilm was comparable to that obtained with amphotericin B (Figure 6).

KSL-W modulated the expression of various *C. albicans* genes

Based on the data showing that KSL-W reduced *C. albicans* proliferation, transition, and biofilm formation, we sought to determine the involvement, if any, of gene regulation. For this purpose, we first investigated the

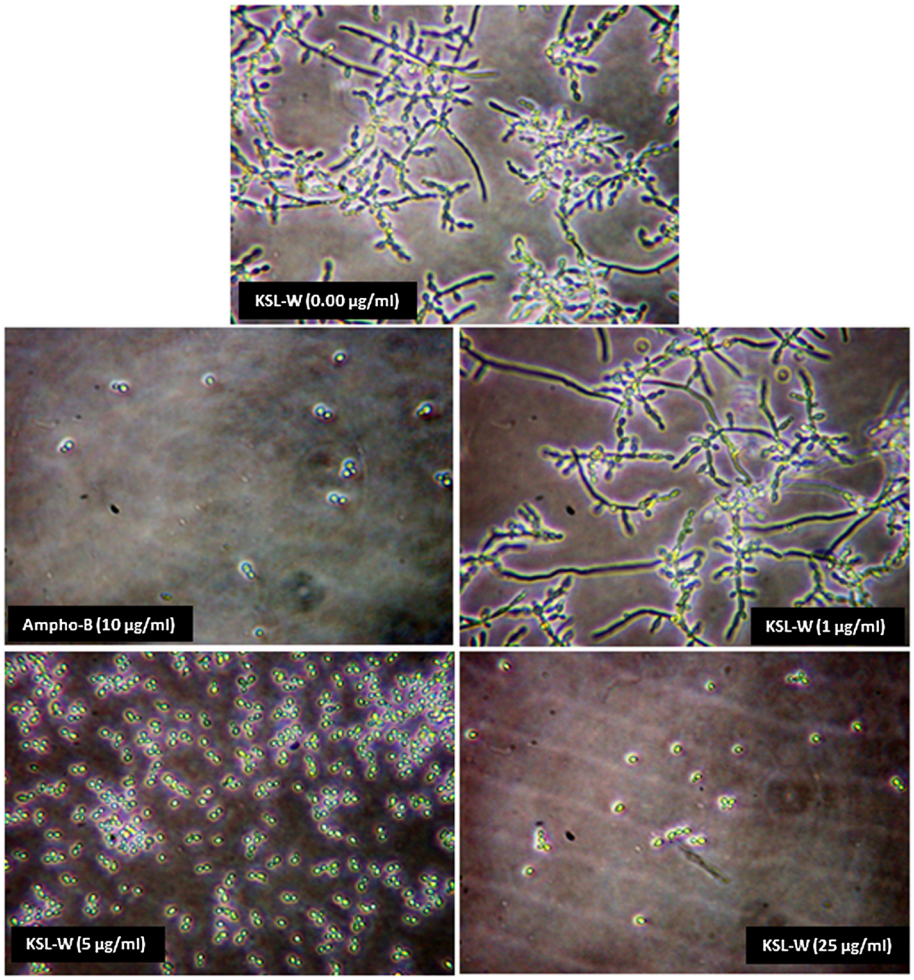

Figure 2 KSL-W inhibited *C. albicans* yeast-to-hyphae transition. *C. albicans* was cultured in Sabouraud medium containing 10% fetal bovine serum with or without KSL-W at various concentrations and was maintained for 4 and 8 h at 37°C. After each time point, the cultures were observed under an inverted microscope and photographed. Representative photos of the morphological changes after 4 h of culture are presented.

Table 1 Estimation of hyphae forms in the *C. albicans* culture

Amphotericin B	1	-	-

This Table depicts the presence of hyphae following 4 and 8 h treatments of *C. albicans* with and without KSL-W or amphotericin B. (–) refers to the absence hyphae form, and (++) refers to the presence high number of hyphae forms. These data were estimated after evaluation over 20 fields from each culture condition, by two independent and blinded examiners.

effect of KSL-W on the activation/repression of various *C. albicans* genes when cultured under normal non-hyphae-inducing conditions. The data in Table 2 indicate that the HWP1 gene was significantly downregulated following exposure of the *C. albicans* to KSL-W for 6 h. This downregulation was comparable to that observed in the amphotericin B treatment. Similarly, SAPs 2, 4, 5, and 6 were significantly downregulated by KSL-W treatment after 6 h (Table 2). This effect was observed with both low and high concentrations of KSL-W. Furthermore, the EAP1 gene, which encodes a glycosylphosphatidylinositol-anchored, glucan-crosslinked cell wall protein in both adhesion and biofilm formation *in vitro* and *in vivo*, was also affected by the KSL-W treatment. Moreover, the expression of this gene was downregulated by KSL-W, yet was upregulated (up to 5-fold) by amphotericin B.

Two other genes involved in regulating *C. albicans* morphogenesis, namely, *EFG1* and *NRG1*, are known to

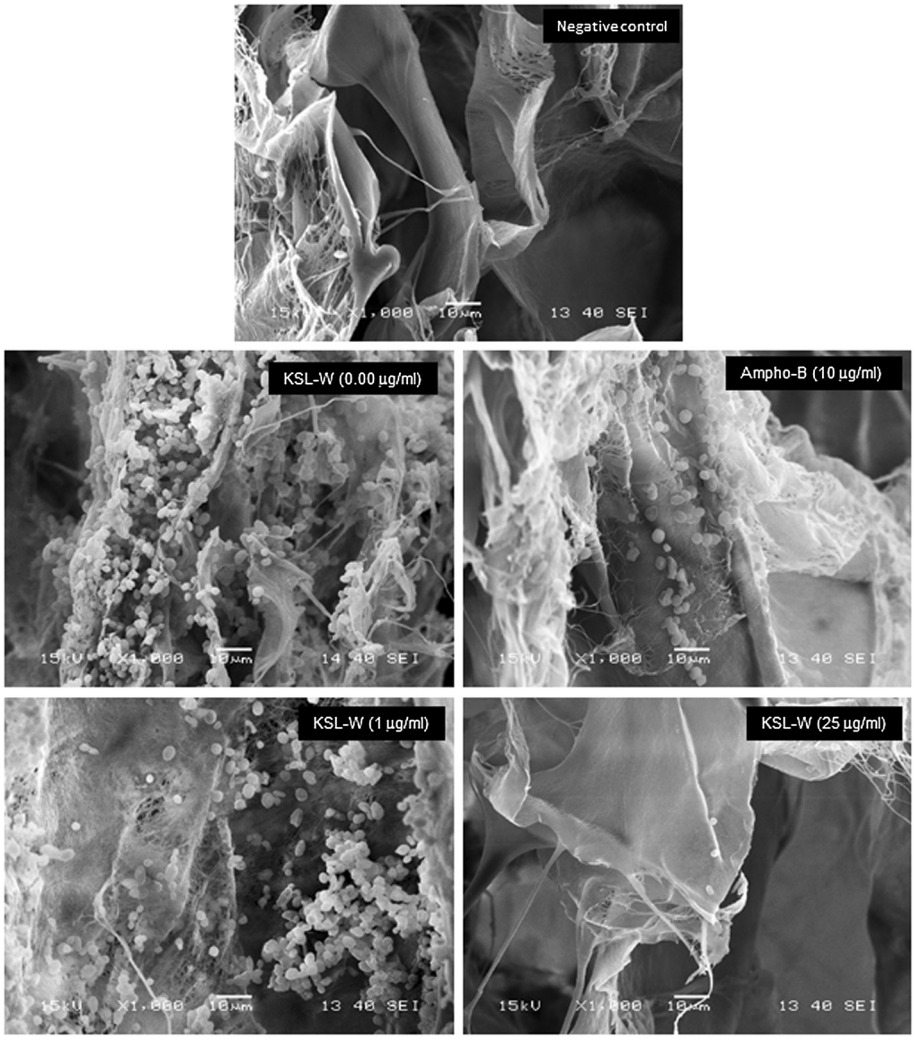

Figure 3 Scanning electron microscope analyses of the biofilm formation. *C. albicans* was cultured in Sabouraud medium with or without KSL-W at various concentrations for 4 days in a porous 3D collagen scaffold. Cultures in the presence of amphotericin B (10 µg/ml) were used as the positive controls. Following incubation, the samples were prepared as described in the Methods section and were observed under a scanning electron microscope. Negative control refers to the non-seeded scaffolds.

be hyphae repressors. In our study, amphotericin B increased both EFG1 and NRG1 mRNA expression, with twice as much expression for *NRG1* than for *EFG1* (Table 3), while KSL-W induced a less significant increase of *EFG1* and *NRG1* mRNA expression. Of interest is that a low KSL-W concentration (25 µg/ml) induced greater gene expression (Table 3).

In a second set of experiments, *C. albicans* was cultured under hyphae-inducing conditions (fetal calf serum-enriched medium with incubation at 37°C) in the presence or not of KSL-W, after which time gene expression/repression was investigated. The data in Table 4 reveal that similar to the results obtained with amphotericin-B, the *HWP1* gene was significantly ($p < 0.0001$) downregulated when *C. albicans* was exposed to KSL-W for 3 h, confirming the results obtained under non-hyphae growth conditions.

SAP genes were also modulated by KSL-W treatment. Table 4 shows that after 3 h of exposure, SAPs 2, 4, 5, and 6 were significantly ($p < 0.05$) downregulated by the KSL-W treatment. In contrast, with amphotericin-B, a significant ($p < 0.05$) increase of *SAP*s 2, 4, and 6 and a decrease of *SAP*5 was observed. It is interesting to note the opposite modulatory effects of KSL-W and amphotericin-B on *SAP* gene expression. After 6 h of treatment with KSL-W, a significant decrease of each tested *SAP* gene was observed in the exposed *C. albicans*, whereas after treatment with amphotericin-B, these same *SAP* genes increased, thus confirming the antagonistic behavior of KSL-W and amphotericin-B on *SAP* gene expression.

