Understanding the origin of unintentional doping in Ga₂O₃ is key to increasing breakdown voltages of Ga₂O₃ based power devices. Therefore, transport and capacitance spectroscopy studies have been performed to better understand the origin of unintentional doping in Ga₂O₃. Previously unobserved unintentional donors in commercially available (201) Ga₂O₃ substrates have been electrically characterized via temperature dependent Hall effect measurements up to 1000 K and found to have a donor energy of 110 meV. The existence of the unintentional donor is confirmed by temperature dependent admittance spectroscopy, with an activation energy of 131 meV determined via that technique, in agreement with Hall effect measurements. With the concentration of this donor determined to be in the mid to high 10¹⁶ cm⁻³ range, elimination of this donor from the drift layer of Ga₂O₃ power electronics devices will be key to pushing the limits of device performance. Indeed, analytical assessment of the specific on-resistance (R_{onsp}) and breakdown voltage of Schottky diodes containing the 110 meV donor indicates that incomplete ionization increases R_{onsp} and decreases breakdown voltage as compared to Ga₂O₃ Schottky diodes containing only the shallow donor. The reduced performance due to incomplete ionization occurs in addition to the usual tradeoff between R_{onsp} and breakdown voltage.

While crystalline Ga₂O₃ has been known for many years, the recent availability of high quality crystalline substrates¹ and the demonstration of Ga₂O₃ MESFETs² and MOSFETs^{3–6} have motivated interest in Ga₂O₃ for next generation ultra-wide bandgap power electronics applications. With a bandgap of 4.5–4.9 eV and estimated critical breakdown field of 8 MV/cm, Ga₂O₃ possesses a Baliga figure of merit 10 times greater than SiC and four times greater than GaN². Indeed, even at this early stage of development, electric fields of at least 3.8 MV/cm⁴ and 5.1 MV/cm⁷ have been demonstrated in lateral Ga₂O₃ FETs and vertical Schottky diodes, respectively, already surpassing bulk critical fields of GaN and SiC. In addition to these promising material properties, melt-growth methods for bulk Ga₂O₃ substrate growth^{8–17} are expected to be more cost-effective than the sublimation techniques used for the growth of SiC substrates, lowering manufacturing costs for Ga₂O₃ based power electronics.

While the large breakdown electric field demonstrated in these early experimental studies is certainly promising, pushing the breakdown voltages of Ga₂O₃ based power electronics devices towards their predicted limits requires further work to understand and eliminate unintentional doping in the material. To illustrate this fact, the dependence of breakdown voltage of p-n single-sided junction and Schottky junction devices, normalized by material parameters, is plotted in Fig. 1. The black line indicates the theoretical limit, assuming the full-depletion approximation and one dimensional electrostatics. By normalizing the breakdown voltages in this way, one can isolate the effect of doping on device breakdown voltage to allow comparisons of devices made from different materials. Comparing early Ga₂O₃ devices to those of more mature semiconductor materials gives insight into the future potential of Ga₂O₃ devices. The plotted experimental data are among the best reported for vertical devices of each material with large breakdown voltage and low doping of the device drift-layer. While edge effects prevent real devices of any material from matching the simplified theoretical limit exactly, the N_d^{-1} trend is nevertheless observed considering the best performing devices of the different material systems. Comparing Ga₂O₃ to the

Figure 1. Normalized breakdown voltage (left axis) vs. doping concentration for single-sided junction power devices. The ideal relationship assuming the full-depletion approximation and 1D electrostatics is shown by the black line. The right axis indicates the projected absolute breakdown voltage for Ga_2O_3 devices for comparison. Square symbols indicate experimental measurements of devices with breakdown voltages among the highest reported for each material: Si³⁸, SiC³⁹, GaN⁴⁰, Ga_2O_3 ⁷.

more mature materials, it is clear that some improvement can be expected from the optimization of device geometries to mitigate edge effects, as shown by the blue arrow. However, much greater improvement in breakdown voltage is possible from reducing drift layer doping in Ga_2O_3 devices, as indicated by the orange arrow. For instance, if the drift layer doping of a Ga_2O_3 device can be reduced to about 10^{14} cm^{-3} like the 21.7 kV SiC device indicated in Fig. 1, then the Ga_2O_3 device will have a breakdown voltage over 100 kV as indicated by the right axis of Fig. 1. Therefore, understanding and mitigating unintentional doping in Ga_2O_3 is key to increasing the maximum achievable breakdown voltages in Ga_2O_3 beyond the recently demonstrated 1 kV devices⁷.

