1	Abstract
2	
3	The Spondweni serogroup (family Flaviviridae, genus Flavivirus) consists of two members: Zika
4	and Spondweni viruses. Both viruses have been historically misidentified and their diseases have
5	been misdiagnosed due to their serological cross-reactivity and similar clinical presentations.
6	Within historic case reports a sub-set of patients has presented with short duration clinical
7	manifestations suggestive of more serious illness.

Viruses within the genus *Flavivirus*, family *Flaviviridae*, are notorious for their serological cross-reactivity. Prior to the advent of genetic sequencing, classic serological assays such as the virus neutralization and hemaggutination-inhibition were used to differentiate the various species of arboviruses. Although not perfect, much of the early work differentiating flaviviruses into various serogroups was later confirmed by sequencing and phylogenetic analyses. Historically, serological assays (the neutralization and complement fixation tests) were also used to determine the prevalence of prior infection and geographic distribution of flaviviruses. Both viruses in the Spondweni serogroup, Zika (ZIKV) and Spondweni (SPONV), exhibit serological cross-reactivity and non-specific febrile illness, making diagnosis challenging in regions where both viruses co-circulate.

ZIKV was first isolated in Uganda in 1947 (strain MR-766) (1) and SPONV was first isolated in Nigeria in 1952 (strain Chuku) (2). Cross-reactivity using the neutralization test led to the misidentification of the SPONV Chuku strain isolated by MacNamara in 1952 as a strain of ZIKV (2-5). This misidentification led to additional studies where this strain of SPONV was reported as ZIKV – confusion that continues to the present day, although the misidentification of this isolate was clarified and widely reported in 1964 (3-5). Consequently, the clinical case reports by MacNamara (2), the work by Bearcroft (6) involving the experimental infection of a human volunteer and vector competence studies in *Aedes aegypti* mosquitoes, and the experimental work by Bearcroft (7) in *Macaca mulatta* monkeys investigating the effect of prior infection, and the subsequent histopathology of the liver and level of cross-protection following

47	exposure to yellow fever virus, all utilized SPONV (Chuku strain) rather than ZIKV.
48	Furthermore, early serosurveys in regions where both ZIKV and SPONV co-circulate are suspect
49	due to serological cross-reactivity or where serological assays only screened for one of the two
50	viruses (2, 8).
51	
52	Both ZIKV and SPONV are arthropod-borne viruses and utilize a mosquito/host (non-human
53	primate and/or human) transmission cycle. ZIKV has a wide geographic distribution that
54	includes East and West Africa, the Indian sub-continent, Southeast Asia, Oceania, South and
55	Central America, and the Caribbean (9-11); whereas SPONV has thus far only been reported
56	from sub-Saharan Africa (12). The lack of continuous historic detection in those regions with
57	ZIKV or SPONV isolations or serological evidence of transmission prior to 2007 is likely due to
58	the lack of surveillance, misdiagnosis, and under-reporting. It is plausible that virus outbreaks
59	did occur in those regions with prior serologic evidence of infection and were attributed to other
60	arboviral infections. Clinical ZIKV and SPONV presentation is similar to classic dengue fever
61	which may have led to historic misdiagnosis (9).
62	
63	In their historic geographic ranges (distribution prior to 2007), both ZIKV and SPONV likely
64	circulated at low levels in sylvatic cycles, whereby low numbers of naïve persons were
65	periodically exposed to infection. While historic case reports of serious clinical manifestations
66	associated with Spondweni Serogroup viruses may have been limited due to poor diagnosis and
67	reporting, it is plausible that the lack of historic reports of congenital birth defects associated
68	with ZIKV infection in utero, were a result of exposure to the virus prior to puberty. Such an
69	infection would likely result in a female being immune to a subsequent infection during her

70	reproductive years. The extent of cross-protection exhibited within the Spondweni Serogroup is
71	unknown, and cross-protection with other flaviviruses such as yellow fever virus and/or the 17D
72	yellow fever virus vaccine appears to be limited (4-6, 13-16).
73	
74	Most cases of ZIKV and SPONV infection are asymptomatic (10, 11). Of symptomatic cases,
75	signs and symptoms appear as early as 3 days following infection for both ZIKV(11) and
76	SPONV (6). The common clinical presentation of ZIKV infection is now well established and a
77	recent literature review lists the most common signs and symptoms reported from 195 patients
78	from 1964 to 2016 as rash (67.2%), fever (63.6%), arthralgia (28.7%), myalgia (23.6%),
79	headache (21.5%), conjunctivitis (20.5%), retro-orbital pain (11.3%), edema (9.7%), puritus
80	(7.7%) and fatigue (7.2%) (11). Less is known regarding the clinical presentation of SPONV as
81	there are few well documented clinical cases reported in the literature ($n = 6$). The most common
82	signs and symptoms reported in those SPONV cases include: fever (100%), headache (83.3%),
83	nausea (83.3%), myalgia (66.6%), arthralgia (50.0%), vertigo (33.3%), conjunctivitis (16.7%),
84	macropapular and pruritic rash (16.7%), and epistaxis (16.7%), photophobia (16.7%), vomiting
85	(16.7%), and disorientation (16.7%) (2, 5, 6, 13, 16). It is clear that both ZIKV and SPONV
86	display similar signs and symptoms making diagnosis difficult in regions where both viruses co-
87	circulate, additionally there are no commercially available serological assays that can
88	differentiate these two viruses. In regions where both viruses co-circulate, diagnosis requires a
89	monotypic reaction to a given serologic assay, PCR confirmation, or virus isolation.
90	
91	While most symptomatic ZIKV and SPONV infections present as a mild to moderate febrile
92	illness, a sub-set of cases present with short duration clinical manifestations suggestive of more

DISTRIBUTION STATEMENT A: Approved for public release; distribution is unlimited.

serious illness. Prior to reports of ZIKV in the Western Hemisphere, Spondweni Serogroup case
reports included: conjunctivitis (ZIKV and SPONV), macropapular rash (ZIKV and SPONV),
pruritic rash (SPONV), hematuria (ZIKV), hematospermia (ZIKV), apthous ulcer (ZIKV), and
epistaxis (SPONV) indicating vascular leakage; and reports of photophobia (ZIKV and SPONV),
vomiting (ZIKV and SPONV), vertigo (SPONV), disorientation (SPONV), meningismus
(SPONV), and bilateral transient ocular paresis (SPONV) were indicative of neurological
involvement (2, 5, 6, 13, 16, 17). Additionally, Guillain-Barré syndrome (18), evidence of sexual
transmission (15), and evidence perinatal transmission (19) were all associated with a sub-set of
ZIKV cases prior to the introduction of the virus in the Western Hemisphere.
In summary, symptomatic cases of ZIKV and SPONV infection present with similar signs and
symptoms and anti-ZIKV and anti-SPONV serological assays exhibit cross-reactivity. Early
work by MacNamara (1954) and Bearcroft (1956 and 1957) misidentified SPONV as ZIKV.
Prior to the introduction of ZIKV into the Western Hemisphere there was evidence of clinical
manifestations indicative of vascular leakage and neurological involvement within the Serogroup
as well as unique transmission mechanisms associated with a sub-set of patients infected with
ZIKV.