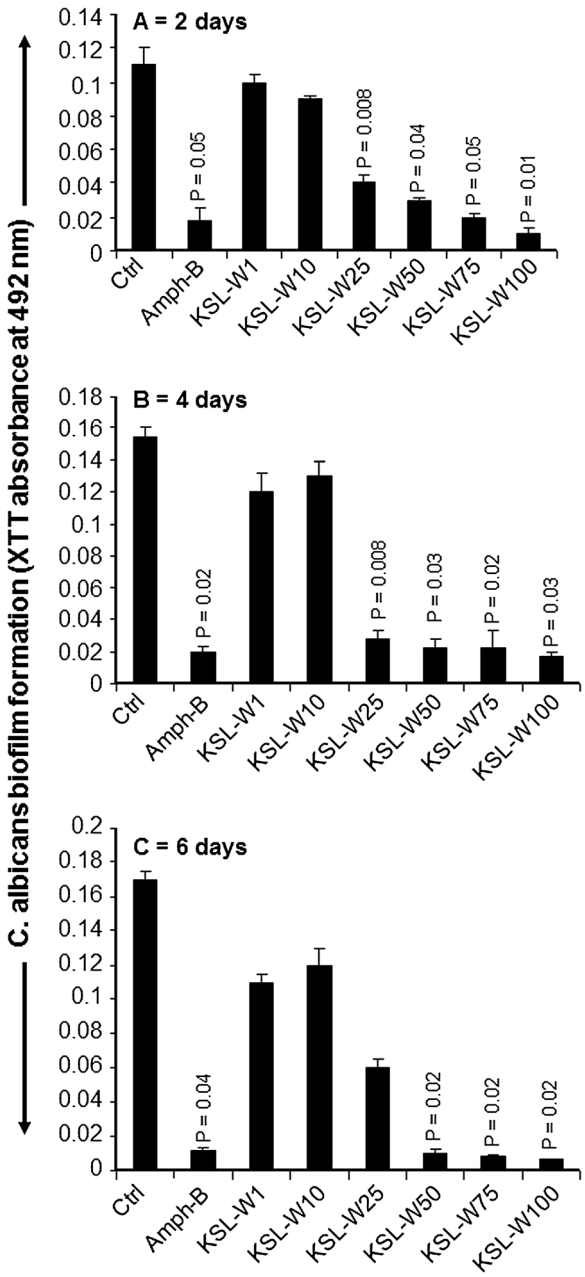

Figure 4 Quantitative measurement of the reduced biofilm formation with KSL-W. *C. albicans* was cultured on a 3D porous scaffold in the presence of KSL-W for 2, 4, and 6 days. After each culture period, the samples were supplemented with XTT solution and incubated for 5 h at 37°C. The absorbance at 450 nm was measured to quantify XTT metabolic product intensity proportional to the number of viable cells. **(A)** 2 days; **(B)** 4 days; **(C)** 6 days. Results are means ± SD for three different separate experiments.

C. albicans EAP1 gene expression was unchanged after 3 h with KSL-W, but significantly ($p < 0.001$) decreased after 6 h, while the expression of this gene was upregulated (close to six folds) by amphotericin B (Tables 4 and 5). Amphotericin B increased NRG1 mRNA expression almost threefold, with no significant effect on the *EFG1* gene, yet significantly decreased HWP1 gene expression. On the other hand, after 3 h (Table 4) and 6 h (Table 5) of incubation, KSL-W downregulated EFG1, NRG1, and HWP1 mRNA expression. Of interest is that except for similar downregulatory effects on *HWP1* gene expression, KSL-W and amphotericin-B produced once again opposite results regarding *EFG1*and *NRG1* gene expression.

Discussion and conclusions

We demonstrated that KSL-W was effective in inhibiting *C. albicans* growth at short and long culture periods. Although growth inhibition obtained with KSL-W was less than that obtained with amphotericin B, the effects of KSL-W nevertheless remain significant ($p < 0.01$). The growth inhibition effects of KSL-W are in accordance with previously reported findings [37] showing a downregulation of *C. albicans* activity induced by a bacteriocin-like peptide isolated from *Lactobacillus pentosus*. Furthermore, our results support other findings [38] reporting the effectiveness of KSL-W in disrupting *P. gingivalis*-induced hemagglutination and its synergistic interaction with host AMPs engaged in innate defense. The results strongly suggest that KSL-W is also effective against fungal growth and may be suitable for use to control *C. albicans* infections. Further studies on the possible synergistic effect of amphotericin B and KSL-W against *C. albicans* growth may provide insight.

C. albicans pathogenesis can also take place through the transition from blastospore to hyphal form [39,40]. Our results indeed show that KSL-W completely inhibited *C. albicans* transition with a concentration as low as 5 μg/ml. These data are consistent with those of other studies with naturally occurring antimicrobial peptides (e.g., β-defensins) which were effective in blocking the morphological shift of *Candida* from yeast to hyphae [41,42]. Thus KSL-W may possibly contribute to the control of *C. albicans* infection by reducing cell growth and yeast-hyphae transition. The effect of KSL-W on *C. albicans* growth can occur either through cytolysis or cell membrane disruption, resulting in cell death similar to what has been demonstrated with histatin-5 [43,44]. Indeed, it was shown that histatin-5 induces the selective leakage of intracellular ions and ATP from yeast cells. This is caused by the translocation of histatin-5 into the intracellular compartment and accumulates to a critical concentration [45]. Further studies are thus warranted to shed light on the fungicidal mechanism of KSL-W.

C. albicans growth and transition from blastospore to hyphal form are particularly important for biofilm formation and *C. albicans* virulence because a strain that is genetically manipulated to grow exclusively in the yeast form is greatly hindered in generating biofilms. In addition, a variety of *C. albicans* mutants known to be

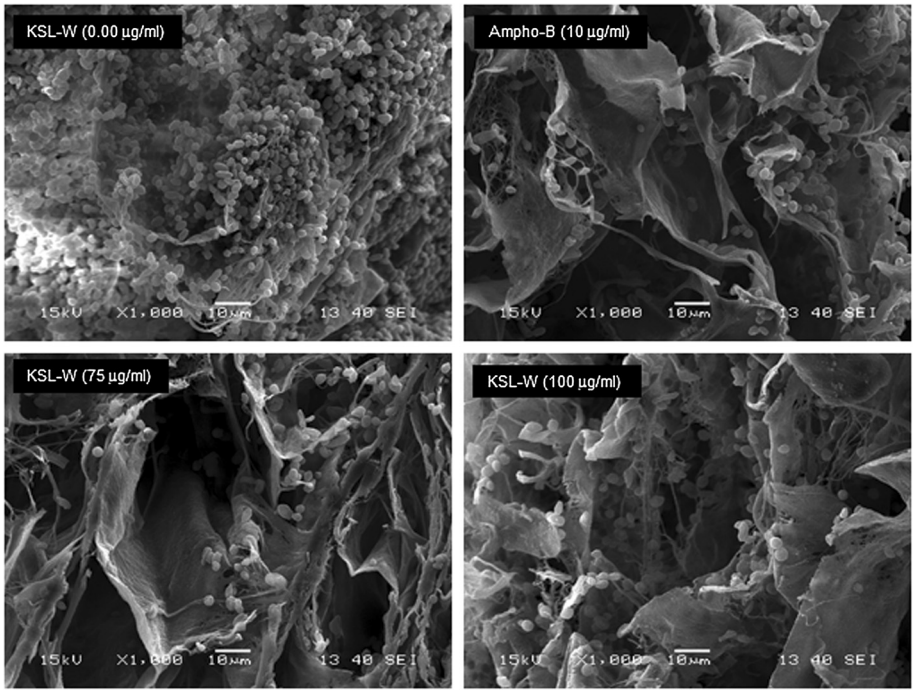

Figure 5 Biofilm ultrastructure following KSL-W treatment. *C. albicans* was cultured in Sabouraud medium without KSL-W for 6 days to promote biofilm formation and maturation. The resulting biofilms were then treated or not with KSL-W or amphotericin B for 6 days, with medium and peptide refreshing every 2 days. Following incubation, the samples were prepared as described in the Methods section and observed under a scanning electron microscope.

unable to form hyphae also show biofilm defects [46,47]. As KSL-W significantly reduced *C. albicans* growth and inhibited its transition from yeast to hyphae, this suggests that KSL-W may inhibit *C. albicans* biofilm formation. Our findings indicate that KSL-W was indeed able to reduce biofilm formation and that its effect was comparable to that obtained with amphotericin B, a well-known antifungal molecule. Also of interest is that a significant inhibition of *C. albicans* biofilm formation was obtained at a concentration of as low as 25 µg/ml of KSL-W antimicrobial peptide. These useful data are comparable to those of other studies showing the positive action of synthetic peptide in controlling and preventing microbial biofilm formation [48]. Thus, with its significant impact in reducing *C. albicans* biofilm formation, KSL-W may show potential for several novel applications in the clinical setting. Further investigations will elucidate this effect.

Biofilm formation can be controlled with anti-biofilm molecules prior to its development, although this is not actually the case in clinical applications, as antifungal and microbial molecules cannot be used on a daily basis to prevent biofilm formation. An effective molecule should ideally be able to prevent biofilm formation, but more importantly to disrupt biofilms that are already formed. We therefore questioned whether KSL-W was capable of disrupting mature *C. albicans* biofilm.

We proceeded to examine the impact of KSL-W on mature biofilm formation and demonstrated a significant disruption of these biofilms following contact with KSL-W, thus suggesting the possible use of this antimicrobial peptide to reduce/eliminate mature biofilms. Further studies should confirm such observations and demonstrate how KSL-W reduces or disrupts *C. albicans* biofilms.