With these motivations, we have undertaken transport and capacitance spectroscopy studies in order to better understand the origin of unintentional doping in Ga_2O_3 . The transport properties of commercially available unintentionally doped (̄01) Ga_2O_3 substrates from Tamura Corporation grown via the EFG method^{13,14} are characterized via temperature dependent Hall effect measurements. High temperature Hall effect measurements up to 1000 K reveal a previously unobserved unintentional donor with an energy level 110 meV below the conduction band edge in addition to previously observed shallow donors attributed to Si^{14,17}. To confirm the existence of this unintentional donor, temperature dependent admittance spectroscopy measurements were performed on a Ga_2O_3 Schottky diode structure, with an activation energy of 131 meV observed via this technique. This activation energy agrees well with the donor energy of 110 meV determined via Hall effect measurements. Finally, using the information obtained from the temperature dependent Hall effect measurements, the effects of the 110 meV donor on the specific on-resistance (R_{onsp}) of Ga_2O_3 Schottky diodes are assessed via analytical calculations, indicating that incomplete ionization of the 110 meV donor increases the R_{onsp} and reduces breakdown voltage as compared to Ga_2O_3 devices with only the shallow donor, beyond the usual tradeoff between on-resistance and breakdown voltage.

Results

Hall Effect Measurements. Figure 2 shows the temperature dependent carrier density, normalized to room temperature, as measured by the Hall effect for two samples. The Hall scattering factor was assumed to be one when calculating the carrier density. The temperature dependent conductivity, mobility, and analysis of the relevant scattering mechanisms for these same samples can be found in the supplementary information. With the increased slope of the log-reciprocal plot from room temperature up to about 450 K, the temperature dependence of the carrier density must be determined by two donors with different energy levels. To estimate the donor energy levels, the data was fit with a model consisting of two donors with a compensating acceptor as shown in Equation (1):

$$N_c e^{\frac{E_f - E_c}{kT}} + N_a = \frac{N_{d1}}{1 + 2e^{\frac{E_f - E_{d1}}{kT}}} + \frac{N_{d2}}{1 + 2e^{\frac{E_f - E_{d2}}{kT}}} \quad (1)$$

where N_c is the effective density of states in the conduction band, N_{d1} and N_{d2} the concentrations of the two donors, N_a the concentration of compensating acceptors, E_c the energy of the conduction band edge, E_f the Fermi level, E_{d1} and E_{d2} the donor energies. An effective mass $m^* = 0.3m_0$ ^{18–20} was used to estimate N_c analytically²¹, while N_{d1} , N_{d2} , E_{d1} , E_{d2} , and N_a are free parameters. The values of the free parameters are summarized in Table 1, and the resulting fit is plotted as a black line in Fig. 2. The model indicates that the increased slope from 300 K to 450 K is the result of a higher energy donor with energy 110 meV. Additionally, a shallow donor is also observed with energy 23 meV, previously identified as silicon from glow discharge mass spectrometry (GDMS) analysis of Tamura samples²². Carrier activation in previous studies of Ga_2O_3 was well described by a single shallow donor which they also attributed to unintentional silicon dopants,^{14,17} however, the second higher energy donor has not been observed previously.

Table 1. Parameters for the carrier density vs. temperature model.

Admittance Spectroscopy Measurements. Admittance spectroscopy measurements confirm the existence of the previously unobserved donor. Figure 3 shows capacitance of a Ga_2O_3 Schottky diode as a function of frequency for several temperatures. The C vs. ω spectrum exhibits a step transition separating two plateaus, C_d at $\omega < \omega_p$ and C_g at $\omega > \omega_p$, which indicates the presence of a trap state. The transition frequency, ω_p , corresponds to the carrier emission rate from the trap level. To determine the activation energy of the trap state, ω_p was obtained from the negative peak in the differential capacitance ($\omega dC/d\omega$ vs ω) spectrum to construct an Arrhenius plot of $\ln(\omega_p/T^2)$ vs $1/(k_B T)$, shown in Fig. 3 inset. From the slope of the plot, the activation energy of the trap is determined to be $E_a = 131 \pm 5 \text{ meV}$. Furthermore, the trap density, calculated from the height of the capacitance step²³, is $N_t = 4.4 \times 10^{16} \text{ cm}^{-3}$. A relative dielectric constant of 10 for Ga_2O_3 was used for this calculation^{24,25}. These data

Distribution A. Approved for public release (PA): distribution unlimited.

are well matched to the previously unobserved donor identified via Hall effect measurements, which indicated a donor energy of 110 meV and donor density of $7.5 \times 10^{16} \text{ cm}^{-3}$ as previously discussed. The small differences between the Hall effect measurements and admittance spectroscopy measurements are not surprising and are consistent with sample to sample variation within the two-inch Ga_2O_3 wafer from which the three samples were cut. Therefore, the trap state observed via admittance spectroscopy confirms the existence of the previously unobserved unintentional donor.