Once it reaches the cell, KSL-W can potentially act on the cytoplasmic membrane as well as on intracellular targets [49-51]. The action of KSL-W against *C. albicans* may operate through the modulated expression of certain *C. albicans* genes that control growth [52], transition [53], and biofilm formation [54]. We therefore examined the effect of KSL-W on a number of genes either directly or indirectly involved in phase transition and biofilm formation. *EFG1* and *NRG1* expression was assessed under hyphae/non-hyphae-inducing conditions. Our results show that KSL-W increased NRG1 mRNA expression twofold under non-hyphae-inducing conditions; however, under hyphae-inducing conditions, KSL-W significantly reduced *NRG1* gene expression. These findings contrast with other reports that an increased NRG1 expression contributes to repressing various hypha-specific genes [55,56]. This confirms that the effect of KSL-W in controlling *C. albicans* virulence does not take place through NRG1. KSL-W was also able to

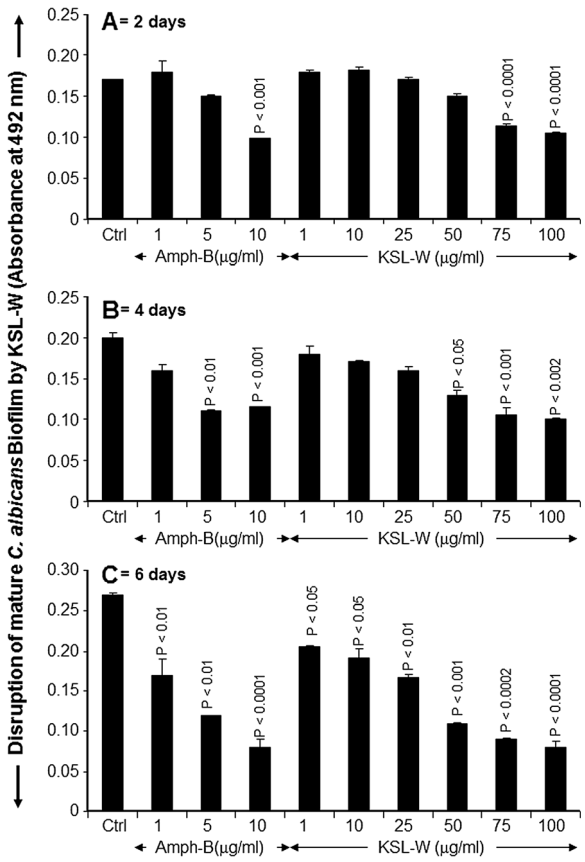

Figure 6 Decrease of biofilm mass following KSL-W treatment. *C. albicans* was cultured in a 3D porous scaffold in Sabouraud medium for 6 days to promote biofilm formation and maturation. The resulting biofilms were exposed or not to KSL-W or amphotericin B for 2, 4, and 6 days. Medium and peptide were refreshed every 2 days. Following each treatment period, the samples were supplemented with XTT solution and subsequently incubated for 5 h at 37°C. Absorbance at 450 nm was measured to quantify XTT metabolic product intensity proportional to the number of viable cells. **(A)** 2 days; **(B)** 4 days; **(C)** 6 days. Results are means ± SD for three separate experiments.

decrease EFG1 mRNA expression, when *C. albicans* was maintained under hyphae-inducing conditions.

EFG1p has been found to be a central regulator of *C. albicans*, as it is required for the development of a true hyphal growth form, and EFG1 is considered to be essential in the interactions between *C. albicans* and human host cells [7,8]. The downregulation of this gene by KSL-W points to the singular role of this antifungal peptide. Thus the effect of KSL-W on *C. albicans* transition can be manifested through a repression of certain genes, such as *EFG1* and *NRG1*.

KSL-W has a significant inhibitory effect on EAP1 mRNA expression. As a member of the GPI-CWP family [5,57], deleting EAP1 can reduce the adhesion of *C. albicans* to different surfaces. This suggests that treatment with KSL-W may reduce EAP1 expression, which in turn may contribute to reducing *C. albicans* adhesion and ultimately, biofilm formation and pathogenesis. KSL-W was also shown to reduce HWP1 mRNA expression, particularly when *C. albicans* was cultured under hyphae-inducing conditions.

HWP1 is a downstream component of the cAMP-dependent PKA pathway and is positively regulated by EFG1 [58]. The transcript level of HWP1 decreased with the KSL-W treatment at low and high concentrations. These data suggest that KSL-W indeed impacts the activity of the cAMP–EFG1 pathway and leads to an alteration of *C. albicans* growth and morphogenesis. Further studies are therefore required to investigate the invasion/virulence of KSL-W-treated *C. albicans*.

It is well known that *Candida* pathogenesis can be established by virtue of *Candida* growth and yeast-to-hyphae morphogenesis. Specific *SAP* genes were found to be preferentially expressed by *Candida* hyphal forms [10,15,59]. Because KSL-W downregulated *C. albicans* growth and transition, this may have occurred through a modulation of the *SAP* genes. Our findings confirm that KSL-W is capable of decreasing SAP2, SAP4, SAP5, and SAP6 mRNA expression in *C. albicans* which may lead to reducing *C. albicans* virulence [60-62].

Our study thus establishes, for the first time, a clear link between an antimicrobial peptide (KSL-W), hyphae

Table 2 Gene expression (6 h) under non-hyphae inducing culture conditions

morphogenesis, and hyphae-modulating SAPs 2, 4, 5, and 6. However, the precise interactions between these SAPs and KSL-W during *C. albicans* pathogenesis remain unclear. Additional studies should focus on identifying the role of SAP subfamilies involved in *Candida* invasion as well as the role of KSL-W in controlling *Candida* virulence/pathogenesis in conjunction with host defenses. In conclusion, this study is the first to demonstrate that synthetic antimicrobial peptide KSL-W downregulates *C. albicans* growth and transition, resulting in a decrease in biofilm formation and a disruption of mature biofilm. Also of interest is that these effects may occur through the modulation of *C. albicans* genes *EFG1*, *NRG1*, *EAP1*, *HWP1*, and *SAP*s. Overall results clearly suggest the potential of KSL-W as an antifungal molecule.

Methods

C. albicans

C. albicans strain ATCC-SC5314 was cultured for 24 h on Sabouraud dextrose agar plates (Becton Dickinson, Oakville, ON, Canada) at 30°C. For the *C. albicans* suspensions, one colony was used to inoculate 10 ml of Sabouraud liquid medium supplemented with 0.1% glucose at pH 5.6. The cultures were grown overnight in a shaking water bath for 18 h at 30°C. The yeast cells were then collected, washed with phosphate-buffered saline (PBS), counted with a haemocytometer, and adjusted to 10^7/ml prior to use.

Antimicrobial peptides

KSL-W (KKVVFWVKFK-NH2) was synthesized by standard solid-phase procedures [63] with 9-fluorenylmethoxycarbonyl (Fmoc) chemistry in an automatic peptide synthesizer (model 90, Advanced ChemTech, Louisville, KY, USA). The synthetic peptides were then purified by reverse-phase HPLC (series 1100, Hewlett Packard) by means of a Vydac C18 column. Peptide purity was confirmed by MALDI-TOF (matrix-assisted laser desorption/ionization-time of flight) MS (AnaSpec Fremont, CA, USA). The final product was stored in lyophilized format -20°C until use. KSL-W solution was prepared, filtered (0.22 um pore size), and used for the experiments. Amphotericin B (Sigma-Aldrich, St. Louis, MO, USA) was dissolved in distilled water to obtain a 250 μg/ml concentration which was also filtered, with the sterile solution stored at -80°C until use.

Effect of KSL-W on *C. albicans* proliferation

Proliferation was investigated by placing 10^4 *C. albicans* in 200 μL of Sabouraud dextrose broth in a round-bottom 96-well plate. The *C. albicans* cultures were supplemented with KSL-W at concentrations of 1, 10, 25, 50, 75, and 100 μg/ml. The negative controls were *C. albicans* cultures not supplemented with KSL-W, while the positive controls were *C. albicans* cultures supplemented with amphotericin B at concentrations of 1, 5, and 10 μg/ml. The plates were incubated for 5, 10, and

[1]Fold change was calculated by PCR product of the gene of interest/the PCR product of ACT1 (the house keeping gene), and normalized to the negative control of untreated *C. albicans* where the expression was considered equal to 1.
[2]P-values were obtained after comparison of test to negative control (untreated *C. albicans*).

15 h prior to cell growth analyses. *C. albicans* growth was assessed using the (3-(4,5-dimethylthiazol-2-yl)-2, 5-diphenyl tetrazolium bromide) MTT assay (Sigma-Aldrich) which measures cell growth as a function of mitochondrial activity [64]. Briefly, an MTT stock solution (5 mg/ml) was prepared in PBS and added to each culture at a final concentration of 10% (v/v). The *C. albicans* cultures were then incubated with the MTT solution at 30°C for 4 h, after which time the plate was centrifuged for 10 min at 1200 rpm and the supernatant was removed. The remaining pellet from each well was then washed with warm PBS, with 200 μl of 0.04 N HCl in isopropanol added to each well, followed by another incubation for 15 min. Absorbance (optical density, OD) was subsequently measured at 550 nm by means of an xMark microplate spectrophotometer (Bio-Rad, Mississauga, ON, Canada). Results are reported as means ± SD of three separate experiments.

Effect of KSL-W on *C. albicans* transition from blastospore to hyphal form

To determine the effect of KSL-W on the yeast-to-hyphae transition, *C. albicans* (10^5 cells) was first grown in 500 ml of Sabouraud dextrose broth supplemented with 0.1% glucose and 10% fetal bovine serum (FBS). KSL-W was then added (or not) to the culture at various concentrations (1, 5, 10, 15, and 25 μg/ml). The negative controls were the *C. albicans* cultures without antimicrobial peptide, while the positive controls represented the *C. albicans* cultures supplemented with amphotericin B (1, 5, and 10 μg/ml). The hyphae-inducing conditions were previously reported [65], consisting of culture medium supplementation with 10% fetal calf serum and subsequent incubation at 37°C. These conditions were used in our experiments. Following incubation for 4 or 8 h, the cultures were observed microscopically and photographed to record *C. albicans* morphology (n = 5) and the density of *C. albicans* transition was measured.

Effect of KSL-W on *C. albicans* gene activation/repression

C. albicans was subcultured overnight in Sabouraud liquid medium supplemented with 0.1% glucose, pH 5.6, in a shaking water bath for 18 h at 30°C. The yeast cells were then collected, washed with PBS, and counted with a hemocytometer, after which time they were co-cultured with or without the antimicrobial peptide under hyphae- or non-hyphae-inducing conditions, as follows.

Effect of KSL-W on gene activation when C. albicans was cultured under non-hyphae-inducing conditions

C. albicans was co-cultured with either KSL-W (1, 25, 100 μg/ml) or amphotericin B (1 μg/ml) or with none of these molecules (controls) in Sabouraud liquid medium supplemented with 0.1% glucose, pH 5.6. The cultures were maintained at 30°C for 3 and 6 h.