Possible Origins of the Donor. While the electrical characterization performed here cannot determine the chemical or crystallographic origin of the 110 meV donor, we nevertheless consider a few hypotheses. It is natural to ask if a native defect is responsible for the observed donor. DFT calculations rule out simple oxygen and gallium vacancies as they are determined to be deep donors²⁶ and acceptors^{27,28}, respectively. However, antisites and interstitials could be responsible. Extrinsic impurities, of course, could also be responsible for the donor, and glow discharge mass spectrometry (GDMS) analysis of Tamura substrates indicates the presence of several impurities whose dopant properties in Ga_2O_3 are unknown²². Last, silicon on the octahedrally coordinated Ga(II) site of Ga_2O_3 could be responsible for the 110 meV donor. DFT calculations indicate that Si prefers the tetrahedrally coordinated Ga(I) site in which it is a shallow donor;²⁶ however, STM analysis of Si donors near the (100) surface of Ga_2O_3 indicates that Si occupies both Ga(I) and Ga(II) lattice sites²⁹. This fact suggests that Si on the Ga(II) site should also be considered as a possible origin of the 110 meV donor.

Discussion

These unintentional donors have implications for the performance of Ga_2O_3 based power devices; namely they reduce the maximum achievable breakdown voltage in a Ga_2O_3 power device. Because the doping of the drift-layer cannot be reduced below the level of unintentional doping, the density of unintentional donors sets the lower limit on electric field at the metal-semiconductor interface and the upper limit on the depletion width of the Ga_2O_3 drift-layer for a given applied voltage. Therefore, a limit is set on the tradeoff which allows higher breakdown voltage to be achieved at the expense of larger on-resistance. To mitigate the presence of previously identified silicon shallow donors in the substrate, several methods including LPCVD³⁰, MOCVD^{31,32}, HVPE^{33,34}, and MBE^{2,3,35,36} have been used to grow homoepitaxial Ga_2O_3 layers on Ga_2O_3 substrates, achieving lower carrier densities by minimizing unintentional doping. However, the carrier concentration due to unintentional doping still remaining in epitaxial layers is typically 10^{15} to 10^{17} cm^{-3} ³⁷. This concentration is similar to the additional carrier concentration due to the 110 meV donor observed in these bulk samples considering incomplete ionization. For example, at a 110 meV donor concentration of $7.5 \times 10^{16} \text{ cm}^{-3}$ as found in this study, with no other donors or acceptors, $3.4 \times 10^{16} \text{ cm}^{-3}$ free electrons are thermally activated into the conduction band at 300 K for an ionization efficiency of 46%. These facts suggest that the 110 meV donor may also play a role in the unintentional doping of epitaxially grown Ga_2O_3 , warranting further study but beyond the scope of this work. The importance of the high temperature Hall effect measurements and admittance spectroscopy measurements should be emphasized. As our calculation indicates, the higher activation energy of the 110 meV donors means that their ionization efficiency N_d^+/N_d is significantly less than 100% at room temperature. Therefore, room temperature and low temperature Hall measurement will not identify the full donor concentration, N_d , which determines the maximum breakdown voltage. Underestimating the concentration of donors could lead to an overestimate of the breakdown voltage without high temperature Hall effect measurements or admittance spectroscopy measurements like those performed in this study.

While unintentional shallow donors and the 110 meV donor both set a limit on the tradeoff between on-resistance and breakdown voltage, the 110 meV donor poses an additional challenge to maximizing breakdown voltage and minimizing on-resistance due to its four times larger donor energy as compared to the shallow donor. Because of the higher donor energy, incomplete ionization of the 110 meV donor is more severe than for the shallow donor, degrading the specific on-resistance vs. breakdown voltage characteristic for Ga_2O_3 based devices. The 110 meV donor is shallow enough in energy that it becomes fully ionized when the Schottky diode is reverse biased, reducing the depletion width, increasing the electric field at the metal-semiconductor interface, and reducing the breakdown voltage in the same way as the shallow donor. However, the 110 meV donor energy is large enough that incomplete ionization can be significant, meaning that only a fraction of the 110 meV donors are ionized when the Schottky diode is forward biased, reducing the carrier concentration available to conduct the on-current. To quantitatively examine those effects, specific on-resistance (R_{onsp}) versus breakdown voltage characteristics have been calculated for Ga_2O_3 Schottky diode devices including the incomplete ionization effect, with the results plotted in Fig. 4. Details of the calculation can be found in the supplementary information. As Fig. 4 shows, the on-resistance versus breakdown voltage characteristics are degraded where the maximum breakdown voltage decreases and the on-resistance increases as the concentration of the 110 meV donor increases. To determine the maximum acceptable concentration of 110 meV donors for a particular target breakdown voltage, the percent increase in R_{onsp} is calculated for a Schottky diode containing both 110 meV donors and shallow donors versus a Schottky diode containing only shallow donors designed for the same breakdown voltage. The results of the calculation are plotted in Fig. 5 with additional details available in the supplementary information. With Fig. 5, we can estimate the maximum concentration of the 110 meV donors acceptable for 10 kV operation of Ga_2O_3 Schottky diode devices. To limit the increase in R_{onsp} to one percent, the concentration of 110 meV donors must be less than $5 \times 10^{14} \text{ cm}^{-3}$. A similar analysis of the percent decrease in breakdown voltage due to 110 meV donors is also presented in the supplementary information.