Effect of KSL-W on gene activation when C. albicans were cultured under hyphae-inducing conditions

C. albicans was co-cultured with either KSL-W (1, 25, 100 μg/ml) or amphotericin B (1 μg/ml) or with none of these molecules (controls) in Sabouraud liquid medium supplemented with 0.1% glucose, pH 5.6. As previously reported, to promote the transition of *C. albicans* from blastospore to hyphal form, the culture medium was supplemented with 10% fetal calf serum and the incubation was performed for 3 and 6 h at 37°C. Following each culture period under both conditions [68], the cultures were centrifuged 10 min at 13,000 rpm, the supernatants were discarded, and each pellet was suspended thereafter in 0.6 ml of lysis buffer (Glycerol 1 M, EDTA 0.1 M). Glass beads (0.425-0.6 mm in diameter; 0.2 ml) were added to each suspended pellet prior to sonication (4 × 1 min, followed by 2 min of incubation in ice) with

a MiniBead-beater (Biospec Products, Bartlesville, OK, USA). Following cell lysis, the total RNA was extracted from each sample by means of the Illustra RNAspin Mini kit (GE Health Care UK Limited, Buckingham, UK). Concentration, purity, and quality of the isolated RNA were determined using the Experion system and RNA StdSens analysis kit according to the instructions provided by the manufacturer (Bio-Rad, Hercules, CA, USA).

Quantitative real-time RT-PCR

The RNA (500 ng of each sample) was reverse transcribed into cDNA by means of the iScript cDNA Synthesis kit (Bio-Rad, Mississauga, ON, Canada). The conditions for the preparation of the cDNA templates for PCR analysis were 5 min at 25°C, 1 h at 42°C, and 5 min at 85°C. Quantitative PCR (qPCR) was carried out as previously described [36]. The quantity of mRNA transcripts was measured with the Bio-Rad CFX96 real-time PCR detection system. Reactions were performed using a PCR supermix, also from Bio-Rad (iQ SYBR Green supermix). Primers (Table 6) were added to the reaction mix to a final concentration of 250 nM. Five microliters of each cDNA sample were added to a 20 μl PCR mixture containing 12.5 μl of the iQ SYBR Green supermix, 0.5 μl of specific primers ACT1, SAP2, SAP4, SAP5, SAP6, HWP1, and EAP1 (Midland Certified Reagent Company, Inc., Midland, TX, USA), as well as EFG1 and NRG1 (Invitrogen Life Technologies Inc., Burlington, ON, Canada), and 7 μl of RNase/DNase-free water (MP Biomedicals, Solon, OH, USA). Each reaction was performed in a Bio-Rad MyCycler Thermal Cycler. For the qPCR, the CT was automatically determined using the accompanying Bio-Rad CFX Manager. The thermocycling conditions for the ACT1, SAPs 2-4-5-6, and EAP1 were established as 5 min at 95°C, followed by 30 cycles of 15 s at 95°C, 30 s at 60°C, and 30 s at 72°C, with each reaction performed in triplicate. For the EFG1 and NRG1, the thermocycling conditions were set for 3 min at 95°C, followed by 45 cycles of 10 s at 95°C, 40 s at 54°C, and 40 s at 72°C, with each reaction also performed in triplicate. For the HWP1, the conditions were 3 min at 95°C, followed by 45 cycles of 10 s at 95°C, 30 s at 54°C, and 40 s at 72°C, with each reaction performed in triplicate. The specificity of each primer pair was determined by the presence of a single melting temperature peak. The ACT1 produced uniform expression levels varying by less than 0.5 CTs between sample conditions and thus became the reference gene for this study. The results were analyzed by means of the $2^{-\Delta\Delta Ct}$ (Livak) relative expression method.

Effect of KSL-W on *C. albicans* biofilm formation

C. albicans biofilms were obtained by culturing the yeast on a porous collagen scaffold which facilitated *C. albicans* penetration through the pores and its adhesion to the scaffold through collagen affinity. This also promoted biofilm formation and handling with no cell loss, thus contributing to maintaining the biofilm structure. For this purpose, 5 mm × 5 mm samples of porous scaffold (Collatape, Zimmer Dental Inc., Carlsbad, CA, USA) were placed into a 24-well plate. The scaffolds were then rinsed twice with culture medium, seeded with *C. albicans* (10^5 cells), and incubated for 30 min at 30°C without shaking to allow for adherence. Fresh Sabouraud medium was added to each well in the presence or absence of various concentrations of KSL-W (1, 10, 25, 50, 75, and 100 μg/ml). Two controls were included in this study: the negative control was *C. albicans* seeded without KSL-W, while the positive control was *C. albicans* seeded with amphotericin B (1, 5, and 10 μg/ml). The *C. albicans*-seeded scaffolds were then incubated for 2, 4, and 6 days at 30°C. The medium, KSL-W, and amphotericin B were refreshed every 48 h. Following each culture period, *C. albicans* growth and biofilm formation was assessed by scanning electron microscopy and XTT-menadione assay.

Scanning electron microscopy (SEM) analysis

Biofilms were fixed in ethylene glycol for 60 min and rinsed once with sterile PBS. Dehydration was performed in a series of 5-min treatments with ethanol

solutions of increasing concentration (50, 70, 90, and twice at 100%). The dehydrated biofilms were kept overnight in a vacuum oven at 25°C, after which time they were sputter-coated with gold, examined, and imaged (n = 4) under a JEOL 6360 LV SEM (Soquelec, Montréal, QC, Canada) operating at a 30 kV accelerating voltage.

XTT reduction assay

To support the hypothesis that KSL-W quantitatively affects *C. albicans* biofilms, an XTT reduction assay was performed on the KSL-W-treated and control biofilms at defined time points. XTT assay is one of the most useful and accurate methods to investigate microbial biofilm formation. The metabolic activity of the biofilm cells was measured as a reflection of viable cell count. To do so, *C. albicans* biofilms formed in the porous scaffold with or without KSL-W treatments for 2, 4, and 6 days were subjected to an XTT assay. Fifty microliters of XTT salt solution (1 mg/ml in PBS; Sigma-Aldrich) and 4 μl of menadione solution (1 mM in acetone; Sigma-Aldrich) were added to wells containing 4 ml of sterile PBS. The biofilms were then added to the mixture and the plates were incubated at 37°C for 5 h, after which time the supernatant was collected to measure the XTT formazan at 492 nm by means of an xMark microplate spectrophotometer (Bio-Rad, Mississauga, ON, Canada).

Effect of KSL-W on the disruption of mature *C. albicans* biofilms

Mature *C. albicans* biofilms were obtained by culturing *C. albicans* (10^5) on a porous 3D collagen scaffold for 6 days at 30°C in Sabouraud liquid medium supplemented with 0.1% glucose at pH 5.6. The culture medium was refreshed every 2 days. At the end of the 6-day culture period, the biofilms were treated (or not) with KSL-W (75 and 100 μg/ml). Amphotericin B-treated biofilms (1, 5, and 10 μg/ml) were used as the positive controls. The biofilms were continuously incubated (or not) with either KSL-W or amphotericin B for 2, 4, and 6 days, with medium changing every day. KSL-W and amphotericin B were also refreshed at each medium changing. Following each incubation period, SEM and XTT analyses were performed, as described above.

Statistical analysis

Each experiment was performed at least four times, with experimental values expressed as means ± SD. The statistical significance of the differences between the control (absence of KSL-W) and test (presence of KSL-W or amphotericin B) values was determined by means of a one-way ANOVA. Posteriori comparisons were performed using Tukey's method. Normality and variance assumptions were verified using the Shapiro-Wilk test and the Brown and Forsythe test, respectively. All of the assumptions were fulfilled. P values were declared significant at ≤ 0.05. The data were analyzed using the SAS version 8.2 statistical package (SAS Institute Inc., Cary, NC, USA).

Authors' contributions

MR, KPL, and AS designed the experiments, supervised the research and wrote the paper. ST, AA, and AS performed the experiments and data analyses and contributed to the writing of the paper. Each author read and approved the final manuscript.

Abstract

Aim: The aim of this study was to investigate the interaction between primary human gingival fibroblasts and KSL-W, an antimicrobial peptide, and the effect of this peptide on gingival fibroblast defense *in vitro* against *Streptococcus mutans*.

Material and Methods: Primary human gingival fibroblasts were used to study the effect of KSL-W peptide on cell adhesion, growth and the secretion of metalloproteinase (MMP). We also investigated the effect of KSL-W on fibroblast migration by mean of scratch assay. Finally we analyzed the effect of antimicrobial activity of KSL-W on *S. mutans* infected fibroblast cultures

Results: The peptide KSL-W promoted fibroblast growth by increasing the S and G2/M cell cycle phases. Peptide KSL-W also regulated the secretion of metalloproteinase (MMP)-1 and -2, through MMP inhibitors such as tissue inhibitors of metalloproteinase (TIMP)-1 and TIMP-2. Using an *in vitro* wound healing assay, we demonstrated that peptide KSL-W promoted fibroblast migration as compared to non-treated cultures. The addition of KSL-W peptide to *S. mutans* infected fibroblast culture prevents adverse effect of the bacteria through fibroblast growth and IL-8 secretion.

Conclusion: These findings therefore show that peptide KSL-W was safe to use with human cells, as it promoted their growth and migration and attenuated *S. mutans* virulence by decreasing its effect on cell viability and IL-8 secretion.

Significance and Impact: This study points to the possibility of using KSL-W as antimicrobial peptide, and as a peptide accelerating the wound healing process.

Introduction

The human body contains millions of microorganisms involved in maintaining health. However, some of these microorganisms are capable of eliciting diseases in a different microenvironment when moving from their normal location of residence (Turnbaugh *et al*., 2007; Ling *et al*., 2010). Throughout the body, various microhabitats contribute to the overall microbiome. The oral cavity, skin, and gut each contain its own microbiome maintaining commensal and symbiotic interactions with the host (Sonnenburgand Fischbach, 2011). In the oral cavity, over 700 species of bacteria have been identified; these bacterial species benefit within the oral cavity, residing on both the hard and soft tissues to interact and form microbial biofilms (Cavalcanti *et al*., 2016; Ng *et al*., 2015). The teeth, gingival sulcus, tongue, cheeks, hard and soft palates, and tonsils also provide enriching environments where microbial communities can adhere, multiply, form biofilms, and potentially induce diseases (Dewhirst *et al*., 2010).

The main factors responsible for initiating microbial oral disease are poor oral hygiene and immune system dysfunctionality (Al-Ahmad *et al*., 2010). Uncontrolled oral hygiene is known to promote microorganism accumulation within biofilm. Failure to remove accumulating biofilm leads to bacterial overgrowth (which may become pathogenic), a reduction of microbial biodiversity, and ultimately, the development of diseases such as dental caries or periodontal disease (Al-Ahmad *et al*., 2010; Zaura *et al*., 2009). A deficient immune system may also be

attractive to microbial infection. As the immune system regulates interactions between the microbiome and the host, a compromised system usually disturbs mutual or commensal relationships (Patil *et al*., 2015; Nguyen *et al*., 2015).