In conclusion, high temperature Hall effect and admittance spectroscopy measurements have revealed a previously unobserved unintentional donor with energy 110 meV below the conduction band edge in commercially available unintentionally doped Ga_2O_3 substrates grown by the EFG method. The existence of these unintentional donors sets a limit on the maximum breakdown voltages that can be achieved in Ga_2O_3 devices and must be mitigated to achieve the full benefits of Ga_2O_3 based power electronics. Additionally, incomplete ionization of the 110 meV donor causes increased on-resistance and decreased breakdown voltage in diodes containing the donor, Distribution A. Approved for public release (PA): distribution unlimited.

Figure 4. Analytical calculation of specific on-resistance (R_{onsp}) vs. breakdown voltage for Ga_2O_3 based Schottky junction devices with 110 meV donors including the effects of incomplete ionization. The label for each curve indicates the fixed concentration of 110 meV donors in units of cm^{-3} . The pink circles, cyan squares, and line segments illustrate the relationship to Fig. 5 and Figure S3 as described in the supplementary information.

Figure 5. Percent increase in specific on-resistance (R_{onsp}) due to incomplete ionization as a function of breakdown voltage comparing Ga_2O_3 Schottky diodes with 110 meV donors to those without. The labels indicate the fixed concentration of 110 meV donors in cm^{-3} for each curve. The pink circle illustrates the relationship to Fig. 4 as described in the supplementary information.

as compared to diodes containing only the shallow donor, beyond the usual tradeoff between on-resistance and breakdown voltage. To achieve 10 kV operation in Ga_2O_3 Schottky diode devices, analysis indicates that the concentration of 110 meV donors must be reduced below $5 \times 10^{14} \text{ cm}^{-3}$ to limit the increase in R_{onsp} to one percent.

Methods

Sample Fabrication and Measurement. Two van der Pauw test samples were diced from the same two inch wafer into $1 \text{ cm} \times 1 \text{ cm}$ square pieces. Following dicing, samples were solvent cleaned and 50 nm/1000 nm Ti/Au contacts were sputtered on the sample corners. To improve contact resistance, the samples were annealed from room temperature up to 450°C with a 15 min ramp in a tube furnace with argon gas flow. A third sample from the same two inch wafer was prepared for admittance spectroscopy by depositing an indium tin oxide (ITO) transparent contact to form a Ga_2O_3 Schottky diode. Following device fabrication, temperature dependent van der Pauw and Hall effect measurements were carried out in two separate Hall effect measurement systems. An electromagnet with vacuum cryostat and closed-loop He refrigerator was used for measurements below room temperature, while an electromagnet with a quartz tube furnace with silicon carbide heater was used for measurements above room temperature. The samples were kept under nitrogen gas flow at atmospheric pressure during high temperature measurements. Admittance spectroscopy measurements were carried out under vacuum in a closed-loop He cryostat using a Keysight Agilent 4990 A impedance analyzer.

Acknowledgements

This material is based upon the work supported by the Air Force Office of Scientific Research under award number FA9550-17RXCOR438 and award number FA9550-15RYCOR163. The authors would like to thank Bill Mitchell and Said Elhamri for valuable discussions and Gerry Landis for experimental assistance.

Author Contributions

S.M. initiated the project. A.T.N. and S.M. performed and analyzed Hall effect measurements. R.L. and J.V.L. performed and analyzed admittance spectroscopy measurements. A.T.N. and S.M. wrote the manuscript with input from J.V.L., D.B.T., K.D.C., and G.H.J. S.M. supervised the project.

Distribution A. Approved for public release (PA): distribution unlimited.