Oral diseases, such as dental caries and periodontal disease, are among the most prevalent diseases worldwide (Horz *et al*., 2007; Hajishengallis*et al*., 2015), affecting nearly all ages and geographic populations. Although a specific microbiome contributing to the development of dental caries has yet to be established (Ling *et al*., 2010), the most common bacteria responsible for dental caries are *S. mutans, S. sobrinus*, and *Lactobacillus acidophilus* (Fernández *et al*., 2015, Johansson *et al*., 2016).

The oral cavity is the primary gateway to the human body; microorganisms inhabiting this area are thus highly capable of spreading to different body sites (Dewhirst *et al*., 2010). Pathogens originating in the oral cavity have been detected in blood cultures and are known to destroy the oral mucosa to reach the circulation, leading to dissemination (Horz *et al*., 2007). While such a situation is rare with a healthy immune system, this does suggest the existence of a mechanism by which pathogens derived from oral infections may lead to systemic body infection.

The oral mucosa is the most important barrier against physical, microbial, and chemical agents that cause local cell injury (Presland and Dale, 2000). The oral mucosa is also involved in the proinflammatory process by producing cytokines and antimicrobial peptides, either constitutively or following a variety of stimuli (Andrian *et al*., 2005, Rouabhia *et al*., 2005). This suggests that the oral mucosa plays an active role in controlling oral infections and maintaining the symbiotic relationship with oral microbial agents. Oral mucosal cells, namely, epithelial cells and

fibroblasts, interact with each other to maintain tissue integrity and function (Mahanonda *et al*., 2009). Gingival fibroblasts, the predominant cell type inhabiting gingival connective tissue, take on a critical role in remodeling and maintaining gingival structure and extracellular matrix (van Beurden *et al*., 2005; Barrientos *et al*., 2008). These fibroblasts are also key contributors to tissue repair and wound healing through their adhesion, migration, growth, and differentiation, as well as their production of extracellular matrix (ECM) (van Beurden *et al*., 2005; Barrientos *et al*., 2008). During ECM remodeling, balance is crucial between matrix metalloproteinases (MMPs) and tissue inhibitors of metalloproteinases (TIMPs) (Page-McCaw *et al*., 2007). TIMPs and MMPs are tightly regulated during normal wound healing, and their imbalance has been reported following infection (Andrian *et al*., 2007, Kanangat *et al*., 2006).

To prevent infection, gingival cells (epithelial cells and fibroblasts) secrete high levels of proinflammatory cytokines, such as IL-1*β*, IL-6, and IL-8 (Mostefaoui *et al*., 2004, Semlali *et al*., 2011). They also produce antimicrobial peptides against the infecting agents. Human gingival fibroblasts secrete several antimicrobial peptides, such as β-defensin-1, -2, -3, and -4 (Derradjia *et al*., 2015; Levón *et al*., 2015; Noronha *et al*., 2014), thus contributing to the defense against various pathogenic microbes (Chen *et al*., 2013; Guo *et al*., 2012). Many synthetic antimicrobial peptides mimicking the structure and function of naturally occurring antimicrobial peptides have been developed as an additional therapeutic initiative, along with available antibiotics to prevent and eliminate human microbial infections, and the need for new antimicrobial agents is a well-documented issue related to world health (Fernandes *et al*., 2006).

Leung *et al*. reported that KKVVFKVKFK (KSL) may be a useful antimicrobial agent to inhibit the growth of oral bacteria associated with caries development and early plaque formation (Leung

et al., 2005; Na *et al*., 2005). Furthermore, KSL analogue KSL-W (H2N-Lys-Lys-Val-Val-Phe-TryVal-Lys-Phe-Lys-COOH) was shown to be stable against salivary trypsin-catalyzed cleavage in the oral cavity, and was determined as the most promising candidate in terms of potential therapeutic activity and safety in the gastrointestinal tract (Na *et al*., 2007). To further investigate the usefulness of peptide KSL-W, the aim of this study was to determine the interactions between KSL-W and human gingival fibroblasts and the influence of this peptide on fibroblast behaviors when in contact with bacteria (*S. mutans*).

Materials and methods

Culture of Primary Human Gingival Fibroblast Cells

Normal human gingival fibroblasts (ScienCell Research Laboratories, Carlsbad, CA, USA) were cultured in Dulbecco's modified Eagle's (DME) medium (Gibco-Thermo Fisher Scientific, Gaithersburg, MD, USA) supplemented with 10% fetal bovine serum (FBS) (Wisent Inc., Saint-Jean-Baptiste, QC, Canada). The medium was changed three times a week. When the culture reached 90% confluence, the cells were detached from the flasks with a 0.05% trypsin (MP Biomedicals LLC, Santa Ana, CA, USA)–0.1% ethylenediaminetetraacetic acid (EDTA) (Merck KGaA, Darmstadt, Germany) solution, washed twice with phosphate-buffered saline (PBS), and suspended in DME-supplemented medium at a final concentration of 10^6 cells/mL. Cells at the third and fourth passages were used to perform the experiments.

Antimicrobial Peptide

Peptide KSL-W was synthesized by standard solid-phase procedures (Hong *et al*., 1998) with 9-fluorenylmethoxycarbonyl (Fmoc) chemistry in an automatic peptide synthesizer (model 90,

Advanced ChemTech, Louisville, KY, USA). The synthetic peptides were then purified by reverse-phase HPLC (series 1100, Agilent Technologies, Santa Clara, CA, USA) by means of a Vydac C18 column. Peptide purity was confirmed by MALDI-TOF (matrix-assisted laser desorption/ionization-time of flight) MS (AnaSpec, Fremont, CA, USA). The final product was stored in lyophilized format at -20°C until use. A KSL-W solution was subsequently prepared, filtered (0.22 um pore size), and used for the experiments.

Bacteria and Growth Conditions

S. mutans (ATCC 25175, Manassas, VA, USA) was used in this study. The bacteria was grown aerobically at 37°C in Todd-Hewitt broth (BBL Microbiology Systems, Cockeysville, MD, USA) supplemented with hemin (Sigma-Aldrich, St. Louis, MO, USA) (10 μg/mL) and vitamin K (Sigma-Aldrich) (10 μg/mL) (THB-HK). For experimental purposes, the *S. mutans* was cultured overnight, then diluted in THB-HK to obtain an optical density at 660 nm (OD_{660}) of 0.2 (corresponding to 1×10^8 colony-forming units (CFU)/mL). Samples (100 µL) were then used to infect the gingival fibroblast monolayer cultures.

Effect of KSL-W on primary human gingival fibroblast adhesion

Prior to cell seeding, five sterile glass slides (Bellco Glass Inc., Vineland, NJ, USA) (0.05 mm in diameter) were inserted into each well of a non-adherent 6-well plate (Sarstedt, Nümbrecht, Germany). Primary human gingival fibroblasts were then seeded at 2×10^5 cells/well in DME supplemented with 10% FBS. Immediately after seeding, various concentrations (0, 10, 50, or 100 µg/mL) of peptide KSL-W were added to the cells. Each concentration was tested in duplicate. The cells were incubated at 37°C in a 5% CO_2 atmosphere for 6 and 24 h and subjected

thereafter to Hoechst staining. The cells were then fixed with methanol (Fisher Scientific Co., Ottawa, ON, Canada) and glacial acetic acid (Merck KGaA) (75/25, v/v) for 3 × 15 min, and subsequently washed 3 times with phosphate-buffered saline (PBS). Thereafter, the cells were incubated with Hoechst 33342 (H42) (Riedel de Haen, Seele, Germany) (1 µg/mL) in PBS for 15 min at room temperature in the dark. After three washes with deionized water, the samples were observed and photographed using an epifluorescence light microscope (Axiophot, Zeiss, Oberkochen, Germany). At least 10 fields from each slide were photographed and used to count the stained cells in each field. Results are reported as the means ± SD of four separate experiments.

Effect of peptide KSL-W on primary human gingival fibroblast growth

Primary human gingival fibroblasts were seeded into 6-well plates (10^4 cells/well) in DME medium supplemented with 10% FBS. The cells were then incubated in a 5% CO_2 humid atmosphere at 37°C for 24 h, after which time the culture medium was refreshed and the cells were treated with 0, 10, 50, or 100 µg/mL of peptide KSL-W. Each concentration was tested in duplicate. The cells were maintained for 3 and 6 days, and the medium was changed every 48 h. At the end of the incubation, the cells were detached from the culture plates with 0.05% trypsin/0.01 EDTA solution and subsequently washed twice with culture medium, with the viable cell numbers assessed by Trypan blue exclusion assay (Gilbert *et al*., 2005). Briefly, 100 µl from each cell suspension were mixed with the same volume of Trypan blue (Sigma-Aldrich) solution (0.4%) and incubated 5 min on ice. Viable cells were determined in triplicate for each suspension by means of an inverted optical microscope to count the Trypan blue-free cells. Results are reported as the means ± SD of five different experiments.

Effect of KSL-W on primary human gingival fibroblast cell cycle

Primary human gingival fibroblasts were seeded into 6-well plates at 10^4 cells/well and incubated for 48 h in a 5% CO_2 humid atmosphere at 37°C, after which time the medium was refreshed, and the cells were treated with peptide KSL-W at concentrations of 0, 10, 50, or 100 µg/mL; two wells per condition. The cells were maintained in culture for 24 h, then detached from the culture plates as described above, washed twice with PBS, and subsequently used for cell cycle analysis. Briefly, the cells were suspended in RNase (Promega, Madison, WI, USA) (10 mg/mL) solution and incubated at 37°C for 1 h, after which time propidium iodide (PI) (Abcam Inc., Toronto, ON, Canada) (50 mg/mL) was added to each cell suspension prior to analysis. The percentage of cells in the G1, S, and G2/M phases of the cell cycle were analyzed using an Epics® Elite ESP flow cytometer (Beckman Coulter, Miami, FL, USA). The single cell population was gated using pulse width *vs*. pulse area to exclude clumps and doublets and the scatter plot was used to exclude any obvious debris. The PI was detected using an FL4 channel *vs*. a cell count histogram plot. Results are reported as the means ± SD of three different experiments.

Cell Migration/Monolayer Wound Repair Assay

In vitro wound repair assays were performed as previously described (Semlali *et al*., 2011). Briefly, primary human gingival fibroblasts were seeded (2×10^5/well) into 6-well plates and grown to confluence. A scratch wound was then created on each confluent monolayer by means of a 200 µL sterile pipette tip (PipetTipFinder, Lab Procurement Services, LLC, Knoxville, TN, USA) perpendicular to the bottom of the dish. This generated a wound approximately 0.44 to 0.50 mm in width. The culture medium was refreshed with new medium, supplemented or not

peptide KSL-W at 10, 50, or 100 μg/mL, and incubated at 37°C in a CO_2 humid atmosphere. At the end of each incubation period (0, 12, 24, and 48 h), the cells were fixed with 4% paraformaldehyde solution (Alfa Aesar, Ward Hill, MA, USA) for 60 min at 4°C, washed twice with PBS, and subjected thereafter to crystal violet staining (Sigma-Aldrich). One milliliter of 1% w/v crystal violet solution in demineralized water was added to each well and the cultures were then incubated at room temperature for 15 min, after which time the non-bound dye was removed from the wells by thorough washing with demineralized water, followed by drying at 37°C. Digital photographs of each wound were taken (Coolpix 950, Nikon Canada, Montréal, QC, Canada) at various time points following the creation of the wound. Wound closure (cell migration) was investigated using the NIH Image J public domain image processing program to measure the distance between the opposite edges of the wound as a function of time. Data (means ± SD, $n = 5$) were collected and presented as the percentage of initial wound (distance at time zero) using the following formula: ((distance at initial scratch – distance after an identified culture period) ÷ (distance at initial scratch)) × 100%. The KSL-W-treated and untreated cell cultures were compared, with the difference considered significant at $p < 0.05$.

Effect of peptide KSL-W on MMP-1, MMP-2, TIMP-1, and TIMP-2 secretion by primary human gingival fibroblasts

Spent culture media were collected to determine MMP-1, MMP-2, TIMP-1 and TIMP-2 protein levels. These were obtained from primary human gingival fibroblasts at 2×10^5/well in 6-well plates treated with peptide KSL-W at 0, 10, 50, or 100 μg/mL, in duplicate, for 3 and 6 days. They were analyzed thereafter by sandwich enzyme-linked immunosorbent assays (ELISA, R&D Systems, Minneapolis, MN, USA). Briefly, the cell culture media were collected in tubes

containing 1 μL of a protease inhibitor cocktail (Sigma-Aldrich) for specific use with mammalian cell and tissue extracts. The culture media were then filtered through 0.22 μm filters and used to quantify MMP-1, MMP-2, TIMP-1, and TIMP-2 concentrations, according to the manufacturer's instructions. The plates were read at 450 nm and analyzed by means of a Model 680 Microplate Reader (Bio-Rad, Hercules, CA, USA). According to the manufacturer, the minimum detectable concentrations were under 1 pg/mL for MMP-1, 0.7 pg/mL for MMP-2, 3.5 pg/mL for TIMP-1, and 3.5 pg/mL for TIMP-2. Each experiment was repeated four times and the means ± SD were calculated and presented.

Effect of peptide KSL-W on primary human gingival fibroblast interaction with *S. mutans*

To investigate the effect of peptide KSL-W on *Streptococcus mutans*-infected primary human gingival fibroblasts, cells were seeded into 6-well plates at 10^4 cells/well and incubated thereafter in a 5% CO_2 humid atmosphere at 37°C for 4 days. The medium was then refreshed and treated with or without peptide KSL-W at 10, 50, or 100 μg/mL; two wells per condition. An *S. mutans* suspension (100 μL) at 1×10^8 CFU/mL was then immediately used to infect the gingival fibroblast monolayer cultures. As a negative control, fibroblast cultures without KSL-W were also infected with 100 μL of *S. mutans* suspension. As a positive control, fibroblast cultures infected with 100 μL of *S. mutans* suspension were immediately supplemented with an antibiotic cocktail (penicillin (30 mg/mL)/streptomycin (50 mg/mL)) (Gibco-Thermo Fisher Scientific, Gaithersburg, MD, USA) to prevent bacterial growth. Following infection with *S. mutans*, the cell cultures were maintained in a 5% CO_2 humid atmosphere at 37°C for 6 h, after which time the culture medium from each condition was collected, filtered by 0.22 μm filters, and used to

quantify IL-8 concentrations using an ELISA kit (R&D Systems). The plates were read at 450 nm and analyzed by means of a Model 680 Microplate Reader (Bio-Rad). According to the manufacturer, the minimum detectable concentration of IL-8 was between 1.5 and 7.5 pg/mL. The experiment was repeated three times and the means ± SD were calculated and presented. Following treatment with KSL-W in the presence or absence of *S. mutans*, adherent cells were washed twice with PBS, fixed with 4% paraformaldehyde for 60 min, and stained thereafter with crystal violet, as described above. The stained cells were then observed under an inverted microscope and photographed. At least 10 fields from each slide were photographed and subsequently used to count the stained cells in each field. Results are reported as the means ± SD of four separate experiments (n = 4).

Results

Peptide KSL-W promoted primary human gingival fibroblast adhesion and growth

Primary human gingival fibroblasts were treated with various concentrations of peptide KSL-W and analyzed to determine the effect of this antimicrobial peptide on their attachment and morphology. As shown in **Fig. 1A**, peptide KSL-W had no adverse effect on cell morphology and adhesion following incubation for 6 and 24 h. The cells were well distributed over the plate, similar to that observed with the untreated control cells. Optical microscope observations showed elongated fibroblasts with a dense nucleus and a small amount of cytoplasm (**Fig. 1A**). Quantitative evaluation (numbering) of the adherent cells (**Fig. 1B**) confirmed that peptide KSL-W did not reduce/inhibit primary human gingival fibroblast adhesion. The numbers of adherent cells in the presence of peptide KSL-W were comparable to those found in the control, and even greater at 6 and 24 h.

Cell growth analyses confirm these data. As shown in **Fig. 2**, compared to the non-KSL-W-stimulated primary human gingival fibroblast culture, a trend showing a slight increase of viable primary human gingival fibroblasts was observed at 3 days, although this was not statistically significant. However, at 6 days, compared to the control, the KSL-W-treated cultures recorded higher viable cell numbers, which was statistically significant. KSL-W was able to cause an increase in the number of viable primary human gingival fibroblasts at as low as 10 μg/mL. This increase was not only maintained but showed a trend of further increases in the presence of 50 or 100 μg/ml of the peptide, although this increase was not statistically significant. Overall results demonstrate that peptide KSL-W promoted primary human gingival fibroblast adhesion and growth.

Peptide KSL-W promoted human gingival fibroblast cell cycle

The KSL-W-induced cell growth increase possibly occurred through a promotion of the cell cycle progression. To monitor the effect of peptide KSL-W on the cell cycle, gingival fibroblasts were treated with various concentrations of KSL-W for 24 or 48 h, after which time the cell percentages were quantified in different cell cycle phases (**Fig. 3**). Quantitatively, in the KSL-W-untreated group at 24 h post-culture, approximately 70% of the cells were in the G_0/G_1 phase, while over 7% of the cells were in the S phase, and close to 14% were in the G_2/M phase (**Fig. 3**). However, following exposure to KSL-W, the G_0/G_1 phase values significantly ($p < 0.05$) decreased, and specifically with 50 and 100 μg/mL of the peptide. In contrast, the S and G_2/M phase values significantly ($p < 0.05$) increased when peptide KSL-W was introduced at 100 μg/mL. Similar results were obtained with fibroblasts stimulated with KSL-W for 48 h (**Fig. 3**).

Peptide KSL-W increased MMP-1, MMP-2, TIMP-1, and TIMP-2 secretion by human gingival fibroblasts

Protein analyses of the spent culture media reveal that peptide KSL-W modulated the levels of remodeling enzyme proteins MMP-1 and MMP-2 secreted by the gingival fibroblasts (**Fig. 4**). The effects were observed after 3 and 6 days of peptide treatment, compared to untreated cultures. At 3 days post-KSL-W treatment, significant ($p < 0.05$) increases in MMP-1 levels were observed with 50 and 100 ug/mL of the peptide, compared to the untreated cells. Similar observations were made for the 6-day fibroblast culture in the presence of 50 and 100 ug/mL of KSL-W. The levels of secreted MMP-1 were greater at 6 days than at 3 days, regardless of the test conditions (control or KSL-W-treated cultures). Comparable data were obtained by MMP-2. **Fig. 4** shows significantly higher ($p < 0.05$) MMP-2 protein levels with 50 and 100 ug/mL of peptide KSL-W, at both 3 and 6 days post-stimulation.

Because peptide KSL-W increased MMP-1 and MMP-2 secretion, we also investigated TIMP-1 and TIMP2, as they are involved in regulating MMP activities. **Fig. 5** shows that peptide KSL-W increased TIMP-1 secretion by the primary gingival fibroblasts. This increase was statistically significant ($p < 0.05$) in the presence of both 50 and 100 ug/ml of KSL-W and at both 3 and 6 days of stimulation with the peptide. A comparable increasing trend was observed for TIMP-2 (**Fig. 5**). Indeed, at 3 days, a significant increase in TIMP-2 secretion was observed in the presence of 50 and 100 µg/mL of peptide KSL-W, and at 6 days, TIMP-2 secretion showed an increased trend at all three concentrations of KSL-W tested. Overall data thus confirm the upregulation of MMP-1 and MMP-2 by peptide KSL-W. The increase of these proteolytic enzymes was paralleled with an increase of protease inhibitors (TIMP-1 and TIMP-2).

Peptide KSL-W promoted cell migration and wound closure

Because peptide KSL-W was found to promote fibroblast adhesion and growth, we investigated its ability to promote fibroblast migration. This was determined by a scratch wound closure experiment. Wounds were created in gingival fibroblast monolayers and cell migration from the edge of the scratch toward the center (wound closure) was recorded at different times post-wounding. The fibroblasts treated with peptide KSL-W actively migrated from both edges and closed the entire wound at 48 h (**Fig. 6**). This healing rate was much more rapid than that of the untreated cells which showed 25 to 30% of the wound to be unhealed at 48 h (**Fig. 6**). Further quantitative analysis revealed that compared to the untreated controls, a significant ($p < 0.05$) reduction of wound distance at 12 and 24 h was observed for the cells treated with 50 and 100 μg/ml of peptide KSL-W (**Fig. 6**). It appears that the higher the peptide concentration, the greater the migration rate.

Peptide KSL-W prevented the adverse effect of S. mutans on fibroblast growth and IL-8 secretion

Following seeding, 4-day-old fibroblast cultures were infected with *S. mutans* in the presence or absence of peptide KSL-W. **Fig. 7A** shows that in the absence of the peptide, a low cell distribution was observed throughout the culture surface. The addition of peptide KSL-W at 50 and 100 μg/mL reduced the adverse effect caused by *S. mutans,* resulting in maintaining a higher number of adherent cells on the culture plate. To quantitatively confirm this observation, cell lysis was performed following crystal violet staining and measurement of its absorbance. As shown in **Fig. 7B**, the KSL-W-supplemented fibroblast culture showed an absorbance level comparable to that obtained by the non-infected culture or the antibiotic-supplemented *S. mutans*-

infected fibroblast culture, suggesting that peptide KSL-W played a preventive role against *S. mutans* infection.

To support this observation, IL-8 secretion was also measured. **Fig. 8** shows that the non-stimulated, non-infected fibroblasts secreted a basal level of IL-8 (approximately 700 pg/mL). Following infection with *S. mutans*, the level of IL-8 increased to 1000 pg/mL. The killing of *S. mutans* by the antibiotics led to a decrease in IL-8 secretion, compared to that recorded by the infected cultures. Interestingly, the addition of 50 and 100 μg/mL of peptide KSL-W resulted in reduced levels of IL-8 secretion, ranging from over 900 pg/mL with 50 μg/ml of KSL-W to less than 750 pg/mL with 100 μg/mL of the peptide. Overall data show that peptide KSL-W decreased the adverse effect of *S. mutans* on gingival fibroblast growth and reduced the inflammatory response against the bacteria by decreasing IL-8 secretion.

Discussion

Various antimicrobial peptides have been shown to display *in vitro* activity against a wide range of bacterial pathogens and are thus being proposed as additional alternatives to develop novel antibacterial disease-control strategies (Martin *et al*., 2015; Yu *et al*., 2016). Among available antimicrobial peptides, peptide KSL-W demonstrated improved stability in simulated oral conditions with broad spectrum antimicrobial activity (Na *et al*., 2005). Furthermore, combined with sub-inhibitory concentrations of benzalkonium chloride, a known cationic surface-active agent (Baker *et al*., 1978), peptide KSL-W was shown to significantly reduce oral biofilm growth *in vitro* (Bernegossi *et al*., 2015).

In addition to the inherent ability of antimicrobial peptide to kill bacteria, some of these peptides, such as LL37, have demonstrated wound healing properties (Grönberg *et al*., 2014). We therefore sought to study the effect of peptide KSL-W on primary human gingival fibroblasts when used orally to control oral biofilm growth. Our results indicate that this antimicrobial peptide was indeed non-toxic. Indeed, even at a high concentration (100 µg/mL), peptide KSL-W did not reduce cell adhesion or growth. We also found that peptide KSL-W, similar to other antimirobial peptides, could be beneficial to human cells. We previously demonstrated that nisin Z, an antimicrobial peptide produced by *Lactococcus lactis subsp.,* significantly reduced fibroblast growth and differentiation (Akerey *et al*., 2009), demonstrating the capacity of nisin Z to promote cell growth under infected conditions. Similar beneficial effects of peptide KSL-W were observed with Hacat cells and human dermal fibroblasts (Kosikowska *et al*., 2015). Furthermore, ocellatin peptides extracted from frog *Leptodactylus pustulatus* skin showed microbial growth control with no adverse effect on human erythrocytes and a murine fibroblast cell line (Marani *et al*., 2015).

In our study, the effect of peptide KSL-W on fibroblast growth appears to have occurred through its influence on the cell cycle, as the KSL-W-treated cell cultures recorded a greater number of cells at the S and G2/M phases. These data provide insight on certain factors contributing to the increased fibroblast growth observed on the KSL-W-treated gingival fibroblasts. This effect is comparable to the naturally occurring peptide catestatin secreted by human keratinocytes. Hoq *et al*. (2011) showed that in addition to inhibiting the growth of pathogens, catestatin peptides promoted keratinocyte proliferation (Hoq *et al*., 2011). Because fibroblasts adhered and proliferated in the presence of KSL-W, this may have increased their physiological activity by

stimulating MMP secretion and that of their inhibitors (TIMPs). Indeed, our results reveal increased levels of MMP-1, MMP-2, TIMP-1, and TIMP-2 secretion by gingival fibroblasts when they were exposed to peptide KSL-W.

Similar to what was reported with β-defensin-3 (Nishimura *et al*., 2004), the increased secretion of MMP-1 and MMP-2 by the KSL-W-stimulated fibroblasts may suggest a role of peptide KSL-W in mediating part of the tissue remodeling processes. Alternatively, changes in MMPs could be considered as an inflammatory response by the fibroblasts to the presence of peptide KSL-W, as previously demonstrated (Nishimura *et al*., 2004) with other antimicrobial peptides, such as human β-defensin-3 which was shown to cause an increase in prostaglandin-(PGE)2 and MMP-1 secretion levels by human gingival fibroblasts. Similar observations were reported with α-defensin-1, which caused increased levels of mRNA expression of IL-6, IL-8, MMP-1, and MMP-3 by fibroblast-like synoviocytes (Ahn *et al*., 2013). In our study, when gingival fibroblasts were exposed to peptide KSL-W, the increased MMP secretion was paralleled by TMIP-1 and TIMP-2 secretion. This is the first study to report an increase in TIMP1 and TIMP-2 secretion by KSL-W-stimulated fibroblasts. Overall, peptide KSL-W treatment stimulated fibroblast growth and increased MMP and TIMP secretion, which suggests that this peptide may play a role in cell migration and wound healing.

To test this hypothesis, KSL-W-stimulated gingival fibroblasts were subjected to an *in vitro* wound scratch assay which showed that peptide KSL-W at 50 and 100 μg/ml promoted fibroblast migration and wound closure. These findings are in agreement with those of earlier studies showing that human β-defensin-2 increased keratinocyte cytokine production and migration

(Niyonsaba *et al*., 2007). Human β-defensin-3 was also shown to be highly expressed by keratinocytes at wound sites to promote cell migration and proliferation (Niyonsaba *et al*., 2007; Sørensen *et al*., 2005; Niyonsaba *et al*., 2005) and to significantly accelerate wound closure when topically applied in a porcine model of infected skin wounds (Hirsch *et al*., 2009). Overall data demonstrate that synthetic peptide KSL-W not only exhibited wound healing properties but played an active role in promoting wound healing, which supports previously reported results with naturally occurring β-defensin peptides. However, the wound healing activity demonstrated by peptide KSL-W will require further investigation using clinically relevant animal wound healing models.

Our results show that peptide KSL-W, similar to the test antibiotic, was able to mitigate the adverse effect of *S. mutans* on cell density in gingival fibroblasts. These findings confirm previous results showing peptide KSL-W to display both bactericidal (Dixon *et al*., 2008) and anti-fungal (Theberge *et al*., 2013) properties. Furthermore, peptide KSL-W controlled the inflammatory response following *S. mutans* infection. The effect of peptide KSL-W on controlling IL-8 secretion following bacterial infection was comparable to that observed with the antibiotic. These results suggest that peptide KSL-W may indirectly help fibroblasts to sense bacterial presence, thus secreting IL-8 when needed. Further studies will shed light on the signaling pathways involved in such controls. Our overall findings thus confirm that antimicrobial peptide KSL-W is non-toxic, has the ability to control infection, and may possess wound healing properties.

Authors' contributions

MR and KPL and AS designed the experiments, supervised the research and wrote the paper. HJP, MS, AS and MR performed the experiments and data analyses and contributed to the writing of the paper. Each author read and approved the final manuscript.

Fig. 1. Peptide KSL-W enhanced the early adhesion of gingival fibroblasts. Cells were cultured with or without peptide KSL-W for 6 or 24 h and then stained with Hoechst**.** (**A**) Representative photos of adherent cells (*bar* 30 µm). (**B**) Count of adherent fibroblasts under the different conditions. Results are means + SD ($n = 4$).

Fig. 2. Peptide KSL-W increased gingival fibroblast growth. Fibroblasts were treated with or without various concentrations of peptide KSL-W for 3 and 6 days. Viable cells were analyzed by Trypan blue exclusion assay. Numbers of live cells were plotted as mean + SD (n = 5). P values were obtained by comparing the KSL-W-treated and untreated values.

Fig. 3. Peptide KSL-W promoted cell division. Following stimulation for 24 or 48 h, the cells were detached and used for cell cycle testing by PI staining. Quantitation of cell percentages at the different phases was determined by FAC analyses. $P < 0.05$ was obtained by comparing the KSL-W-treated and untreated cells ($n = 3$).

Fig. 4. Peptide KSL-W increased metalloproteinase (MMP-1 and MMP-2) secretion. Fibroblasts were stimulated for 3 and 6 days with different concentrations of peptide KSL-W. The cell supernatants were used to measure the MMPs using specific ELISA kits. Note the increased MMP levels with the high doses of peptide KSL-W at 3 and 6 days. $P < 0.05$ was obtained by comparing the KSL-W-treated and untreated cells and the levels at 3 and 6 days ($n = 4$).

Fig. 5. Peptide KSL-W enhanced metalloproteinase inhibitor (TIMP-1 and TIMP-2) secretion. Note the increased levels of TIMPs with the high doses of peptide KSL-W at 3 and 6 days.

$P < 0.05$ was obtained by comparing the KSL-W-treated and untreated cells and the levels at 3 and 6 days ($n = 4$).

Fig. 6. Peptide KSL-W increased gingival fibroblast migration/repair. Cells were cultured up to 100% confluence. Scratches were then made on each monolayer and the medium was refreshed and immediately treated with or without peptide KSL-W at different concentrations. The cultures were maintained for various time periods prior to observation and determination of the wound recovery. (**A**) Representative photos at 12 and 48 h post-wound (*bar* 50 µm). (**B**) Values are means ± SD ($n = 5$). The KSL-W-treated and untreated cultures were compared, with the difference considered significant at (*) $p < 0.05$.

Fig. 7. Peptide KSL-W reduced the adverse effect of *S. mutans* on gingival fibroblast adhesion/density. At confluence, fibroblasts were pulsed with *S. mutans* in the presence or not of peptide KSL-W. (**A**) Representative photos of adherent cells after 6 h of contact with *S. mutans* in the presence or not of peptide KSL-W. (**B**) Density of live adherent cells assessed by crystal violet staining were plotted as mean + SD ($n = 4$). P values were obtained by comparing the *S. mutans*-infected, KSL-W-treated, and untreated cultures.

Fig. 8. Peptide KSL-W reduced the adverse effect of *S. mutans* on gingival fibroblast IL-8 secretion. IL-8 levels were obtained by ELISA measurement and were plotted as mean + SD ($n = 4$). P values were obtained by comparing the *S. mutans*-infected, KSL-W-treated, and untreated cultures.

Appendix 1

Le décapeptide KSL-W réduit la croissance de *Candida albicans* et dégrade les biofilms en diminuant l'expression de plusieurs gènes de virulence.

Theberge Simon[1], Semlali Abdelhabib[1,2], Alamri Abdullah[1], Leung P. Kai[3], and Rouabhia Mahmoud[1]

[1]Oral Ecology Research Group, Faculty of Dentistry, Laval University, Quebec, QC, Canada,
[2]Genome Research Chair, Department of Biochemistry, College of Science King Saud University, Riyadh, Kingdom of Saudi Arabia
[3]Dental and Trauma Research Detachment, US Army Institute of Surgical Research, Fort Sam Houston, TX, United States

Introduction : *Candida albicans* est le plus fréquent pathogène fongique impliqué dans les infections nosocomiales en Amérique du Nord[1]. Suivant l'utilisation courante d'antifongiques, *C. albicans* peut développer des résistances aux traitements conventionnels. Afin de pallier cet obstacle, le décapeptide KSL-W a été développé et présente un large spectre antimicrobien pouvant affecter *C. albicans*[2,3].
L'objectif de cette étude est d'évaluer l'effet du KSL-W sur la croissance, la transformation de *C. albicans*, ainsi que sur l'expression des gènes impliqués dans la virulence de *C. albicans*.
Matériels et Méthodes : L'effet du KSL-W a été étudié en analysant la transformation de *C. albicans-SC5314* en présence et en absence de KSL-W à l'aide de suivis microscopiques. Des analyses spécifiques au MTT et au XTT ont été réalisées afin de déterminer l'effet du KSL-W sur la prolifération ainsi que sur la formation et la dégradation de biofilm. Ces travaux ont été soutenus par l'analyse de l'expression des gènes *Sap2*, *Sap4*, *Sap5*, *Sap6*, *HWP1*, *EAP1*, *EFG1* et *NRG1* par la technique RT-qPCR. Tous les effets ont été comparés à l'amphotéricine B, un antifongique utilisé en clinique.
Résultats et conclusions : La transformation levure-hyphe est inhibée à partir de concentrations de 5μg/ml. La prolifération est diminuée suivant une exposition de 5h à des concentrations de 10μg/ml et persiste jusqu'à 10h avec des concentrations ≥50μg/ml. La formation de biofilm est inhibée par des concentrations de ≥25μg/ml. Les biofilms sont dégradés à partir de concentrations de 75μg/ml. Le KSL-W réprime l'expression des gènes de virulence *Sap2*, *Sap4*, *Sap5*, *Sap6*, *HWP1*, *EAP1*. Les gènes *EFG1* et *NRG1* ont été régulés à la hausse par le KSL-W. Les effets sont comparables à l'amphotéricine B. Par ses effets sur les facteurs de virulence et par son effet sur les gènes de virulence, le KSL-W présente une alternative de traitement intéressante dans le contrôle des infections fongique à *C. albicans* (This study was supported financially by the United States Army Medical Research and Materiel Command (Award number ERMS No. 12304006) and by a grant from the Fonds Émile-Beaulieu, a Université Laval foundation).

Appendix 2 :

Journée de la recherche faculté de médecine – 30 mai – soumission avant 4 avril

Un nouveau peptide antimicrobien contrôle la virulence de Candida en réduisant sa viabilité via un processus d'apoptose et de nécrose.

THEBERGE SIMON[1], Jacques Éric[1] and Leung Kai P[2] and Rouabhia Mahmoud[1]

[1] Groupe de recherche en écologie buccale, Université Laval
[2] Microbiology Branch, US Army Dental and Trauma Research Detachment, Institute of Surgical Research, Fort Sam Houston, TX, USA

OBJECTIF : Le décapeptide KSL-W présente un large spectre antimicrobien affectant plusieurs pathogènes dont *S. mutans* et *C albicans*. Ce peptide semble réduire la croissance de C. albicans ainsi que la formation de biofilm en agissant sur certains gènes spécifiques. Cependant les mécanismes d'action du KSL-W ne sont pas encore élucidés. Dans cette étude, nous avons évalué la cinétique et l'atteinte de l'intégrité morphologique ainsi que le type de mort cellulaire (apoptotique/nécrotique) induites par le KSL-W sur C. albicans en comparaison à une autre souche soit : *C. parapsilosis*.
MÉTHODES : Les souches de Candida ont été mises en culture en présence et en absence de KSL-W. l'effet de KSL-W sur la viabilité cellulaire a été déterminé à l'aide du test d'exclusion du bleu trypan. Ces travaux ont été confirmés par des analyses de l'activité apoptotique ou nécrotique du KSL-W par cytométrie en flux à l'aide d'un marquage à l'annexin V-FITC/PI. Des analyses par microscopie électronique à transmission ont été effectuées afin de visualiser l'effet sur la paroi cellulaire et les autres composantes intracellulaires. Les effets du KSL-W ont tous été comparés à ceux de l'amphotéricine B.
RÉSULTATS : L'effet antifongique du KSL-W s'amorce dès les premières 30 minutes d'exposition de *C. albicans* et *C. parapsilosis* au KSL-W à des doses de 10 µg/ml. Le KSL-W induit également la nécrose de *C. albicans* à partir de concentrations de 1µg ml-1 (49,0%) et 25µg/ml (97,7%). L'activité du KSL-W sur *C parapsilosis* est principalement apoptotique (42,2%) après 3 heures d'exposition à 25µg/ml de KSL-W. Les analyses en microscopie à transmission montrent une atteinte de la membrane de *C. albicans* et de *C. parapsilosis* suivant des traitements de KSL-W à 25µg/ml.
CONCLUSIONS : Nos travaux démontrent une activité antifongique de KSL-W. Cette activité est parfois comparable, parfois non comparable à celle de l'amphotéricine B, (suggérant un mécanisme d'action différent de celui de l'amphotéricine B). Ces travaux suggèrent l'utilisation du KSL-W comme molécule de choix pour le contrôle des infections fongiques à *Candida.*

Appendix 3

Titre : Le KSL-W réduite la croissance Candida albicans et la formation de biofilm en diminuant l'expression de plusieurs gène de virulence.

Auteurs : Simon Théberge, Abdelhabib Semlali, Kai P Lung, Abdullah Alamri and Mahmoud Rouabhia

Présentation : Poster

Objectifs : Le décapeptide α-hélicoïdal synthétique, le KSL-W (KKVVFWVKFK) possède un large spectre affectant plusieurs souches de pathogènes bactériens oraux. Cependant effet de ce peptide sur des souches fongiques dont Candida *albicans* reste à démontrer. Le but est d'étudier de l'effet du KSL-W sur les différents facteurs de virulence du C. *albicans*. **Méthodologie :** L'effet de KSL-W a été étudié en analysant la transformation, la prolifération en utilisant la microscopie et le MTT. Ces travaux ont été supportés par des analyses spécifiques à la formation de biofilm (XTT) et à l'activation de certains gènes à l'aide de la technique qRT-PCR. Une analyse de l'activité apoptotique/anti-apoptotique du KSL-W a été réalisée à l'aide d'Annexin V-FITC/IP. Tous les effets étudiés du KSL-W ont été comparés à l'amphotéricine B. **Résultats :** Le KSL-W inhibe la transformation à partir de concentrations de 5µg ml^{-1}. Il s'est montré efficace à inhiber la formation de biofilms à des concentrations de 50µg ml^{-1} et à réduire la viabilité à l'intérieur d'un biofilm mature à des concentrations de 50µg ml^{-1} et est d'efficacité comparable à l'amphotéricine B dans les deux cas. Les analyses ultrastucturales confirment l'efficacité du KSL-W à réduire et à dégrader le biofilm.. L'efficacité du KSL-W passe aussi par la réduction de l'expression de plusieurs gènes dont SAP2, 4, 5, 6, EFG1 et HWP1 impliqués dans la pathogénèse de C. albicans. . **Conclusion : Par ses effets importants sur C. albicans,** le KSL-W pourrait être considéré dans le contrôle de Candida *albicans* ((This study was supported financially by the United States Army Medical Research and Materiel Command (Award number ERMS No. 12304006) and by a grant from the Fonds Émile-Beaulieu, a Université Laval foundation).

Investigating the effect of an antimicrobial peptide (KSL-W) on gingival fibroblast growth, migration, and defense against microbial infection

ABSTRACT

Aim: The aim of this study was to investigate the interaction between primary human gingival fibroblasts and KSL-W, an antimicrobial peptide, and the effect of this peptide on gingival fibroblast defense *in vitro* against *Streptococcus mutans*.

Material and Methods: Primary human gingival fibroblasts were used to study the effect of KSL-W peptide on cell adhesion, growth and the secretion of metalloproteinase (MMP). We also investigated the effect of KSL-W on fibroblast migration by mean of scratch assay. Finally we analyzed the effect of antimicrobial activity of KSL-W on *S. mutans* infected fibroblast cultures

Results: The peptide KSL-W promoted fibroblast growth by increasing the S and G2/M cell cycle phases. Peptide KSL-W also regulated the secretion of metalloproteinase (MMP)-1 and -2, through MMP inhibitors such as tissue inhibitors of metalloproteinase (TIMP)-1 and TIMP-2. Using an *in vitro* wound healing assay, we demonstrated that peptide KSL-W promoted fibroblast migration as compared to non-treated cultures. The addition of KSL-W peptide to *S. mutans* infected fibroblast culture prevents adverse effect of the bacteria through fibroblast growth and IL-8 secretion.

Conclusion: These findings therefore show that peptide KSL-W was safe to use with human cells, as it promoted their growth and migration and attenuated *S. mutans* virulence by decreasing its effect on cell viability and IL-8 secretion.

Significance and Impact: This study points to the possibility of using KSL-W as antimicrobial peptide, and as a peptide accelerating the wound healing process.
